Acknowledgements

My first acknowledgment goes to my thesis directors, Prof. Giovanni De Micheli and Dr. MER Sandro Carrara. In these four years they taught me the meaning and method in doing research, and they gave me the possibility to work on interesting and innovative projects, giving me advices and freedom to explore new idea. Moreover, they created an amazing environment in the lab, where I have been always surrounded by competent colleagues and friends. It will be difficult to find a better environment to work.

I want to thank Prof. Fabio Grassi and Prof. Catherine Dehollain to have been helpful partners in the project I have been involved with, and to have and offered me their knowledge and advices. Financial supports were from the Swiss National Science Foundation Sinergia Project, code CRSII2 1275471 and title "Innovative Enabling Micro-Nano-Bio-technologies for Implantable systems in molecular medicine and personalized therapy".

Giuseppe D. Albini is acknowledged for his help for the Monte Carlo simulations. SEM images were acquired in the facilities at the CIME (EPFL) with the aid of Prof. Cantoni and Mrs. Fabienne Bobard. The microfabrication of the platform was realized with the precious help of the CMI staff.

I want to thank Mrs. Marie Halm for taking care of all the Ph.D. students in the doctoral program of Microsystems and Microelectronics.

A special thanks goes to Christina for her patience in answering to the hundreds of questions that all the people in LSI ask her every single day, and for her efficiency in administering all the lab issues. Many thanks also to Anil and Rodolphe for helping me every time it was needed. I also want to thank Mr. Badertscher for his help in many practical works that were very critical in the realization of the implantable device, and for the interesting discussions that we had sometimes.

A special thanks to Andrea. For the enthusiasm that you show for every plan I make, for your wise advice, for your collaboration during our Ph.D., for tolerate my changing mood even in difficult days, and for your unconditioned support for every choice I make.

A special thanks to Irene. We actually started our first project together long time ago (2008) for the Bachelor thesis, then we ended up in LSI for our master project in 2010. Then we started our Ph.D. on the same day and after four years we are reaching the end of this experience. Thanks for the mutual support and for the precious technical collaboration. I will definitely miss it.

Another special thanks to Michele, my flatmate/colleague and friend for his help in technical matters, his philosophical discussions and for sharing the everyday-life.

Acknowledgements

I want to thank the "Sinergia" team. Working with you towards the realization of this project has been the most challenging and exciting part of my work: thanks to Sara for the realization of the read-out IC and for all the measurements that we run together; to Enver for the realization of the power management unit; to Stefano for his work on the receiving unit and for the helpful discussions that we had on electronics; to Francesca for the realization of the Android interface; to Tanja for the in-vivo tests with animals and for her help in preparing manuscripts. We all together proved that a good team can bring very good results. A thanks goes also to Christian for his help in providing me the reconstituted cytochrome and for his collaboration. In these four years I had the chance to share the lab with colleagues that became friends. Thanks to Cristina, a perfect lab-mate, office-mate and party-mate; to Francesca for sharing good and bad time in the lab and also during volleyball matches; to Fede for his help in revising manuscripts and for his organization skills very helpful during our trips around the world; to Vasilis for his wise advice and his friendship; to Jack for your unmissable anecdote. A thanks to all the actual and former lab members that made great my time in LSI: Wenqi, Jaume, Alena, Julien, Shashi, Pierre-Emmanuel, Srinu, Gözen, Somayyeh, Hu, Ciprian, Francesco, Eleni, Hassan, Nima, Ioulia, Davide, Aya, Jiang, Xifang, Luca, Maxime, Winston.

A special thanks to the group of the "coffee break in Coupole": Matteo, Annina, Ludo, Ican, Pableras, Ruben, Michela, Max and Karim. Thanks for the random discussions, sometimes philosophical conversations, for all the parties and dinners, for the trips that we organized together and for your friendship.

Thanks to all the friends that I met in Lausanne outside the lab: to my flatmate Egle, for the motivation you are able to transmit; to Nicee, Sophie, to "les amis" (Lucio, Diego, Matteo, Antonio), and to "les filles" of the Ecublens team.

Thanks to Josefine and Rosa for our long-distance friendship.

I want to thank my friends in Italy: to Clelia, Kristen, Tiziana, Simone, Alessandro, Daniele and Andrea, because I can always count on you. To Ele, for your never-ending friendship, and to my "Brocchi" friends because they will support me wherever I will go.

To conclude I want to thank my family. I feel so lucky to have such an amazing family that for me is a source of inspiration, motivation and strength. I have many relatives but all of them are always been present in the important moments of my life to support me and to celebrate. A very special thanks to my brother, to mum and dad for their unconditioned love and support, and for the time together that is never enough.

Abstract

Nowadays, scientific advances are leading to the discovery of newer, better, more targeted treatments that will improve the human health. However, despite the promising results and the major advantages in treatments offered to patients, these personalized medical treatments are limited to few cases.

Translational medicine research with animals is needed to find innovative, safe and life-saving solutions for patients, especially in drug development. Although technological improvements may lead one day to the end of animal testing, today those strategies are not sufficient, due to the complexity of living organisms.

The living conditions of these animals are of primary importance because high stress levels can affect the experimental results. In this respect, the monitoring of the animals in a small living space by means of a fully implantable device, can contribute to minimize the human intervention, increasing the comfort for the animals.

The objective of this thesis is the design and characterization of a fully implantable biosensor array for the real-time detection of endogenous and exogenous metabolites, for the monitoring of small caged animals in drug development, and for future applications in personalized medicine.

The fully implantable device consists of: a passive sensing platform consisting of an array of four independent electrochemical biosensors, together with a pH sensor and a temperature sensor for the optimization of the sensing performances in different physiological conditions; integrated circuits capable of performing multiple electrochemical measurements; a coil for remote powering of the integrated circuit and the short-range data transmission to an external device; a membrane packaging ensuring measurements with high signal-to-noise ratio, biocompatibility and selectivity against possible interfering molecules in biological fluids.

This thesis describes in detail the implantable device highlighting the following results:

- *In vitro* monitoring of four anti-cancer drugs and an anti-inflammatory drug within the pharmacological ranges in undiluted human serum;
- Demonstration of the *in vitro* functionality of the complete system, showing that the external powering system correctly operate the device, and receive the data from the sensors;
- *In vivo* biocompatibility tests of the packaging, showing after 30 days a significant reduction of the inflammatory response in time, suggesting normal host recovery;

Acknowledgements

- *In vivo* continuous monitoring of an anti-inflammatory drug, demonstrating the proof-of-concept of the system for future personalized medicine applications.

Résumé

Aujourd'hui, les progrès scientifiques aboutissent à la découverte de nouveaux traitements, plus ciblés, destinés à améliorer la santé humaine. Cependant, en dépit de résultats prometteurs et des avantages qu'ils apportent auprès des patients, ces traitements médicaux personnalisés sont restreints à quelques cas.

La recherche en médecine translationnelle sur les animaux est nécessaire pour trouver des solutions innovantes et sûres pour les patients, en particulier dans le développement de médicaments. Bien que les améliorations technologiques pourront conduire un jour à la fin de l'expérimentation animale, ces stratégies ne sont pas encore suffisantes aujourd'hui, en raison de la complexité des organismes vivants.

Les conditions de vie des animaux sont d'une importance capitale étant donné que des niveaux élevés de stress peuvent affecter les résultats expérimentaux. Ainsi, la surveillance des animaux dans une petite surface habitable, au travers d'un dispositif totalement implantable, peut contribuer à réduire au minimum l'intervention humaine et à augmenter le confort.

L'objectif de cette thèse est la conception et la caractérisation d'une matrice de biocapteurs totalement implantable dédiée à la détection en temps réel de métabolites endogènes et exogènes, pour la surveillance de petits animaux en cage dans le développement de médicaments et pour les futures applications de médecine personnalisée.

Le dispositif entièrement implantable se compose : d'une plate-forme de détection passive, constituée d'un réseau de quatre biocapteurs électrochimiques indépendants, d'un capteur de pH et d'un capteur de température pour l'optimisation des performances de détection à diverses conditions physiologiques ; de circuits intégrés capables d'effectuer de multiples mesures électrochimiques ; d'une bobine pour l'alimentation à distance des circuits intégrés et la transmission de donnée à courte portée vers un dispositif externe ; d'une encapsulation par membranes permettant des mesures avec un rapport signal sur bruit élevé et assurant biocompatibilité et sélectivité par rapport à des molécules parasites présentes dans les fluides biologiques.

Cette thèse décrit en détail le dispositif implantable réalisé et met en évidence les résultats suivants :

- Surveillance *in vitro* de quatre médicaments anticancéreux et d'un médicament anti-inflammatoire dans les intervalles pharmacologiques du sérum humain non dilué ;
- Démonstration de la fonctionnalité *in vitro* de l'ensemble du système, validant le système d'alimentation externe et la transmission correcte des données provenant des

Acknowledgements

capteurs ;

- Tests *in vivo* de biocompatibilité montrant après 30 jours une importante réduction de la réponse inflammatoire, ce qui suggère la guérison normale de l'hôte ;
- Suivi continu *in vivo* d'un médicament anti-inflammatoire, montrant la preuve de concept du système pour les futures applications en médecine personnalisée.

Sommario

Sempre piú innovazioni nel mondo scientifico stanno portando alla scoperta di trattamenti farmacologici piú nuovi e personalizzati, che miglioreranno la qualità della vita. Nonostante i risultati promettenti e i miglioramenti nei trattamenti offerti ai pazienti, fin'ora le terapie personalizzate sono casi limitati.

La ricerca in medicina traslazionale necessita la sperimentazione animale per trovare soluzioni innovative, sicure per i pazienti, soprattutto nel settore di ricerca e sviluppo di farmaci. Nonostante gli avanzamenti tecnologici potrebbero, un giorno, portare alla fine della sperimentazione animale, tutt'ora la ricerca non ne può fare a meno, vista la complessità degli organismi viventi.

Le condizioni di vita degli animali da laboratorio sono di fondamentale importanza dal momento che le condizioni di stress a cui gli animali sono sottoposti possono condizionare notevolmente i risultati sperimentali. Per questo motivo, la possibilità di monitorare gli animali in un ridotto spazio vitale a cui sono abituati, potrebbe migliorare la loro condizione riducendo l'intervento umano.

L'obiettivo di questa tesi é lo sviluppo e la caratterizzazione di un biosensore impiantabile per il monitoraggio in tempo reale di metaboliti endogeni ed esogeni, per applicazioni in ricerca farmaceutica e in medicina personalizzata. Il biosensore é impiantato in animali da laboratorio di piccola taglia (topi), liberi di muoversi in una gabbia.

Il biosensore impiantabile é composto da: una piattaforma che consiste in un array di quattro sensori elettrochimici, con un sensore per il pH e uno per la temperatura che permettono di ottimizzare le prestazioni dei sensori in diverse condizioni fisiologiche; circuiti integrati che possono misurare diversi parametri contemporaneamente; un'antenna per alimentare a distanza i circuiti integrati e per trasmettere i dati esternamente ad un computer o un tablet; un sistema di membrane e un packaging esterno che assicura contemporaneamente la biocompatibilità, misure con un elevato rapporto segnale-rumore, e selettività verso i metaboliti di interesse, filtrando le molecole interferenti presenti nei fluidi biologici.

Il lavoro di questa tesi descrive in dettaglio il sistema impiantabile, in particolare focalizzandosi sui seguenti risultati:

- Il monitoraggio *in vitro* di quattro farmaci anti-tumorali e di un farmaco anti-infiammatorio, misurando livelli di concentrazione fisiologici;
- Dimostrazione del funzionamento *in vitro* del sistema completo, mostrando che il sistema di alimentazione esterno trasmette correttamente la potenza al sensore e riceve

Acknowledgements

i dati dal sensore;

- Test *in vivo* di biocompatibilità del packaging, provando che dopo 30 giorni il livello di infiammazione cala notevolmente, dimostrando la biocompatibilità del sistema impiantabile;
- Monitoraggio continuo *in vivo* di un farmaco anti-infiammatorio e di glucosio, dimostrando che il sistema presenta un potenziale per essere migliorato in futuro per ricerche su animali in medicina personalizzata.

1 Introduction

“It’s far more important to know what person the disease has than what disease the person has.”

Hippocrates (460-370 BC)

1.1 Personalized medicine

Despite the continuous advances in the discovery and design of new drugs, the inter-individual variability in the response to the standard dose of a given drug remains a serious problem in clinical practice [1]. The inter-individual variability consists in genetic differences [2] that modulate the drug pharmacokinetics and/or pharmacodynamics, which lead to different therapeutic outcomes, or even to severe side effects or adverse drug reactions. Moreover, individual differences in response to drugs also depend on a complex intersection of environmental, social and cultural factors [3], including nutrition, organ function, age, sex, body weight, infections, diseases, and co-medications [4].

Nowadays typically clinicians have no choice but to follow a non-optimal approach to prescribing drugs and other treatments. This approach relies on the *trial-and-error* model: the doctor takes a decision about what drugs to prescribe based only on general information about what might actually work for that particular patient. If the medication does not work after a few weeks, the doctor may change drug or dosage. The effect of the combination of this *trial-and-error* model with intrinsic variability among individuals leads to patient dissatisfaction, adverse drug responses, with a significant effect on the quality and cost of health care. A 2001 study showed that the response rates of patients to medications from different therapeutic classes ranged from 25% (oncology) to 62% (depression), as shown in Fig. 1.1, [5]. In addition, an estimated 2.2 million (6-7% of all hospitalization) adverse drug reactions occur each year in the U.S., including more than 100,000 deaths [3], costing to the health care system billions of dollars. Another study demonstrated that adverse drug events result in more than 770,000 cases, among injuries and deaths each year in the U.S. [6], and result in

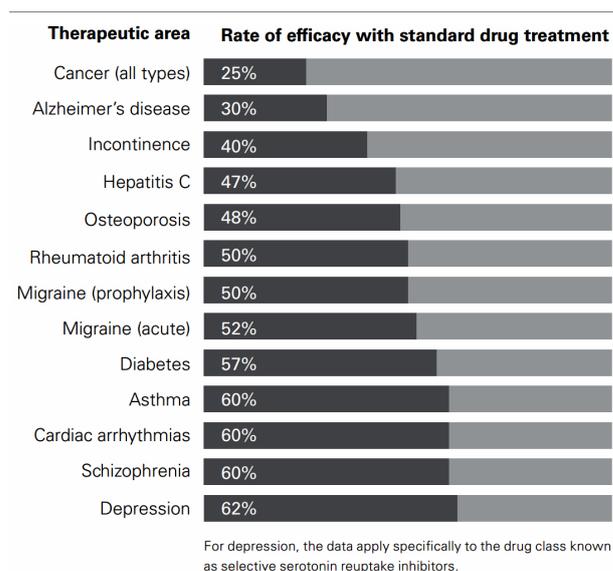

Figure 1.1 – Rate of efficacy of standard drug treatments for some common diseases. Adapted with permission from [5].

an average increase of length of stay in hospital of 3.1 days [7]. A recent statistics [8], ranks adverse drug reactions as one of the top 10 causes of death and illness in the developed world, claiming 100'000 to 218'000 lives in the U.S. each year. The direct medical costs of adverse drug reactions in the US are US\$30 to \$130 billion annually. These estimates are even more meaningful when compared to other high-cost diseases such as diabetes (\$45 billion), obesity (\$70 billion), and cardiovascular diseases (\$199 billion) [8].

This picture clearly shows how the current model, the so called "one-drug-fits-all" approach (also called blockbuster model), will be unsustainable in the future and that a new approach is necessary for a significant improvement of the outcomes of drug therapies. Over the last decade there has been a vast interest in the implementation of *personalized medicine* as a valid alternative in prescription and follow-up of the therapy.

The concept behind personalized medicine can be summarized in this statement: "In the best of all possible worlds, before administering a drug, clinicians would ascertain what dose in each and every patient would provide maximum efficacy and what dose would cause toxicity" [9]. It means that personalized medicine aims in tailoring the medical treatment to the individual characteristics and needs of patients during all stages of care, from the diagnosis to the treatment and follow-up. More simply, "personalized medicine" can be described as providing "the patient with the right drug at the drug dose at the right time" [4].

In general, to improve patient conditions, personalized medicine typically involves the use of two medical products, a diagnostic tool, to identify the patient's unique physiology and a therapeutic product, such as a drug, which need to be correctly dosed. Diagnostic tools can be *in-vitro* tests, such as assays for measurements of genetic factors, or *in-vivo* tests, such as electroencephalography, diagnostic imaging tools, or physiological sensors [3].

In the last decades, advances in the scientific research have contributed to advancements in

1.2. Current State-of-the-art in Personalized Medicine

technology with the realization of new diagnostic approaches which led to the introduction of personalized medicine approaches in clinical practice. In the past two years, the *Food and Drug Administration* (FDA) has approved some "targeted therapies", such as the drug for cystic fibrosis ivacaftor, for patients with a specific genetic mutation, or the anti-cancer drugs crizotinib, vemurafenib, dabrafenib, and trametinib, for patients whose tumors have specific genetic characteristics, which were previously identified by a diagnostic test [3].

Personalized medicine has the potential to decrease the costs associated with health care in enabling clinicians to provide more effective treatments, reducing the number of side effects and adverse drug episodes. Moreover, personalized medicine promises to enhance drug research and development by shortening the overall drug development and review times, with the final results of significantly reducing the costs. A recent statistics reports that at present, in the U.S., 15 years are needed to completely develop a single drug, from discovery to market availability, and the average cost of the overall process is between \$800 million and \$1 billion, due to the high number of failures (approximately 7,500 compounds fail for every one that receives approval). Thus, any reduction in drug research and development costs, could considerably decrease the overall cost of health care [10, 11].

However, despite the promising results and the major advantages in treatments offered to patients, these personalized medical treatments are few cases, and the *trial-and-error* approach still persists. The reason is that a complete transition from *trial-and-error* medicine to *personalized* medicine meets some important technological barriers but also industrial constraints [12]. There is now a general consensus that the "one-drug-fits-all" approach has significant limitations and nowadays pharmaceutical industry is highly interested in investing in personalized medicine, as revealed by the growing number of companion diagnostic companies [13, 14]. Nevertheless, in general the pharmaceutical industry still bases most of the drug development on the blockbuster model [13].

The next section will review the current state-of-the-art of the disciplines employed for the personalization of drug therapies.

1.2 Current State-of-the-art in Personalized Medicine

1.2.1 The predictive methods: the "-omics" sciences

The so-called *-omics* sciences, *pharmacogenomics*, *transcriptomics*, *proteomics* and *pharmacometabonomics* represent the state-of-the-art in our ability to predict the reaction of a patient to a specific therapy [9].

Pharmacogenetics or pharmacogenomics, is "the study of how individual genetic differences affect drug response" [10]. More specifically, pharmacogenetics is the study of single genes and their effects on inter-individual differences in drug-metabolizing enzymes, while pharmacogenomics represents the whole genome application of pharmacogenetics. The goal of pharmacogenomics is to optimize a therapy according to the unique genotype of patients, by ensuring maximum efficiency with minimal adverse effects. For instance, pharmacogenomic assessment of drug metabolizing enzymes can improve the optimization of drug dosage [12].

Chapter 1. Introduction

The first pharmacogenetic test that was approved by the FDA in January 2005, is the AmpliChip CYP450 test, a commercial assay for the detection of cytochrome P450 2D6 and P450 2C19 genetic variability [15], which play a major role in the metabolism of an estimated 25% of all prescribed drugs. It is intended to aid the clinicians in determining therapeutic strategy and dosages for drugs metabolized by the CYP2D6 or CYP2C19 gene product.

In 2013, the FDA published a list of more than 100 pharmacogenomic biomarkers (from germline or somatic gene variants, functional deficiencies, chromosomal abnormalities, to selected protein biomarkers that are used to select patients for treatment) that can be used to identify responders and non-responders to medications, avoiding adverse events, and optimizing the dosage for more than 100 drugs [16]. Many *in vitro* diagnostic devices or imaging tools are nowadays produced to detect these biomarkers, with the objective to provide essential information for the safe and effective use of a corresponding drug. Twenty of the pharmacogenomic biomarkers (53%) had a corresponding diagnostic device approved in the USA [17]. Among them, only three showed successful drug diagnostic co-development, while for the other 17 biomarkers, the drug and its diagnostic device were developed and approved separately [18].

An interesting example of a shortcoming in pharmacogenomic testing is the polymorphism in the gene that encodes cytochrome P450 1A2 (CYP1A2) that participates in the metabolism of almost two dozen drugs (*e.g.* tacrine, caffeine, theophylline, erythromycin, propranolol, naproxen and verapamil). The human genome contains 57 *cytochrome P450 genes* (CYPs) that encode for the enzyme family of *cytochrome P450* (P450), involved in phase I drug metabolism, when enzymes introduce reactive and polar groups into their substrates [19]. However, less than 12 P450 enzymes, mostly members of the P4501, P4502 and P4503 families, are responsible for the metabolism of virtually all drugs. In the human populations studied, over 60 variant alleles of the CYP1A2 gene have been detected. Therefore, unless every variant site in the genome that affects CYP1A2 expression is tested, it is difficult to conclude that a patient is a poor, intermediate, efficient, or ultra-rapid metabolizer, because of the complexity of the genome. At present, a DNA test cannot provide absolute certainty in predicting drug responses for individual patients [9]. The unequivocal prediction of drug response is also not possible for other genes that encode other drug-metabolizing enzymes or transporters (*e.g.* is even worse the case of the gene CYP2D6). Therefore, as recent studies [20, 10] concluded, pharmacogenomics alone cannot provide absolute certainty in predicting drug responses for individual patients.

Moreover, the translation of pharmacogenomics research findings into clinical practice has been slow, due to the lack of consistent interpretation of pharmacogenomics test results, availability of clinical guidelines for prescribing on the basis of test results, and adequate knowledge-based decision support systems [22].

Transcriptomics is the discipline that studies the gene transcription¹. With respect to personalized therapy, transcriptomics aims to find some correlations between the gene expression

¹In *transcription*, a portion of a double-stranded DNA template gives rise to a single-stranded RNA molecule. The RNA molecule can be a "finished product" that serves some important function within the cell, or it goes through a translation step, which ultimately results in the production of a protein molecule [23].

1.2. Current State-of-the-art in Personalized Medicine

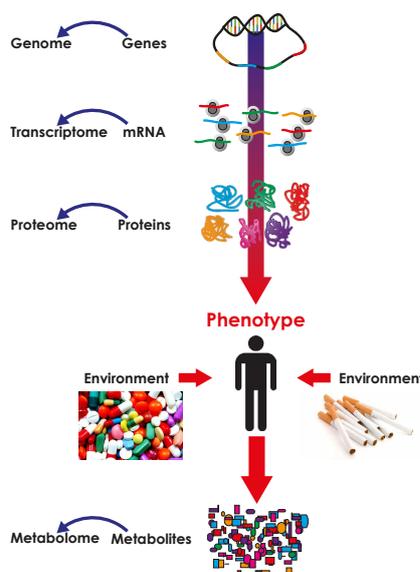

Figure 1.2 – Schematic of the "omic" hierarchy: genomics, transcriptomics, proteomics, and metabolomics. Adapted with permission from [21].

and patient responsiveness to drug therapies. Transcriptomics, is normally analyzed usually using cDNA expression microarrays [9]. Some interesting results have been obtained with the transcriptome analysis of some tumors, as shown in recent studies [24, 25]. **Proteomics** is the following step in the study of biological systems, since it is the large-scale study of proteins. After translation, proteins can be modified in a myriad of ways, each of which is capable of producing a functional alteration that potentially affects disease development and therapeutic response. Proteomics has given us insight into the perturbations of signaling pathways, in particular within tumor cells, that was not possible with the two previous disciplines, and has improved the discovery of new drug targets [26]. Recent studies [27] found that the integration of proteomic approaches with existing genomic and transcriptomic methods may lead to different treatment approaches tailored to the unique expression pattern of each patient. Despite the promising results, both transcriptomics and proteomics suffer from some important limitations, such as the lack of sources for performing microarray analyses (*e.g.* blood, urine and feces), and tissue that contains the relevant cDNA (*e.g.* surgical biopsy of tumor, other tissue biopsies, placenta and foreskin). Tissue biopsies require an invasive intervention on patients, thus preventing the mass application of transcriptomics and proteomics.

What emerges from the analysis of pharmacogenomics, transcriptomics and proteomics, is that they can only offer approximate predictions on the patient predisposition to drug response. The genotype, the DNA transcription and translation into proteins, are all strongly influenced by environmental factors, represented by diet, lifestyle as well as the individual physiopathological conditions. And these factors will ultimately generate alterations in the metabolism, including drug metabolism. In conclusions, pharmacogenomics, transcriptomics and proteomics offer a partial understanding of the reasons behind the drug metabolism alterations, without considering the direct causes, *i.e.* the environmental factors.

Metabolites are the final products of cellular regulatory process, and their levels can be regarded as the ultimate response of biological systems to genetic or environmental changes [28], (Fig. 1.2). **Metabonomics**, the study of metabolite profiling in multicellular systems (*e.g.* intact laboratory animals and patients), is the complement of **metabolomics**, the study of metabolites in isolated cell systems (*e.g.* organ and cell cultures) [19]. The novel approach that combines metabolite profiling and chemometrics² to model and predict efficacy or toxicity of drug on an individual subject is called **pharmaco-metabonomics** [30]. The main assumption behind the pharmaco-metabonomics is that the pre-dose metabolite profile of an individual could contains sufficient information to enable the prediction of aspects of drug metabolism and toxicity without any prior knowledge of the genomic profile of that individual [9].

Unlike genomics and proteomics, metabolomics deals with a great number of molecules characterized by a huge chemical diversity that makes the analysis of full cellular metabolomes very challenging. The principal analytical technologies or platforms that have been developed to detect and quantify metabolites are preferentially based on nuclear magnetic resonance spectroscopy, hyphenated mass spectrometry techniques (often combined with high-performance liquid chromatography) [9]. Currently, no single point-of-care methods enable the complete coverage of all metabolites present at the cellular level or in biological fluids and only a relatively limited fraction of known metabolomes can be analyzed [28].

The appeal of metabonomics is that, for example, a dose of a specific drug in a patient can be monitored for its phenotype (drug disposition, efficacy, therapeutic failure and toxicity), by profiling in the urine either the drug metabolites or the patterns of the thousands of small metabolites. Specific patterns might indicate an individual's predisposition to a toxic drug response long before clinical effects become evident. Hence, in principle, this technique offers great promise for attaining personalized drug therapy [31]. Few encouraging studies predicted the drug clearance based on metabolomic investigation in a clinical setting, with regard to the immunosuppressant drug, tacrolimus [32], and the anti-inflammatory drug acetaminophen [30]. However, the use of metabolomics in the clinical setting is still far from reality, because it requires analytical and clinical validation of the metabolomic approach, and, finally, a clinical utility.

In summary, a single approach (*e.g.* genomics, proteomics, transcriptomics and metabonomics) seems to be non sufficient to identify all the genes and gene products that are responsible for either the efficacy or toxicity of a particular drug. The above-mentioned approaches must be used in combination, and they are still under development. Pharmaco-metabonomics seems promising but for the moment, it is too advanced, because it requires high sensitivity techniques and profiling of hundreds of different metabolites at once. Moreover, for some applications a simple prediction of drug response is not enough for a safe drug administration, such as the cases reported in Table 1.1. A very promising alternative approach to these 'predictive' methods, for an effective optimization of a drug therapy, is a 'corrective' method, based on the direct quantification of the drug response after the administration. This is what is currently done with the *therapeutic drug monitoring* (TDM), a multi-disciplinary clinical discipline

²Chemometrics is the branch of chemistry concerned with the analysis of chemical data (extracting information from data) and ensuring that experimental data contain maximum information [29].

1.2. Current State-of-the-art in Personalized Medicine

Table 1.1 – Clinical pharmacological cases when TDM is essential.

<i>List of pharmacological cases</i>
Toxicity suspected, or whether the minimum toxic concentration level has to be defined.
Lack of response, or whether the minimum effective concentration level has to be defined.
Assessment of compliance with medication regimen.
Assess therapy following a change in dosage regimen.
Change in clinical state of the patient.
Potential drug interaction due to change in co-medications.
Manifestations of toxicity and disease state are similar.

focused to improve patient care by individually adjusting the dose of drugs according to the individual pharmacokinetic profile.

1.2.2 Therapeutic Drug Monitoring

Therapeutic drug monitoring (TDM) is defined as "the direct measurement of drug levels that, with appropriate clinical pharmacological interpretation, will directly affect prescribing procedures" [33]. The aim of TDM is to measure the concentration of the drug at steady-state (or the maximum drug concentration) and to modify the dose to obtain a desired drug concentration known to be associated with efficacy and not toxicity [34]. Before going into details on the TDM current practice, we first need to introduce some basic concepts of pharmacokinetics. Pharmacokinetics describes the time course of the concentration of a drug in a body fluid, preferably plasma or blood, that results from the administration of a certain dosage regimen. In simple words, pharmacokinetics describes the ensemble of actions of the body on a drug, divided in four main phases: *Absorption, Distribution, Metabolism, Excretion*, (ADME)³. By measuring the drug concentration in body fluids over the time we can follow the path of the drug along the ADME phases. A typical plasma concentration time profile after oral drug administration is shown in Fig. 1.3. MEC, defined as the "minimum effective concentration", is the minimum concentration needed to produce the desired pharmacological effect. MTC, defined as the "maximum tolerated concentration", or alternatively "minimum toxic concentration", is an upper limit of concentration beyond which toxic effect or dangerous side effects start showing up⁴.

³*Absorption* happens when the drug is administered orally, and it is the phase when the drug goes across several physiological barriers, like the gastrointestinal tract. The percentage of drug that actually reaches the systemic circulation is defined as *bioavailability*. *Distribution* occurs when the drug leaves the vascular system to different compartments, either tissues or organs. In the *metabolism* phase, normally mediated by specific enzymes, the drugs are converted into molecules that are easier to eliminate. *Excretion* is the irreversible elimination of a compound from the body.

⁴These definitions are valid assuming that there is rapid and homogeneous equilibration of the drug concentration between plasma and the target site, and the pharmacologic effects are directly related to the concentration at the target site.

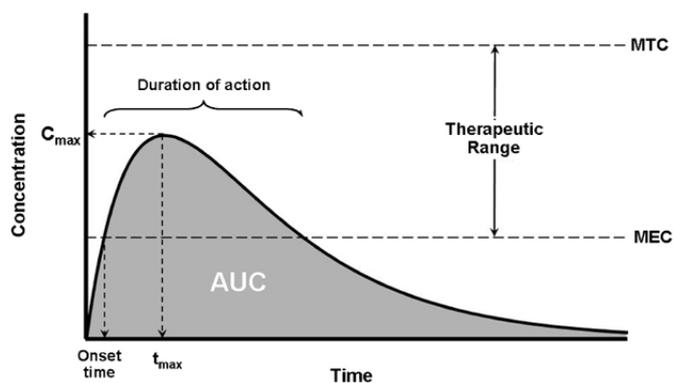

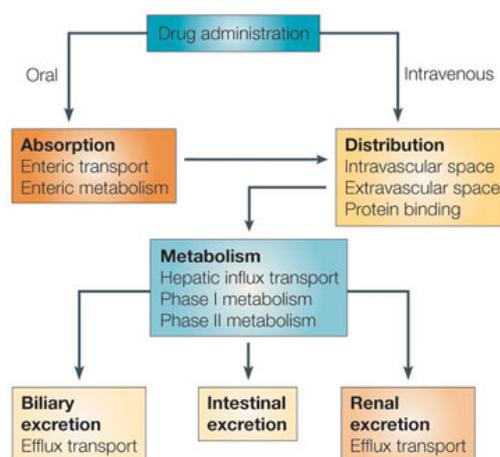

Figure 1.3 – Pharmacokinetic parameters describing a typical plasma concentration time profile after an oral drug administration. Reprinted with permission from [36].

Pharmacokinetics: ADME and drug concentration in body fluids

The maximum concentration achieved in body fluids, denoted by C_{max} , depends on the extent of the drug absorption, whereas t_{max} , the time required to achieve C_{max} , is indicative of the rate of absorption. The *area under the curve* (AUC) represents the overall systemic exposure to the drug. After the C_{max} peak, plasma concentration gradually decreases due to distribution, metabolism and excretion. The figure presents other important parameters: the *therapeutic range* is the plasma concentration comprised between the MEC and the MTC. Alternatively, it can be defined as a range of drug concentrations within which the probability of desired clinical response for the considered patient is relatively high and the probability of unacceptable toxicity is relatively low. The *duration of action* is how long the plasma drug levels stays within the therapeutic range. In case of multiple doses we need to consider the steady-state concentration instead of the peak concentration [35]. When the drug is in the systemic circulation, it might interact with plasma or tissue proteins to form drug–macromolecule complexes, which might reduce the percentage of free drug in the body, affecting the drug disposition and efficacy. Thus, only free drug concentrations are ultimately relevant to pharmacotherapy [36]. Drug formulation, delivery route and frequency of administration, as well as the patient compliance affect all the stages of pharmacokinetics, by introducing variability, as shown in Fig. 1.4. Moreover, genetic variability, inter-individual differences, and environmental factors, such as lifestyle, nutrition, physiopathology conditions, age, gender, etc., affect the drug metabolism, as explained in the previous section, so they will further increase the pharmacokinetics variability. The pharmacokinetic variability ultimately results in inter-patient variability in MEC and MTC in plasma concentration-time profiles. The TDM focuses on drugs subjected to high pharmacokinetic variability. The utility of TDM applied to pharmacokinetics consists of deciding the optimum dosage regimen, that is, the best way to administer a given drug, maintaining the concentration within the therapeutic range. In other words, TDM helps the clinicians in answering the questions ‘How Much?’ and ‘How Often?’ a drug must be administered to achieve this objective.

1.2. Current State-of-the-art in Personalized Medicine

Nature Reviews | Cancer

Figure 1.4 – The process of drug disposition divided in four phases (ADME). Interindividual and intraindividual differences in these steps are potential sources of pharmacokinetic variability. Reprinted with permission from [37].

What is currently done in TDM.

TDM methodological approaches have developed more than 40 years ago, with conventional TDM of psychotropic drugs. In 2004, the first consensus guidelines on the indications for TDM and recommended plasma levels of antidepressants and antipsychotic drugs were published. TDM is based on the hypothesis that the concentration of a drug in the blood (plasma or serum) reflects the concentration at the target site better than the given dose. It is also based on the assumption that a relationship between blood concentrations and clinical effects (therapeutic, adverse or toxic effects), can be defined [1].

Blood samples are collected at a prescribed time after the dose is administered, to capture the peak (or at steady state) concentration, and the trough level. The blood sample timing depends by the drug type, the route of administration, and adsorption. The measurements of drug concentration are then run in laboratory settings with techniques such as chromatography, ultrafiltration, mass spectrometry, and immunoassay techniques [34]. The results become available within a single working day. The clinicians will evaluate the results by combining important information, such as the time at which the blood sample was taken the dosage, the patient demographic information (*i.e.* sex, age, concomitant disease ethnicity, etc.), co-medications and therapeutic range for the drug. The final decision might includes a change in dosage, a change in medication or the continuation of the therapy.

Nowadays, TDM has been established for the monitoring of lithium, anticancer drugs, immunosuppressant drugs, antifungal drugs, anticonvulsant drugs, antidepressants, antipsychotics, antiretroviral drugs, certain antibiotics, for theophylline, aminoglycosides, and mood stabilizers [33, 1, 38, 39].

Limits of TDM

Despite the promising results in clinical applications of TDM, so far it has been introduced to a limited number of patients and on few drugs [33], in my opinion for the following reasons:

- *Technology*: Current analytical techniques in TDM practice grant highly accurate, selective, and reproducible drug measurements. However these techniques are time consuming and require highly-trained staff, and they can be performed in only a limited number of laboratories or specific centers, at high costs and at the expense of a longer time lag between TDM request and reporting of results.
- *Human error*: A recent study on the clinical use of TDM on antidepressants reveals that between 25% and 40% of the requests for TDM were inappropriate and that the interpretation of the results led to about 20% of the therapeutic adjustments being incorrect [33]. Most of the reasons are due to human errors in misinterpretation of the results. Additionally, repetitive manual data handling represents an additional source of errors in diagnosis. For the optimal evaluation and decision in TDM, a team of experts is needed, which should consist of pharmacologists, clinical pharmacists and analytical scientists.
- *Incorrect timing*: The same study [33] reports that in the majority of the cases, blood samples were collected at a non-optimal time frame. The timing in sample collection and also in drug administration is essential for a precise tuning of the patient's dosage [34].
- *Drug Development*: A reason for the slow development of TDM is the lack of sufficient information regarding the pharmacokinetic/pharmacodynamic of drugs. It is common belief that TDM should also be introduced during drug development and in pharmacovigilance. Although high-throughput laboratory methods are now available, clinical trials usually do not include measurements of blood concentrations. These should be implemented in the near future to provide earlier insight about the correlation between drug concentrations and clinical outcomes, thus enabling the development of compounds with a higher degree of therapy personalization [33].

The success of personalized medicine and TDM depends on having accurate diagnostic tests that could overcome these limitations. As it will be explained in the next section, TDM and personalized medicine would greatly benefit from the introduction of innovative biosensors in clinical practice.

1.3 Biosensors: towards the optimization of personalized medicine

The analysis of the current state-of-the-art in personalized medicine raises the need for a new innovative technology that should present the following features:

1.3. Biosensors: towards the optimization of personalized medicine

- *Point-of-care, cheap, disposable and reliable*: The development of a quick, easy, and inexpensive diagnostic technology can be the driving force to encourage patients and industry to adopt personalized therapy policies.
- *Wearable m-health device*: Recently, more and more companies, like Google or Apple, are investing in *mobile-health* (m-health), *i.e.* the practice of medicine supported by mobile devices [40]. A "smart" technology able to monitor the patient's status and transmit in real-time this information to doctors would enable a more effective patient monitoring and treatment outside the traditional medical care settings of hospitals. Instead, more people would be treated at home and at work, and would also be able to maintain their lifestyle and quality of life.
- *Small, miniaturized device and compatible with the current electronic technology*: Miniaturization and integration of the technology in a small device is essential for the development of portable and non-expensive devices and it can be achieved by microelectronic compatible technologies.
- *Continuous monitoring*: Some applications might require single time self-testing, such as for a pregnancy test, in other cases there is a daily need for measurement, as for glucose monitoring in diabetes. For drug monitoring, as it emerges from TDM practice, blood samples are collected once the drug concentrations have reached the steady-state, *i.e.* at least 3.3 half-live at the current dosage regimen [34]. However drugs with long half-lives, especially if toxicity is suspected, should be monitored at early stage. While in some cases disposable devices are more indicated, for other cases, especially for drug monitoring, the realization of fully implantable systems for continuous measurements would represent a major breakthrough, and improve the TDM practice. With an implantable sensor the measurement can be activated from outside, thus tuning and adapting the measurement timing to the specific drug monitored. An implantable sensor would offer much more flexibility and accuracy at the same time.
- *Multiparameter*: Even in TDM it is important to control other parameters, such as endogenous metabolites, blood pressure, pH and temperature, for an accurate therapy, finely tuned towards individual patients [3]. Moreover, the possibility to measure several drug concentrations would improve the accuracy of TDM when assuming drug cocktails, to control the drug interactions. Drug interactions are by far one of the most important source of variability in drug response [12].

The technology that best match all these requirements would be an implantable or disposable electrochemical biosensor for real-time and continuous drug monitoring, able to monitor other parameters, with fully electronics that could actuate the device, collect the data and transmit the data to an external user.

Biosensors are generally concerned with sensing and measuring particular chemicals which may even not be biological molecules themselves and which are usually known as the substrate or analyte (see Fig. 1.5). The presence of the analyte is detected through a recognition

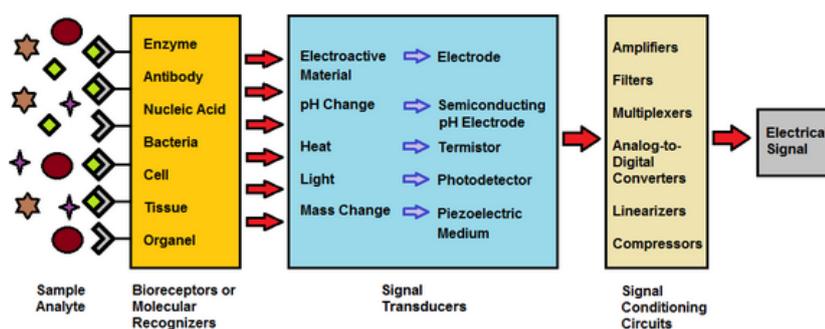

Figure 1.5 – Classification and main components of biosensors. Reprinted with permission from [41].

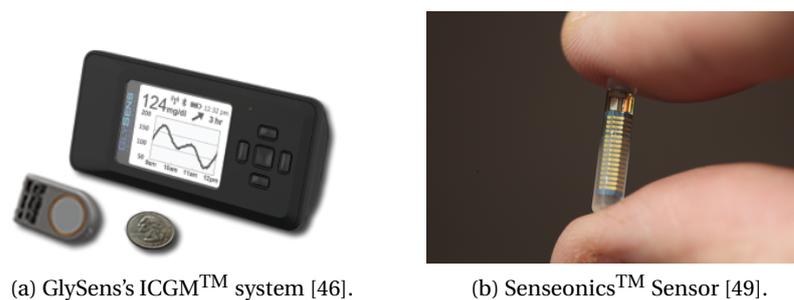

system, normally a biochemical mechanism, which transfers this information to the transducer element. The biological recognition system translates information from the biochemical domain, usually an analyte concentration, into a chemical or physical output signal with a defined sensitivity. In biosensors, the most common recognition element is an enzyme, but also antibodies, nucleic acids and receptors are possible. Electrochemical amperometric biosensors are of great interest for the development of point-of-care devices due to their low cost of fabrication, ease of use and the possibility of miniaturization. Basic concepts about electrochemical biosensor classification and fabrication are extensively reviewed in literature [42, 43].

The adoption of biosensor technology is emerging in health care applications, as demonstrated by the increasing interest of the market towards the development of point-of-care biosensors. The development of a disposable or implantable biosensor for drug monitoring would improve the patients' compliance and the TDM practice. Moreover, the introduction of fully implantable sensors might be also useful in preclinical drug research on animals, by allowing a constant monitoring of pharmacokinetics during efficacy or toxicology investigations and by reducing at the same time the human intervention on animals.

1.4 Implantable sensors for drugs: market analysis

The global market for biosensors in medical diagnostics is forecast to grow to a value estimated to reach \$8.5 billion in 2012 and larger than \$16 billion by 2017. More than 85% of the global biosensor market is focused on glucose biosensors, including *continuous glucose monitoring* (CGM) systems. The CGM device market is currently estimated at \$92.2 million and is estimated to reach ≈\$200 million by 2017. A recent work [44], extensively review examples of commercial CGM systems available nowadays. Since 1999, CGM systems have been approved by the FDA but only percutaneously implanted electrochemical glucose sensors are currently available for sale in the United States. Percutaneous devices for CGM have been developed that combine through-the-skin and skin-adhered components with an implantable catheter that can last 6-7 days maximum [45]. However, these sensors require frequent calibration using

1.4. Implantable sensors for drugs: market analysis

(b) Senseonics™ Sensor [49].

Figure 1.6 – Implantable CGM devices available in the market.

intermittent glucose monitoring through finger pricks, due to errors in analytical performance. Because of limitations of the sensor lifetimes imposed by FDA regulations (5-7 days), the devices must be replaced on a regular basis with significant financial impact on the patient, resulting in a low compliance regarding the use of such devices. Furthermore, percutaneous devices penetrate through an opening in the dermis thus creating concomitant infection risks. Up to date, few prototypes of commercial fully implantable biosensors have been developed, although not yet approved for commercialization. The glucose monitoring device GlySens's ICGM™ is currently under development and is not yet approved [46]. It is a promising prototype (Fig. 1.6,a) for CGM, which can be successfully implanted in pigs and can maintain its functionality for one year or longer life (it was demonstrated up to 18 months in preclinical studies) [47]. The GlySens sensor has been designed to be fully implantable, and it is designed to allow automated measurements without user interaction and without the inherent variability associated with changing sensor sites every few days. The basic system is comprised of the fully implanted sensor, and of an external receiver with a monitor. The external receiver is designed to offer a convenient means for continuous glucose display, recording, and alerts regarding hypo- or hyperglycemic glucose excursions.

The miniaturized Senseonics™ Sensor (Fig. 1.6,b) is designed to measure glucose in the interstitial fluid for up to six months. Unlike current glucose sensors, the Senseonics Sensor is intended to be implanted subcutaneously on the upper arm with no sensor part protruding from the skin. Clinical performances over a 28 day implant period in 12 type 1 diabetic patients are reported. The implantable sensor is based on a fluorescent, boronic-acid based glucose indicating polymer coated onto a miniaturized, polymer-encased optical detection system. The external transmitter wirelessly communicates with and powers the sensor and contains Bluetooth capability for interfacing with a Smartphone application [48, 49].

The only available drug sensors in the market are screening tests for drug abuse, which can analyze both blood and urine samples. Drug tests such as Signify®ER drug screen test, Triage®Drug of abuse Panel, Alere™ Toxicology drug screening system, QuickScreen™ Pro-Multi Drug Screening Tests and Rapid Drug Screen™, are some examples [50, 51]. For instance, the Alere™ Toxicology system can measure up to 11 drugs with one device, such as acetaminophen, amphetamines, barbiturates, benzodiazepines, methamphetamines, tricyclic antidepressants, as well as narcotic substances (*e.g.* cocaine, marijuana, etc.) [52].

At the moment, the market shows an enormous demand of point-of-care devices for glucose monitoring, but not yet for drugs. The research is currently interested in developing sensors for drug monitoring, and new sensors would represent a new interesting market opportunity.

1.5 Research contribution

The objective of this thesis is the design and characterization of an implantable electrochemical biosensor platform for the real-time and continuous monitoring of drug and other parameters, such as endogenous metabolite concentrations, pH and temperature, to be further fully equipped with electronics that could actuate the device, collect the data and transmit the data to an external user.

The present research is part of a bigger project⁵ that aims to develop an implantable system for drug monitoring in mice used in research on animals. Small animal models are increasingly being used in the first phase of clinical trials for drug development. The living conditions of these animals are of primary importance because the stress level can affect the measurement results. This means that the animal must be in a comfortable environment and capable to move freely. Therefore, the final aim of this project is to monitor the animal in a living space, such as a cage, by means of a fully implantable device, in order to minimize the human intervention. The device must be battery-less, thus an intelligent powering system is designed to continuously transfer the power to the implantable system according to the position of the animal. The fully implantable device consists of: 1) a passive sensing platform, 2) *integrated circuits* (ICs) to perform electrochemical measurements and 3) a coil for power and data transmission⁶. The device is intended to be implanted subcutaneously in mice. The present work will mostly focus on the realization of the passive sensing platform, and on the integration with the other components for the development of a working prototype.

The realization of such a device has to take into account several requirements: it must be *biocompatible and retain the sensor functionality*, in order to ensure a correct integration with the body as well as electrical integrity; it has to guarantee high sensitivity and selectivity for the detection of several molecules within the physiological ranges. The next chapter will present all the design choices that have been made in this thesis to fulfill these requirements, with details on the current state-of-the-art.

Concerning the presented state-of-the-art, this thesis presents innovative contributions on:

- *Multiple drug detection*. Selective detection of drugs and drug pairs has been achieved with different strategies, which combine the electrode functionalization with nanomaterials and enzymes. Several drugs have been monitored within the pharmacological ranges in undiluted human serum. As a proof-of-concept, the continuous monitoring of an anti-inflammatory drug was accomplished, thus showing the potential of the presented method as a valid alternative in TDM practice.

⁵SNF Sinergia Project, code CRSII2_147694/1 and title "Innovative Enabling Micro-Nano-Bio-technologies for Implantable systems in molecular medicine and personalised therapy, project prolongation".

⁶The powering system and the ICs have been realized by other collaborators.

- *Monitoring multiple parameters.* The electrochemical platform was designed to host four independent biosensors, for the monitoring of drugs and endogenous metabolites, a pH sensor, and a temperature sensor. The design of a sensing platform for electrochemical measurement, combined with the presence of a pH and a temperature sensor, is a strategy to optimize the sensing performance in different physiological conditions, since changes in pH and temperature can affect the sensor specificity.
- *System design, fabrication, characterization and integration.* The research is focused on the complete design and fabrication of the sensing platform and its integration with the electronics and an intelligent powering system for real-time monitoring molecules in freely-moving animals.
- *Biocompatibility and packaging.* This work deals with the complex integration of micro-fabricated sensors, nanomaterials, enzymes, system of membranes and an external packaging, to ensure at the same time measurements with high signal-to-noise ratio, biocompatibility and selectivity against possible interfering molecules in biological fluids.

1.6 Thesis organization

Following the Introduction, the thesis is organized as follows:

Chapter 2 gives an overview on the state-of-the-art concerning the strategies that were chosen in the present research for the realization of the fully implantable device. Biosensing strategies, the use of nanomaterials, as well as the choice of a complex packaging are discussed and compared.

Chapter 3 presents several possibilities of biosensors for drug monitoring. The sensor based on cytochrome P450 and carbon-nanotubes is employed for single and multiple drug detection. The continuous monitoring of the anti-inflammatory drug Naproxen is presented in this chapter, with particular concern on its potentiality and limitations. Detection of drugs without enzymes is also shown. Finally, a discussion on possible strategies for enhancing the specificity of the sensor in case of multiple drug detection is presented.

Chapter 4 presents the design, fabrication and characterization of the electrochemical sensing platform, with respect to the constraints given by the integration with the electronics and by the final application. The calibration towards drugs, endogenous metabolites, pH and temperature with the micro-fabricated platform is reported, proving the flexibility and accuracy of this designed platform.

Chapter 5 shows the complex system of membranes and polymers for the realization of the final packaging for the implantable system, that could ensure a good level of biocompatibility and the permselective ability against interfering molecules present in biological fluids.

Chapter 1. Introduction

Chapter 6 focuses on the assembly of the implantable system, on the *in-vitro* and *in-vivo* characterization, with a detailed description of the complete system.

2 Implantable biosensor: theory and state-of-the-art

“If I have seen further it is by standing on the shoulders of Giants.”

Isaac Newton, (1642-1727)

As stated in the Introduction, the objective of this thesis is the design and characterization of an implantable electrochemical biosensor for real-time and continuous monitoring of drug and other parameters, such as endogenous metabolite concentrations, pH and temperature, which can be further integrated with electronics that could actuate the device, collect the data and transmit them to an external user. The realization of this device has to take into account several requirements: the biosensors are electrochemical-based devices, able to perform *electroanalytical techniques*; *high signal-to-noise ratio* is required to achieve high precision in the quantification of the drugs and metabolites in biological fluids within the pharmacological and physiological ranges; the sensing platform is intended to measure *drugs, drug cocktails and endogenous metabolites*, as glucose and lactate; the device must be protected with a *biocompatible* packaging, in order to ensure the integration within the body as well as electrical integrity; it needs *autonomy* in terms of power supply and sensor actuation. This chapter will present design strategies to fulfill these requirements, with an overview on the theory and the current state-of-the-art. More specifically, this chapter will address these questions:

- How electrochemical measurements are done?
- How the sensor signal can be enhanced to fit the physiological range?
- What can be measured by electrochemical sensor?
- Which are the main issues to be considered for the design of a biocompatible packaging?
- How the sensor can be integrated in a small implantable device?

2.1 Electrochemical sensing techniques: an overview

2.1.1 Background on electroanalytical techniques

Electrochemical sensors for the measurement of analytes of interest in clinical chemistry are ideally suited for the realization of portable or implantable devices, due to their high sensitivity and selectivity, portable field-based size, rapid response time and low-cost [43]. Furthermore, electrochemical sensors can be employed in numerous applications in clinical diagnosis, environmental monitoring and food analysis [53]. Summarizing the complete state-of-the-art for electrochemical sensors is a difficult task, as an enormous amount of possibilities exists in terms of techniques and applications. However, some reviews synthesize well the main concepts and applications for electrochemical sensors [54, 55].

The typical electrochemical biosensor configuration is based on a two- or three-electrode cell topology. An electrolytic cell is created by placing metallic electrodes into an electrolyte. The electrolyte is usually a conductive solution made by water or other solvents in which ions are solvated. In biosensors, the electrolytes are biological samples, since body fluids, such as blood or interstitial fluids, are salt and water-based, thus conductive solutions.

The *oxidation/reduction* (redox) reactions occurring onto metallic electrodes when they are placed inside an electrolytic solution, are responsible for producing charge separation at the interface between the solid metal and the solution. Once they are separated, the charged particles create an electrostatic field and its associated potential difference. A potential difference can be measured between the two electrodes, one called *working electrode* (WE) and the other *reference electrode* (RE). The potential of the cell, which corresponds to the potential difference between the two electrodes, is expressed by the *Nernst equation*:

$$E = [E_{O/R}^{\ominus}]_{SHE} + \frac{RT}{nF} \ln \frac{C_O}{C_R} \quad (2.1)$$

where E is the differential potential between the two electrodes, $[E_{O/R}^{\ominus}]_{SHE}$ is the standard redox potential referred to the *standard hydrogen electrode* (SHE), R is the gas constant, T the absolute temperature, n the number of electrons exchanged in the redox reaction, F the Faraday constant, and C_O and C_R are the concentration of the oxidized and reduced species, respectively. The standard redox potential is measured under standard conditions, at 10 °C, a 1 M concentration for each ion participating in the reaction, with a partial gas pressure of 1 atm for each gas that is part of the reaction, and metals in their pure state. Values of the standard redox potential for different redox couples have been measured with respect to the SHE reference electrode. However many other standard reference electrodes can be used, such as the *silver silver-chloride* ($Ag/AgCl$) electrode, or the *saturated calomel electrode* (SCE), by adjusting the potential with respect to the standard SHE [56]. The equilibrium potential is measured when the redox reaction reaches the equilibrium. In this condition, as demonstrated from the Eq. 2.1, the concentration of oxidized species equalizes the concentration of reduced species. Thus, by applying a varying potential, the equilibrium between the concentration of oxidized and reduced species will change, accordingly. The Nernst equation (Eq. 2.1) is a

2.1. Electrochemical sensing techniques: an overview

fundamental expression that specifies the relationship between the potential difference and the concentrations of the two species (designated O and R) involved in the redox reaction.

When an external potential is applied to the electrodes, a current flow is generated across the cell, and it can be measured and related to the concentration of the oxidized/reduced species. By applying a potential higher than the equilibrium redox potential, the concentration of oxidized species will be predominant and an anodic current will be measured, while vice-versa, a cathodic current will be measured. The total current recorded in the electrochemical cell is the sum of the anodic and the cathodic current.

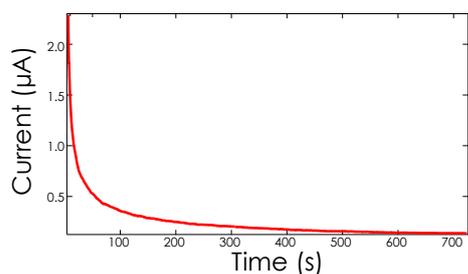

With the 2-electrode configuration, it is extremely difficult to maintain a constant potential at the RE: the RE acts at the same time as electron supplier as well as reference for the potential, with the consequence that the current could change its potential [57]. To solve this problem a third electrode, the *counter electrode* (CE) is introduced. In the 3-electrode cell topology, the reference electrode acts as reference in measuring and controlling the WE potential and it does not enable any current flow; the CE pumps (or collects) the current needed to balance the current required (or measured) at the WE. The WE is typically the electrode where the analyte of interest undergoes reduction or oxidation. Thus, the current flowing between WE and CE is indicative of the concentration of the oxidized and/or the reduced species, according to the polarization (*e.g* the direction of the applied potential).

In practice, currents and potentials in the 3-electrode cell are regulated by a potentiostat, which controls the potential difference between RE and WE by adjusting the current at the CE. A fully implantable electrochemical sensor will therefore require a miniaturized 3-electrode cell, a potentiostat circuit, and a power supply.

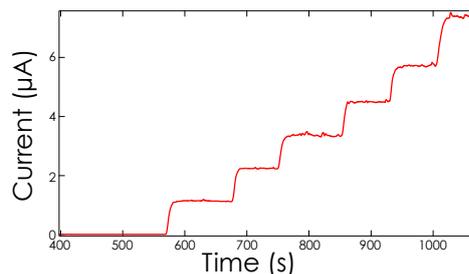

Many electroanalytical techniques are currently employed in electrochemical sensors: the most common are potentiostatic methods and potentiodynamic methods. The next section will focus on the methods that were employed in this thesis: chronoamperometry, an example of potentiostatic method, cyclic voltammetry and square-wave voltammetry, as potentiodynamic methods. The main principle is that these techniques are used to measure the concentration of a specific analyte (or substance), which is electrochemically active and undergoes reduction or oxidation.

In an electroanalytical experiment, the applied potential forces the ratio $\frac{C_O}{C_R}$ to adopt a specific value consistent with the Nernst equation (eq. 2.1). In general, however, the concentration of the species C_O and C_R at the electrode surface are not the same as those in the bulk solution. Thus, a driving diffusion force transports the analyte to, or from the electrode surface. This transport of analyte towards the electrode surface, coupled with its oxidation or reduction, as it arrives at the surface, determines the magnitude of the current that will be measured. The difference in concentration between the solution near the electrode surface and the bulk solution, is determined by the value of the applied potential, according to the Nernst equation (eq. 2.1). Thus, by combining Fick's first law of diffusion with Faraday's law, a fundamental relationship is obtained, used to calculate the current in any electroanalytical experiment [56]:

$$i(t) = \frac{dQ}{dt} = -nF(Flux) = nFAD \left(\frac{\delta C}{\delta x} \right)_{x=0} \quad (2.2)$$

(a) Single measurement in presence of a fix concentration of analyte (hydrogen peroxide).

Figure 2.1 – Typical current *vs* time profiles in CA.

where Q is the charge passed for that oxidation or reduction, n is the number of electrons exchanged in the redox, the *Flux* is the moles of material diffusing per unit area, per unit of time, D is the diffusion coefficient of the analyte, C is the analyte concentration, A is the electrode area. The full solution of $\left(\frac{\delta C}{\delta x}\right)_{x=0}$ *vs.* time, and therefore of current *vs.* time, depends in part on how the applied potential is varied over the time, as the potential determines the ratio $\frac{C_O}{C_R}$ at the electrode surface. The next sections will present the solution for the specific cases of chronoamperometry, cyclic voltammetry, and square wave voltammetry. Definitions and the description of the methods used to obtain calibration curves from electroanalytical techniques are reported in Appendix: "Methods for analysis of calibration curves".

Chronoamperometry

Chronoamperometry (CA) consists of the application of a fixed potential while monitoring the current as a function of time. The applied potential typically corresponds to the oxidation or the reduction potential of the analyte. The net current flowing through the cell is described by *Cottrell* equation:

$$i(t) = \frac{nFAC\sqrt{D}}{\sqrt{\pi t}} \quad (2.3)$$

where, $i(t)$ is the current measured as function of time; n the electrons exchanged in the redox; F is the Faraday constant; A is the electroactive area; C is the analyte concentration; D is the diffusion coefficient of the analyte.

Current generally decays over the time due to dependence of current on the root square of time in Eq. 2.3 and it reaches an approximative steady-state after a certain time, which intensity is proportional to the analyte concentration, C . An example of the current trend in CA is shown in Fig. 2.1, (a). Further additions of the analyte results in further steps at increased current levels as shown in Fig. 2.1, (b), where the initial current decay has been removed.

Cyclic voltammetry

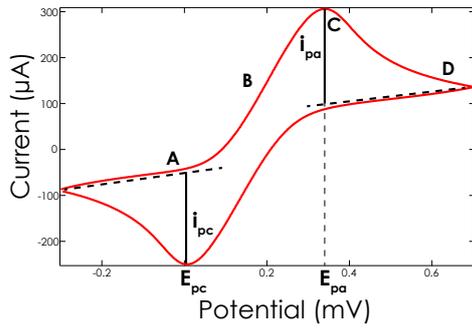

Voltammetry is the study of the current flowing between the WE and CE as function of the applied potential, which is variable in time. *Cyclic voltammetry* (CV) is perhaps the most versatile electroanalytical technique for the study of electroactive species. CV is often the first experiment performed in an electrochemical study of a compound, a biological material, or an electrode surface. The effectiveness of CV results from its capability for rapidly observing the redox behavior over a wide potential range.

In CV, the potential is linearly swept forward and backward at a constant rate, called scan rate, between two extreme values, defining the potential range. The values of the scan rate and the potential range are normally fixed by the user, depending on the redox properties of the analyte. The current is measured as the dependent variable, as a function of the applied potential. The total current measured in the cell is the difference between the oxidative current and the reductive current: the oxidation current (or anodic current) is generated by the potential sweep towards more positive values, and the reductive current (or cathodic current) is produced when the potential is swept backwards more negative values. The behavior of the current generated by the applied potential is described by the *Butler-Volmer equation*:

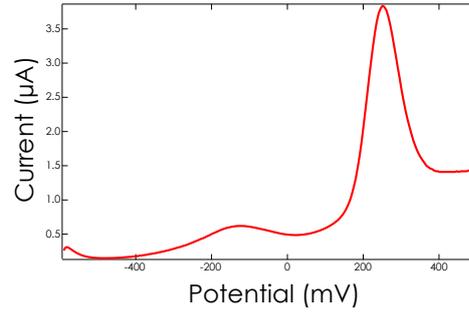

$$I = I_{ox} - I_{red} = nFAk_0 \left\{ [O] e^{\frac{-n\alpha F(E - [E_{O/R}^\ominus]_{SHE})}{RT}} - [R] e^{\frac{(1-\alpha)nF(E - [E_{O/R}^\ominus]_{SHE})}{RT}} \right\} \quad (2.4)$$

where, I is the total current of the cell; I_{ox} and I_{red} are the absolute values of oxidation and the reduction current, respectively; E is the applied potential; $[E_{O/R}^\ominus]_{SHE}$ is the standard potential of the redox couple; F the Faraday constant; R the universal gas constant; T the absolute temperature; n the electrons exchanged in the redox; A the electroactive area; α is the transfer coefficient; $[O]$ and $[R]$ are the concentration of the oxidant and reductor species, respectively; the constant k_0 is the standard heterogeneous constant: small values of k_0 indicate very slow redox processes [56].

The current generated during the potential scan is the sum of a capacitive current and a faradic current. The *capacitive current* originates when the solution is polarized and ions migrate to the electrode with an opposite charge. The accumulation of charged ions at the interface generates an electrical double layer that behaves like a capacitor with area equivalent to the electroactive surface. In voltammetric analysis, the capacitive current is considered a non-specific background signal and must be subtracted from the total current to obtain the faradic contribution. The *faradic current* is due to the electron transfer at the electrode interface, as provided by the redox, and it represents the signal of interest for the electrochemical detection. In steady state conditions, the faradic current assumes a peak shape with the current maximum centered on the reduction or oxidation potential of the analyte (Fig. 2.2 (a)). Starting from the positive potential sweep, as the voltage start to linearly increase, the equilibrium at the surface begins to alter and the current start flowing. At this point the current rises as the voltage is swept further from its initial value and the equilibrium position is shifted further towards products, thus converting more reactant (*e.g.* the oxidizing analyte). The peak occurs (i_{pa}), as at some point the diffusion layer has grown sufficiently above the electrode so that the flux of

(a) Typical plot obtained in CV, in presence of 20mM Potassium Ferricyanide.

(b) Typical plot obtained in SWV, in presence of 0.3mM Acetaminophen.

Figure 2.2 – Typical current *vs* time profiles in CV and SWV.

reactant to the electrode is not fast enough to satisfy that required by the Nernst equation. In this situation the current begins to drop, as predicted by the Cottrell equation (Eq. 2.2). When the potential is swept in the opposite direction, symmetric mechanisms take place and the whole oxidized species is reduced again. The peak current intensity for a reversible couple is given by the *Randles-Sevcik equation*:

$$i_p = 0.4463nFAC \left(\frac{nFvD}{RT} \right)^{\frac{1}{2}} \quad (2.5)$$

where i_p is the peak current, C the analyte concentration, v the scan rate, and D the diffusion coefficient of the analyte. This equation states that the peak current is directly proportional to concentration and increases with the square root of the scan rate. The current peaks are commonly measured by extrapolating the baseline current, as shown in Fig. 2.2 (a). The position of the peaks on the potential axis (of the oxidation peak, E_{pa} , and of the reduction peak, E_{pc}), is related to the standard potential of the redox process. The equilibrium potential $E_{1/2}$ for a reversible couple is centered between E_{pa} and E_{pc} [56]:

$$E_{1/2} = \frac{E_{pa} + E_{pc}}{2} \quad (2.6)$$

which generally corresponds to the standard potential of the redox couple (Eq. 2.1).

In conclusion, the CV plot gives qualitative and quantitative information about the detected target analyte. The reliable measurement of the faradic current represents one of the core aspects of the sensor characterization. This aspects will be analyzed later in the next chapters presenting some results.

Square wave voltammetry

In *square wave voltammetry* (SWV), the potential is applied as pulses, generated from the combination of a synchronized square wave and staircase potential [58]. In this way, the

2.1. Electrochemical sensing techniques: an overview

double layer charging current may be made negligible by measurement at a suitable time after the pulses occur. The staircase allows the electrode potential to be swept over the useful potential range. The theory for a reversible redox couple predicts that the resulting current-time behavior should be symmetrical showing a well-defined bellshaped peak at $E_{1/2}$. The peak current is a linear function of the concentration and the square root of the square wave frequency. The peak current is a more complicated function of square wave amplitude, measurement time, and staircase amplitude [59], as shown in the following equation:

$$i = \left[\frac{nFAC\sqrt{D}}{\sqrt{\pi t_p}} \right] \Psi(\Delta E_S, E_{SW}) \quad (2.7)$$

where the current response is expressed in terms of a normalized current function Ψ . In Equation 2.7, i is the measured current on each pulse; n is the number of electrons transferred; F is the Faraday constant; A is the area of the electrode; D is the analyte diffusion constant; C is the bulk concentration of the analyte; t_p is the pulse width (half the staircase period); the entire quantity in the square brackets is the maximum current that would be obtained with a normal pulse experiment under the same conditions; Ψ is the dimensionless current function, which depends on the step height ΔE_S , and the square wave amplitude E_{SW} [58]. The non-normalized current response depends on the frequency \sqrt{f} , according to Equation 2.7, (the reciprocal of the pulse width t_p). Thus, by increasing the square wave frequency, the square wave peak current will increase, and hence the sensitivity.

Not only SWV provides a convenient symmetrical peak with high sensitivity, but the SWV also gives excellent rejection of background current [58]. Figure 2.2 (b) shows a typical SWV plot, where the oxidation current is reported *vs.* the potential.

2.1.2 Enhanced sensitivity in biosensing

Electroanalytical techniques are used to characterize the sensor, *i.e.* to quantify the sensor response upon a variation in the analyte concentration. As main requirement, the sensor response has to be accurate enough to measure every significant physiological variation of the analyte concentration. For many applications, sensors are required to detect analytes in the micro-molar, nano-molar, or even lower ranges. Several strategies have been investigated in research, to enhance the output signals of the sensor, and to suit the small sizes of the miniaturized devices.

Recent developments in nanotechnology have revealed new nano-structured materials, which have useful properties for numerous electrochemical sensor and biosensor applications [60]. Nanostructures enable the control over the fundamental properties of electrode materials, thus improving the signal response [61].

Moreover, when proteins and enzymes are immobilized on electrodes, nanostructures enhance the electron transfer between the electrode and the protein, thus improving the catalytic reaction [62]. In general, nano-structured materials improve the electron transfer between the electrode and an electroactive specie. The enhancement of electron transfer is an extremely

important challenge in the case of enzymatic biosensors, because a protein shell electrically insulates the redox-active site of most enzymes [63]. Nanomaterials such as carbon-nanotubes or nanoparticles have a promotion effect on the direct electron transfer between enzymes and the surface of the electrode, thus obviating the need for mediators or co-substrates [64]. Owing similar dimensions of redox proteins, nanomaterials can be used for an effective electrical wiring of redox enzymes [65]. Many nanomaterials have been used as intermediate layers for integrating electrodes with biomolecules (enzymes, antibodies, etc.), to enhance the performance of electrochemical biosensors [64, 66]. The most successful implementations of nanomaterials are: carbon-nanotubes [67], nanowires [68, 69], nanoparticles [70], conductive polymers or conductive polymer/nanocomposites [71, 72], graphene, graphite petals and flowers [73], and hybrid composite materials. The next section will focus on carbon-nanotubes, as they were used in the present research.

Carbon-nanotubes

Carbon-nanotubes (CNTs) have been recognized as very promising nanomaterials for enhancing electron transfer in biosensing, thanks to their electrical and electrochemical properties. CNTs are well-ordered, hollow graphitic nanomaterials made of cylinders of sp^2 -hybridized carbon atoms. CNTs can be classed as *single-walled nanotubes* (SWNTs), which are single sheets of graphene "rolled" into tubes, or *multi-walled nanotubes* (MWNTs), which consist of several concentric tubes sharing a common longitudinal axis. Single- or multi-walled nature, roll up angle, presence of imperfections in their structure, length, diameter and chemical groups significantly affect the ensemble of CNT properties. CNTs have lengths that can vary from several hundreds of nanometers to few millimeters, but their diameters vary upon their class: SWNTs are 0.4–2 nm in diameter and MWNTs are 2–100 nm in diameter [74].

The favorable electrochemical properties of CNTs have been extensively exploited to enhance sensor performance in terms of sensitivity and *limit of detection* (LOD), for many different electrochemical sensing devices, ranging from enzymatic to DNA-hybridization biosensors. The role of CNTs for the construction of novel biosensing devices has been recently reviewed [75, 62, 76, 77, 78].

For biosensing applications, CNTs present several advantages: small size with larger surface area, high conductivity, high chemical stability and sensitivity, high electrocatalytic effect and a fast electron-transfer rate [79, 80, 81]. Recent studies [82, 83] have proved that CNTs enhance the electrochemical reactivity of enzymes with retention of their biocatalytic activity. However, one of the main contributions to the enhancement of the sensor sensitivity is due to the increase in electroactive area available for the enzyme immobilization. The nano-tubes and enzyme molecules are of similar dimensions, which facilitates the adsorption of the enzyme without significant loss of its biocatalytic shape, form or function [76]. Various methods are available for the immobilization of enzymes on CNTs, as described in many papers [83, 84, 85, 86].

The biosensors described in this thesis are based on MWCNTs. More details about the properties and fabrication of CNTs can be found in the Appendix: "Details on CNTs".

2.2 Detection of drugs and metabolites with electrochemical sensors

After an overview on electroanalytical techniques and methods to enhance the sensor signal, the following section will answer to the question "What can be measured by electrochemical sensors?". Electrochemical sensors can detect electrochemically active substances, while electrochemical biosensors, *i.e.* when an enzyme is immobilized on the electrode, can monitor electrochemically inert substances. The review on recent developments in the state of the art is focused on the monitoring of drugs, such as anti-cancer or anti-inflammatory drugs, and of endogenous metabolites, in particular glucose and lactate.

2.2.1 Measurements of electroactive substances

Electrochemical sensors can be employed to detect electrochemically active, or "electroactive" species without the need for a biological recognition system. An electroactive species can undergo oxidation/reduction when the potential of the electrochemical cell is properly changed, according to the Nernst Equation 2.1.

Several drug compounds are electroactive, *i.e.* they can be readily oxidized or reduced without the mediation of an enzyme. In the human body, drugs can be metabolized by oxidation, reduction, hydrolysis, hydration, conjugation, condensation, or isomerization; whatever the process, the goal is to make the drug easier to excrete. Electroactive drugs can be artificially oxidized or reduced through electroanalytical techniques, assuming that the oxidation/reduction mechanisms taking place at the electrode and in the body share similar principles.

The redox properties of drugs can offer insights into their pharmacological activity, useful in drug research, as well as the possibility of monitoring drugs in several biological fluids for the development of effective sensors. The selectivity of voltammetric methods is normally excellent because the drug can be readily identified by its voltammetric peaks. Fig. 2.3 shows as an example the CV of acetaminophen, an anti-inflammatory drug, at a glassy carbon electrode. The voltammogram shows an anodic peak (A1) and a cathodic counterpart peak (C1), which corresponds to the transformation of acetaminophen (1) into its oxidized form, *N*-acetyl-*p*-benzoquinone-imine (NAPQI) (2), and vice-versa within a quasi-reversible two-electron process [87].

The use of various electrodes, *e.g.* mercury, solids, and modified electrodes, for electroanalytical measurements of drugs has increased in recent years because of the great potential for application in clinical and pharmaceutical analysis. Recent works [88, 89, 90, 91, 92], systematically review the various applications of voltammetry to drug determination covering the period from 1995 to 2014. These reviews include the voltammetric determination of pharmaceuticals of various classes, *e.g.* antibiotics, antiemetics, antiemetic, hypolipidemic, antipsychotic, cardiovascular, hypoglycemic, analgesics, coagulants, antiplatelet, anthelmintic, sedatives, gastrointestinal, antidepressant, antiarrhythmic, opioid analgesics, and others.

The main voltammetric techniques developed for the electrochemical determination of drugs include non-stripping voltammetric techniques, such as *linear sweep voltammetry* (LSV),

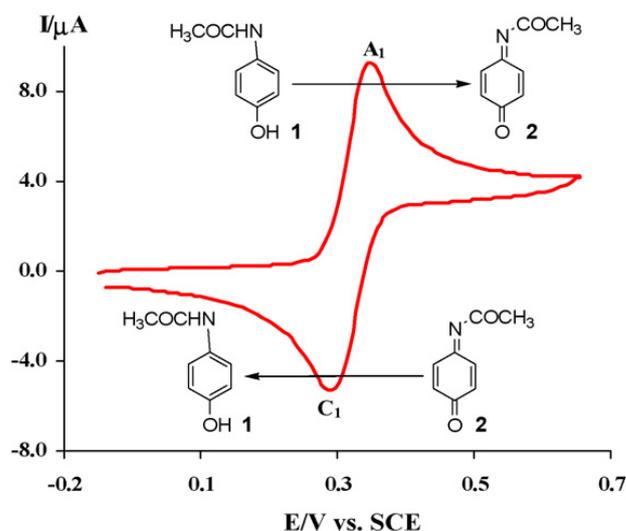

Figure 2.3 – Cyclic voltammogram of 1mM acetaminophen (1) at glassy carbon electrode, in ammonia buffer solution (pH = 9.0). Reprinted with permission from [87].

CV, differential pulse voltammetry (DPV), SWV, and sensitive stripping techniques. Several chemical modification of the electrode have been investigated, including the immobilization of: CNT, MWCNTs, and polymer-modified CNTs, nano-Au self-assembly, gold nanoparticles, Nafion films, fullerene C_{60} , composite polymers, boron-doped diamond electrodes, synthetic zeolites and others [91, 89].

However, since many drug therapies are based on combinations of drugs, it is necessary to monitor multiple drugs at the same time in order to get a more complete overview of the ongoing therapy and to enable a more precise dosage adjustment. Simultaneous determination of different drugs can be achieved by exploiting the differences in redox potential with voltammetric techniques. Recently, MWCNT-modified paste electrodes were used for simultaneous voltammetric determination of morphine and diclofenac [93]. In another study, a partial least squares calibration method was employed for the simultaneous voltammetric determination of indomethacin, acetaminophen, piroxicam and tenoxicam [94]. Ghorbani-Bidkorbeh et al., [95] measured tramadol and acetaminophen using a carbon nanoparticles modified glassy carbon electrode. Voltammetric determination of chlorpromazine hydrochloride and promethazine hydrochloride was suggested with the use of a multivariate calibration [96]. Graphene- $CoFe_2O_4$ nanocomposite modified carbon paste electrodes were used for the simultaneous electrochemical determination of codeine and acetaminophen in pharmaceutical samples and biological fluids [97]. Navaee et al., [98], developed a graphene nanosheets modified glassy carbon electrode for detection of heroine, morphine and noscapine. In another work [99], the authors show a nanostructured mesoporous electrochemical sensor for simultaneous determination of norepinephrine, paracetamol and folic acid. Furthermore, a glassy carbon electrode modified with SWCNTs, was developed for the determination of ranitidine and metronidazole [100]. At present, very few papers report electrochemical sensors capable of continuous drug monitoring [101, 102].

2.3 Strategies for the detection of non-electroactive substances

In biosensors, a biological recognition element is necessary when the analyte of interest does not present any electroactive properties, *i.e.* a biological mediator is needed to transform the electrochemically inert analyte into an active one. Biological recognition elements can be antibodies, enzymes, DNA strand and other proteins. Electrochemical biosensors are classified into two main categories based on the nature of the biological element. "Affinity" biosensors rely on a selective binding interaction between the analyte and a biological component such as an antibody, nucleic acid or receptor. Examples of affinity sensors are immunosensors and DNA-hybridization biosensor with electrochemical detection. "Biocatalytic" sensors incorporate enzymes that recognize the target analyte and produce an electrochemically active species. Enzymes add specificity, as they specifically catalyze a single substrate or a small range of substrates. When enzymes are used as recognition element in sensors, they are immobilized on the electrode and once they catalyze the substrate (*i.e.* the analyte), a variation of the sensor output signal is produced.

Various methods are available for immobilization of enzymes on electrodes, but not always appropriate for manufacturing biosensors. Several problems related to the functioning of the enzyme system must be accounted for, like the loss of enzyme activity and maintenance of enzyme stability. An efficient enzyme deposition method must satisfy the following requirements [86]: (i) The immobilization of the enzyme on transducer surfaces must be stable and provide an efficient electron transfer; (ii) The enzyme must retain its biological activity (and enzyme stability); (iii) The enzyme must be accessible when immobilized; (iv) The material used for immobilizing the enzyme must be compatible and chemically inert towards the host environment. The main immobilization techniques for enzymes on electrodes are: adsorption, entrapment, intermolecular cross-linking, covalent binding and affinity, [83, 84, 85], as shown in Fig. 2.4. A detailed description and review on the different technique is out of topic for this thesis, but the paper [66], reviews the main techniques for enzyme immobilization in biosensors.

The next sections present detection of endogenous metabolites (glucose and lactate), mediated by an enzyme family called oxidase, and the detection of exogenous metabolites (drugs), mediated by another enzyme family, the cytochromes P450.

2.3.1 Detection of glucose and lactate with *oxidases*

In the human body, the main endogenous metabolites, such as glucose, lactate, glutamate, and cholesterol are catalyzed by enzymes called *oxidases*. In general, these enzymes act by binding the substrate (*i.e.* glucose, lactate, glutamate, and cholesterol) in the active site with an oxygen molecule, and by transforming the substrate into a redox product (*i.e.* the glucose in gluconic acid, the lactate in pyruvate, etc.), and hydrogen peroxide.

In enzymatic electrochemical biosensors for detection of glucose, lactate and other metabolites, the oxidase enzyme is immobilized onto the electrode and hydrogen peroxide is detected as product of the catalytic reaction between the oxidase and its substrate. The equation

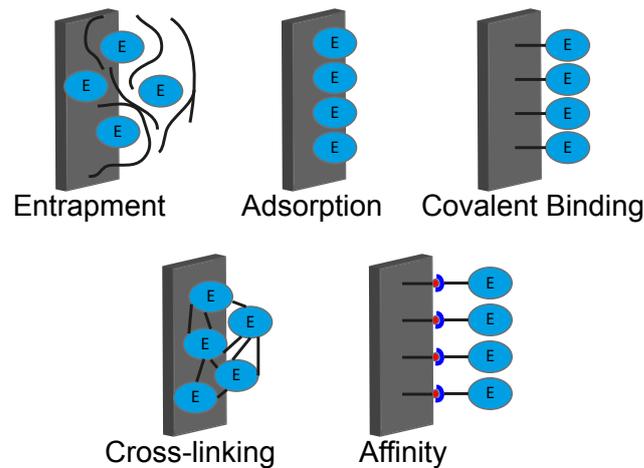

Figure 2.4 – Schematic representation of the main different methods of enzyme immobilization. E: enzyme. Adapted with permission from [85].

describing the reaction between the oxidase and its substrate is:

where Ox is the oxidase, FAD , (Flavin adenine dinucleotide) is an enzyme cofactor, X is the metabolite (*i.e.* glucose or lactate), and X_p is the redox product. To return to its initial state and get ready to start the catalysis of a new molecule, the cofactor needs to release the molecule of hydrogen:

One molecule of hydrogen peroxide is then produced for each substrate molecule metabolized, and can be quantified by normally measuring the current produced by its oxidation:

when a fixed redox potential of 650mV is applied [65, 103]. This oxidation produces two electrons per molecule of hydrogen peroxide, which create a current at the electrode interface that is correlated to the concentration of the metabolite transformed by the oxidase. The measurement of this current is the amperometric detection of metabolites. Usually CA is the amperometric technique used for real-time metabolite monitoring. In CA the current depends on the metabolite concentration according to Equation 2.3.

Oxidases are most frequently used for implantable applications, because the co-substrate, oxygen, is relatively abundant in biological tissues. Glucose detection requires the immobilization of *glucose oxidase* (GOx) on the electrode. Amperometric detection can be direct or with the addition of mediators [104], such as ferrocene derivatives. The reaction catalyzed by

2.3. Strategies for the detection of non-electroactive substances

GOx in presence of glucose is:

Lactate monitoring can be performed with comparable results either with *lactate oxidase* (LOx) or *lactate dehydrogenase* (LDH). LOx is an oxidase and it catalyzes lactate transformation similarly to the GOx with glucose:

For both glucose and lactate biosensors, different immobilization strategies have been exploited in literature [104, 65, 105].

Among all the metabolites of clinical interest, for this thesis, glucose was selected because it is one of the most important parameters of the cell metabolism, because it is a parameter of some diseases, and because, nowadays, the market is particularly interested in devices for glucose monitoring. The results will show that this approach could be potentially extended to other enzymes, *e.g.* LOx, dehydrogenases, multienzyme systems, etc., overcoming some intrinsic limitations of the electrochemical immobilization technique.

In the last decade, researchers started investigating the simultaneous monitoring of molecules within one single electrochemical platform. Concerning electrochemical monitoring, most of the studies focus on the simultaneous detection of endogenous metabolites or tumor markers [106]. Rizzi et al., [107] proposed the simultaneous monitoring of glucose and lactate by an interference and cross-talk free dual electrode amperometric biosensor based on electropolymerized thin films. Microsensors for glucose and insulin monitoring were developed by Lu et al., [108]. A recent work [109] shows continuous and simultaneous electrochemical measurements of glucose, lactate, and ascorbate in rat brain. Cordeiro et al., present in another recent study, a multiplexed biosensor device for real-time continuous and simultaneous monitoring of glucose, lactate and pyruvate [110]. An amperometric biosensor system for simultaneous determination of Adenosine-5'-Triphosphate and glucose was developed by Kucherenko et al., [111]. In another study [112], polyaniline was employed for the simultaneous determination of a quaternary mixture of ascorbic acid, dopamine, uric acid, and tryptophan. Moser et al., implemented a biosensor array in a micro flow-system for simultaneous measurement of glucose, lactate, glutamine and glutamate [113].

2.3.2 Detection of non-electroactive drugs with Cytochrome P450

Cytochrome P450 belongs to a multigene family of proteins which catalyse the metabolism of over 1'000'000 different xenobiotic and endobiotic lipophilic substrates and regulate a wide array of metabolic activities that are essential to homeostasis.

The liver is the main organ responsible for the biotransformation of drugs and chemicals, and the cytochrome P450 with other metabolizing enzymes resides in the hepatocytes. The primary function of cytochromes P450 and other biotransforming enzymes is to transform

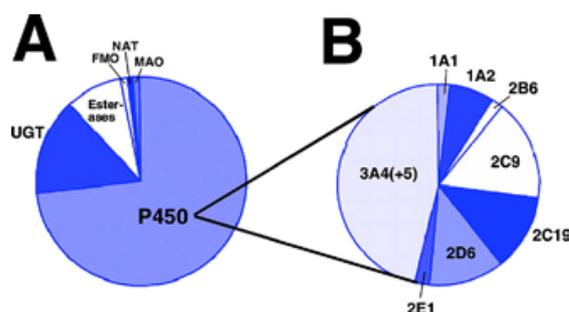

Figure 2.5 – Contributions of enzymes to the metabolism of marketed drugs: (A) Fraction of reactions on drugs catalyzed by various human enzymes. FMO, flavin-containing monooxygenase; NAT, Nacetyltransferase; and MAO, monoamine oxidase. (B) Fractions of cytochrome P450 oxidations on drugs catalyzed by individual cytochrome P450 enzymes. Reprinted with permission from [115].

very lipophilic molecules into highly hydrophilic molecules, so that they can be easily cleared by the kidneys into urine and eliminated [114].

P450 are enzymes involved in the metabolism of ~75% of all known pharmacological compounds (Fig. 2.5A). In all humans, over 7'700 individual cytochromes P450 have been described and identified, although only 57 have been identified in human hepatocytes; of these, only 15 metabolize drugs and other chemicals. Among these 15, five are involved in ~95% of biotransformation reactions of drugs (Fig. 2.5B), and each one is specific for different substrates [115]. The nomenclature is based on naming *P450* the cytochrome enzyme and *CYP* the gene that codes for that enzyme, followed by a number indicating the gene family (such as P450 1, P450 2, P450 3, etc.), a letter indicating the subfamily (*i.e.* P450 1A, P450 2A, P450 2B, P450 2C, etc.) and a number for the gene that identifies the 'isoforms', which are different proteins coded by an individual gene within the subfamily. In order to have the same gene number the genes must have the same function and exhibit high conservation of the protein structure [2]. That is, two isoforms (*e.g.* P450 1A1 and P450 1A2) have 97% of their general sequence in common. In general, there are only three P450 families which are mainly involved in drug and toxin biotransformation in humans, including the P450 1, P450 2, and P450 3 family [2]. For sake of simplicity we will refer to "cytochrome P450" as "P450", as we are interested in the protein more than the gene.

Main featured of P450s

Although P450s in general are capable of metabolizing almost any chemical structure and catalyze around 60 different classes of biotransforming reactions, they have a number of features in common, including [114]:

1. P450 enzymes share a common **3D-topology** (Fig. 2.6(a)): the P450 core is formed by a four- α helix bundle composed of three parallel helices labeled D, L, and I and one anti-parallel helix E [116]. The α helices hold in place the active site of the enzyme,

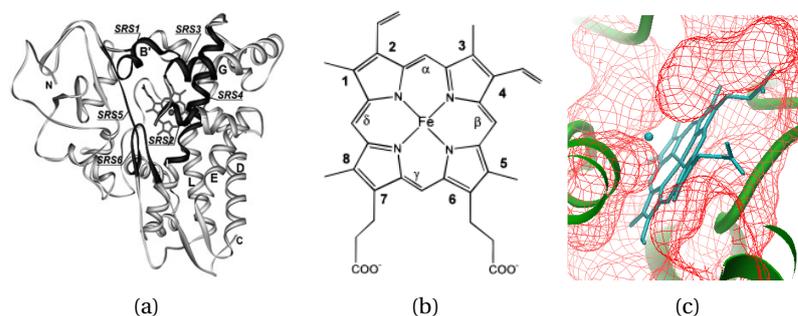

Figure 2.6 – (a): Ribbon representation (distal face) of cytochrome P450s fold. Substrate recognition sites (SRS), and α -Helixes are shown and labeled. Reprinted with permission from [116]. (b): Heme group chemical structure. Reprinted with permission from [117]. (c) Heme group in the substrate binding cavity (meshed surface) of human P450 3A4 (obtained by PDB Protein Databank Europe).

the **heme-iron group** (Fig. 2.6(b)), which in most P450s is a relative rigid part of the protein structure. The heme moiety, also known as ferriprotoporphyryn-9, has a highly specialized lattice structure that supports an iron molecule, which is the core of the enzyme and is responsible for the substrate oxidation [114, 117].

- The **active site** in the P450 structure (Fig. 2.6 (c)) is a very flexible region that can undergo big changes to accommodate substrates of different sizes [114]. Furthermore, P450s have one or more binding areas (or "*substrate recognition sites*" (SRS), presented in Fig. 2.6(a)), inside their active site, which determines for most part their variations and their ability to metabolize specific groups of chemicals [116]. It has been reported that several P450 isoforms, including 3A4, 1A2, 2E1, 2D6, and 2C9, exhibit atypical kinetics in vitro [118]. This atypical kinetic behavior is characteristic for the enzymes that shows multiple substrate recognition sites, as P450s, and it is due to the conformational or chemical changes that occur in the enzyme active site after binding a first substrate [119].
- Thanks to the heme group, P450s exploit the ability of a metal to gain or lose electrons, thus catalyzing substrate oxidations and reductions, according to the **NADPH-monooxygenation reaction**, described by the equation:

where a substrate (RH) is hydroxylated (ROH) through the insertion of one oxygen atom, while the second atom of oxygen is reduced to water. In summary, the electrocatalytic transformation of a substrate is coupled to the electrocatalytic reduction of oxygen [120]. The substrate is thus transformed in a hydrosoluble compound, easier to be excreted in the urine. In catalyzing monooxygenation reactions P450 is able to utilize either NADH or NADPH (nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide

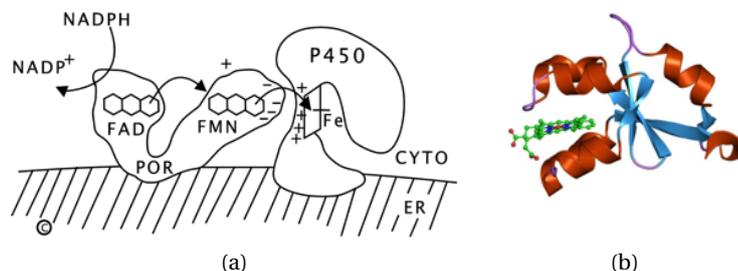

Figure 2.7 – (a): Relationship of POR to a microsomal P450 enzyme. ER is the endoplasmic reticulum and CYTO is the cytoplasm. Reprinted with permission from [121]. (b): Cytochrome b_5 structure (from PDBe Protein Data Bank Europe).

phosphate, respectively) as electron donors (Equation 2.13).

4. All P450s have closely associated **redox partners**, the cytochrome b_5 and *P450 oxidoreductase* (POR), able to supply them with electrons for their catalytic activities. POR is a flavoprotein complex, that binds two flavins, FAD (flavin adenine dinucleotide) and FMN (flavin mononucleotide), which act as electron carriers. POR complex operates as follows (Fig. 2.7 (a)): the electrons from the transformation of the cellular NADPH to NADP^+ , are taken up by the FAD moiety, which is reduced to FADH_2 . Then FADH_2 reduces FMN to FMNH_2 , which in turn passes its two electrons to the P450 heme group [121]. Cytochrome b_5 (Fig. 2.7 (b)) is an electron transport heme-protein that, similarly to P450, is built around a central heme group. In nature this protein converts in the cells NADH to NAD^+ , building up proton gradients which stimulate the flow of electrons [114].

5. The overall reaction of Eq. 2.13, in reality is a quite complex **catalytic cycle**, reported in Fig. 2.8. In this cycle, RH is the P450 substrate, while ROH is its the oxidised form. The first step is the substrate (RH) binding to the P450 active site (2) followed by the first electron transfer, that causes the reduction of the ferric heme (Fe^{3+} to Fe^{2+}), (3). The introduction of oxygen activates the heme group and induces the creation of an intermediate, the *oxy-P450 complex*, (4). The second electron transfer, which is the rate limiting step of the cycle, generates a *peroxo-ferric* intermediate (5a), and then its protonated form *hydroperoxo-ferric* intermediate (5b). It follows the heterolysis of the O – O bond that causes the release of a water molecule and the creation of a highly active *Iron(IV)-oxo ferryl* intermediate (6). This reactive intermediate forces the transfer of an oxygen atom into the substrate that leads to the formation and release of the ROH product (7), with the regeneration of the initial state of the heme group (1) [115]. The three abortive reactions "shunts" shown in Fig. 2.8, are due to some instable intermediates that lead to substrate dissociation, production of intermediary products with the regeneration of the active site to the initial condition, step (1).

2.3. Strategies for the detection of non-electroactive substances

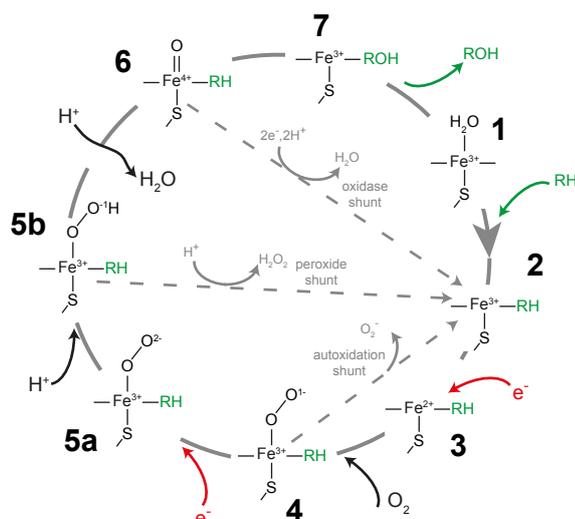

Figure 2.8 – P450 catalytic cycle. Adapted with permission from [116].

In electrochemical P450 biosensors, the electrons needed for the completion of monooxygenation reaction are supplied by the electrode.

2.3.3 P450 based biosensors: state of the art

Since the publication in the mid-1990s of several studies on the electrochemistry of bacterial P450s in solution or on bare electrodes, many attempts were carried out to build up P450-based biosensors for the detection of drugs [122]. To avoid the need of the regeneration of cofactor NADH and NADPH, amperometric biosensors were thought to be the most suitable for sensing applications: several attempts to improve the electron transfer between the P450-enzymes and the electrodes, through an electrochemically active mediator, resulted in highly efficient electrochemical biosensors. Cobalt(III) sepulchrate trichloride was used as mediator for the electrocatalytical reduction of proteins containing different cytochrome P450s and NADPH-P450 reductase to catalyze the hydroxylation of steroids and the N-demethylation of drugs [123]. Otherwise mediators such as flavin mononucleotide, flavin-adenine dinucleotide or riboflavins [124, 125] were covalently bound to cytochrome P450 2B4 and 1A2 cross-linked onto a screen-printed rhodium graphite electrode for the direct amperometric measurement of cholesterol or aminopyrine. Unfortunately, these redox mediators, used in conjunction with redox enzymes, facilitate not only the electron transfer between electrode and enzyme but also other various interfering reactions, resulting in a detection with low-specificity.

The most suitable approach for the design of a P450-based biosensor is the direct mediator-less electron supply from the electrode to the P450 active site. This class of biosensors usually offers better selectivity, because they are able to operate in a potential range closer to the redox potential of the enzyme, becoming less exposed to reactions with interferences. The electrode is used as electron source for the P450 cathodic reduction which is coupled with the

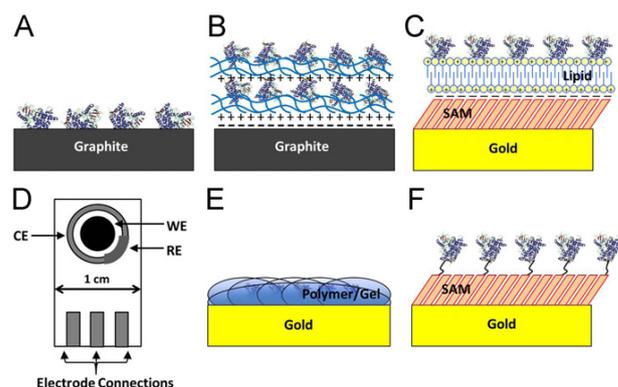

Figure 2.9 – Electrode immobilization strategies for the construction of P450 biosensors: (A) Adsorption to a bare electrode; (B) LBL adsorption; (C) Adsorption to a thin film; (D) Screen-printed electrode; (E) Encapsulation in polymers or gels; (F) Covalent attachment to self-assembled monolayers (SAMs) on a gold electrode. substrate transformation. The generation and the measurement of a cathodic current is the direct indicator of P450-dependent substrate transformation.

In this mediator-less approach, the immobilization of P450 on the electrode surface has to be deeply controlled to obtain a high probability for the protein to be attached to the electrode in a proper orientation that could optimize the electron transfer to the heme group, as it is deeply immersed in the cytochrome structure. In addition, the immobilization techniques should avoid the formation of an insulating protein layer that prevents the electron transfer, due to the adsorptive denaturation of proteins onto bare metal electrodes [63]. Electrochemical measurements have been carried out with P450s immobilized onto bare electrodes showing that P450s were absorbed, but the electron transfer estimated with these systems was low and poorly efficient [122, 126].

Recently published reviews [127, 128] describe the progresses made in the last 20 years on the strategies for P450 immobilization on electrode surfaces, for their successful biotechnological applications and commercial exploitation. The main progress has been made possible through a combination of both enzyme and electrode engineering methods.

Electrode engineering: immobilization techniques

Several methods for the immobilization of P450 enzymes have been investigated (Fig. 2.9). Here we just want to introduce that most common methods, while a detailed review is presented in [122, 127, 128, 129].

1. *Biomembrane-like structures, vesicle systems, and polymer modified electrodes*: surfactant molecules, colloidal clay suspensions, or synthetic phospholipids have been used for the construction of membrane-like structures forming stable films.

2.3. Strategies for the detection of non-electroactive substances

2. *Layer-by-layer (LBL) or Langmuir-Blodgett (LB) films*: multiple layers of oppositely charged polyelectrolytes were adsorbed as a multi-layer film via electrostatic attraction.
3. *Covalent bonding on Self-assembled monolayers (SAMs)*: SAMs were made by alkane-thiols or other thiol-terminated chains that terminate with a chemical group that can bind specifically amino acids on the enzyme.
4. *Nanomaterial-modified electrodes*: several nanostructures have been used to immobilize P450s, including gold, colloidal gold, clay, SiO_2 , MnO_2 , ZrO_2 , and TiO_2 nanoparticles, and carbon nanotubes.
5. *Encapsulation in polymers or gels*: conductive polymer polypyrrole, hydrophilic gels such as agarose, chitosan, and sol-gels have also been used to encapsulate P450s on electrodes and facilitate electron transfer.

Enzyme engineering: Recombinant proteins and microsomes

Instead of acting on the electrode surface, an alternative approach is to directly engineer the enzyme, conferring improved functionalities. An interesting approach, described as *Molecular Lego* [127] is based on the construction of recombinant enzymes using domains taken from different proteins that own improved functionalities. Examples of domains are special amino acids anchoring the protein to the plasmatic membrane, amino acids responsible for the interaction with other proteins, or more efficient reductase domains [130]. This protein-engineering method promotes not only a correct covalent-oriented immobilization, but also the modulation of the catalytic performance of P450s.

Another option is to include the natural redox partners with the P450 in vesicular systems, called *microsomes* or *microsome systems containing P450 and POR* (msP450s). A microsome is a construct obtained from the fragmentation of the endoplasmic reticulum of the proteins (P450, POR, cytochrome b_5), and its reconstruction in vesicles that can be isolated by centrifugation. These protein/membrane systems are used by pharmaceutical companies in assays for drug research due to their low production costs respect to recombinant P450s. Microsomes provide a natural environment for both P450s and their natural redox partners. In a study [131] msP450s were immobilized on a polycation-coated electrode and the authors proved that the direct electron transfer occurred according to the natural electron transfer path (*i.e.* electrode \rightarrow POR \rightarrow P450). A more recent work [132] proved that a hydrophobic electrode surface facilitates the immobilization of msP450, because of the presence of hydrophobic regions in the surface structure of P450 and of the lipids that compose the microsome. The catalysis of a substrate was successfully detected [132], proving that microsomes offer a better environment for P450, as the presence of POR improves the efficiency of the enzyme.

Electrochemistry of P450 applied for biosensing

The P450 biosensors presented in this thesis rely on a technique called *catalytic protein film cyclic voltammetry* [134]. Voltammetric techniques are the ideal choices for P450-based detection, as they address the need to analyze the P450 response at different potentials. In the absence of substrate a redox enzyme immobilized onto an electrode gives peak-like signals resulting from the reversible transformation of its redox center. The potential sweeping in cyclic voltammetry is used to artificially activate/inactivate the redox center, by supplying the 2 electrons needed for the monooxygenation reaction (Eq. 2.13). Those electrons are artificially provided by the electrode (Fig. 2.10), when enough energy for the electron transfer is supplied, *i.e.* when the right potential is applied. In absence of substrate, this current flow will continue until all the immobilized enzymes will have their redox center reduced, *i.e.* they are active. As result, a peak-shape faradic current is generated. Ideally, a potential sweep in the opposite direction will regenerate the active site producing a symmetrical peak.

In the presence of a P450 substrate, a catalysis reaction occurs, and the electrons from the active site are further transferred to the substrate, allowing the heme to accept new electrons

2.3. Strategies for the detection of non-electroactive substances

from the electrode and producing a faradic contribution known as *catalytic current*. The faradic current detected is associated only to the electron transfer between enzyme and electrode, since the substrate is not electroactive. Thus, it will increase in presence of any P450 substrate, e.g. a drug, or even oxygen [115, 133].

CV has been extensively applied to study the electrochemical behavior of P450 and msP450 immobilized on electrodes. When experiments are conducted under anaerobic conditions, P450 shows a well-defined pair of oxidation/reduction peaks attributed to the redox of the heme group. In the presence of oxygen, the reduction peak increases and the oxidation peak almost completely disappears, while the addition of a substrate results in a further increase of the reduction peak current [133]. In Fig. 2.11 a comparison between cyclic voltammograms obtained with argon-saturated buffer, air-saturated buffer, and air-saturated buffer in presence of the P450 2B6 substrate, is reported [133].

P450-based biosensors have already been developed for a vast range of drugs [128] and they can also be employed to measure drug metabolism reactions which are extremely valuable for the identification of drug-drug interactions in drug development. Recent review papers [127, 128] report P450 biosensors based on many different techniques of protein immobilization, but also on several enzyme preparations: purified P450, recombinant P450 or microsome systems. From an analysis of the literature it emerges that the oxidation/reduction of the heme group of different P450-systems results in CV peaks at potentials that can significantly vary according to the way the enzyme is immobilized, the presence of a nanostructure, the electrode material, and the enzyme preparation [122, 146]. Table 2.1 reports a survey of biosensors based on P450 1A2 and P450 3A4 showing different reduction potentials at different electrode surface modifications. From this analysis, it emerges that for each electrode modification and P450 preparation it is necessary to identify the voltammetric peaks due to the reduction of P450. With P450-based biosensors no continuous long-time measurements have been performed so far, neither simultaneous detection of several drugs or measurements in biological fluids, such as human serum. For electroactive drugs, still few studies report multiple-drug detection and they do not consider the problem of the interfering substances, which are present in biological fluids. Chapter 3 and 4 will show results that prove a significant improvement of the current state-of-the-art in drug monitoring.

2.4 Implantable electrochemical biosensors

The final aim of the present research is to develop an implantable device. It means that an electrochemical platform, functionalized with enzymes and/or nanomaterials, has to be integrated with appropriate miniaturized electronics and finally implanted in laboratory animals. The electronics should actuate the sensor, read and transmit the data to an external device, and should also be autonomous as power supply. Furthermore the sensor must be assembled in a small device and implanted. This section reviews all the issues connected with the implantation of the sensor in animals, in both term of biocompatibility and sensor functionality. In the end, a quick overview of the state-of-the-art of the electronics and powering system for implantable sensors is presented.

2.4.1 Biocompatibility and sensor functionality

Any kind of artificial device, from a hip prosthesis to a needle-type glucose sensor, perturbs the environment and initiates a response, when it is implanted in the human body. In reality, this response is a complex sequence of stages called *foreign body reaction* (FBR) [147]. FBR can greatly affect the final integration of the implant and its performance. For instance, some studies on implantable sensors showed that FBR can induce up to a 100% loss of sensitivity *in vivo* as compared to *in vitro* values [148, 149]. The final outcome of FBR depends on the level of biocompatibility of the implanted device.

For an implantable electrochemical sensor the term "biocompatible" means that the materials,

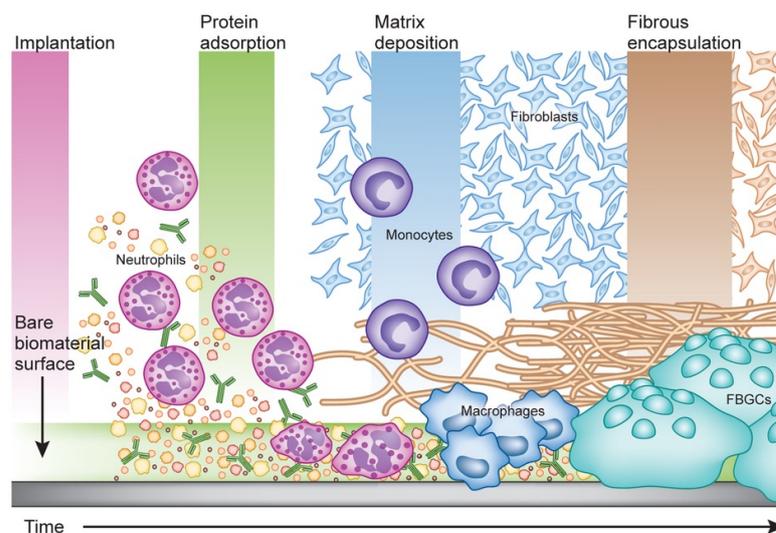

Figure 2.12 – Temporal representation of the FBR, from the initial host response leading to encapsulation of the implanted material. Reprinted with permission from [150].

dimensions and shape of the implant must be well tolerated by the host, in order to achieve a proper integration with the surrounding tissue. As counterpart, the sensor electronics must be protected against the corrosive action of body fluids and finally strategies to preserve the sensor functionality must be adopted.

If the sensor does not produce the expected response it is often difficult to identify the causes, as they are numerous and quite complex [147]. The exact timing, action, and intensity of the response are dependent on the nature of the foreign body, which relates to size, shape, and physical and chemical properties of the implant. In the next sections the main causes of an incorrect sensor response and the possible solutions to improve it will be identified.

The foreign body reaction and consequences on sensor performance

The *foreign body reaction* (FBR) is the most significant issue for implantable devices. The FBR process (Fig. 2.12) starts immediately upon the insertion of any material in the body and upon the contact with body fluids (*e.g.*, blood, lymph, interstitial fluids), starting after the creation of a wound that triggers the wound healing cascade. The first body reaction is a spontaneous adsorption of host proteins on the implant surface, and it might be followed by the biofouling, *i.e.* the accumulation of microorganisms on the implant surface. The resulting surface is covered by several protein species in various conformations and adsorption states. Ideally, this initial protein interface promotes the subsequent adhesion of inflammatory cells, responsible for the normal wound healing, which will stimulate blood clotting and the development of a provisional matrix. Within hours, neutrophils are attracted at the implant tissue site and react by producing cytokines, chemokines, reactive oxygen species and other enzymes. In the following several days, these neutrophil products recruit macrophages, monocytes and mast cells to the wound site, taking the place of neutrophils. Macrophages respond to the implant by

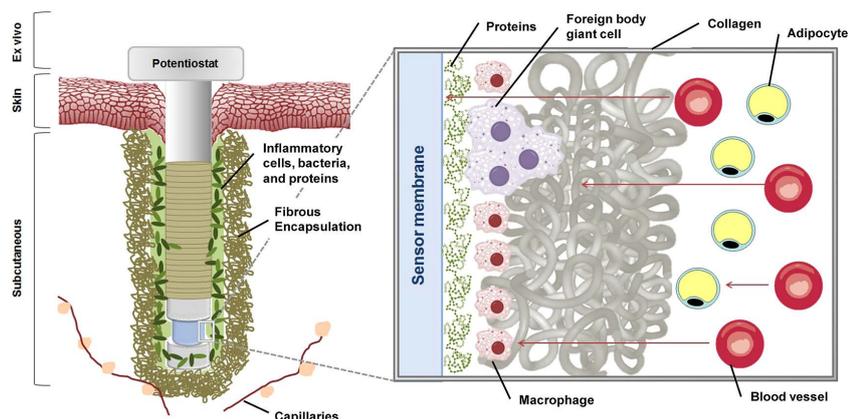

Figure 2.13 – Diffusion of glucose from blood vessels toward the sensor through native tissue (the adipocytes in the example), the collagen capsule, localized inflammatory cells, and biofouling layer near the sensor surface. Reprinted with permission from [44].

producing their own set of signaling molecules, which attract fibroblasts. Fibroblasts produce excess collagen. The concentrations and types of these released mediators stimulate further cell recruitment and the phagocytosis, as the body attempts to digest the implant. This process will result in a local increase of acidity, with a drop in pH, which might become lower than 3.6, which might affect the biosensor performances, as the activity of GOx is pH dependent [44]. As the macrophages will not succeed in phagocytose the implant, they will fuse into *foreign body giant cells* (FBGCs) that attempt to further digest the implant. After one to two weeks, fibroblasts deposit a collagen matrix that insulates the implant from the host tissue. Ultimately a fibrotic capsule is formed, isolating the implant physically and physiologically from the host tissue [150]. This collagen encapsulation lacks the microvasculature of native tissue.

Most long-term medical implants to date, *i.e.* prosthesis, are considered biocompatible once the device is encapsulated by collagen. However, for implantable biosensors, as blood vessels are the primary source of glucose and drugs, the collagen capsule around the implant negatively impacts sensor performance with respect to sensitivity and response, as illustrated in Fig. 2.13. The extent of capsule development is dependent on all stages of the FBR [147].

As the actual outcomes are difficult to determine, due to complexities that connect various events in the FBR with tissue integration, several solutions have been proposed so far to improve a correct integration of the sensor. If the level of biocompatibility of the implant is good enough, the collagen capsule should not be too thick and dense, and after few days the capsule is formed, angiogenesis should create new capillaries.

Strategies to mitigate the FBR effect on sensor performance As all the stages in the FBR directly impact the utility of implanted biosensors, researchers have focused on improving the reduction of the scar tissue of the device to improve sensor performance. These strategies include chemical alteration at the tissue-biosensor interface, changes in physical properties of the device, and the release of biologically active molecules to control the tissue response.

1. *Anti-fouling sensor coatings*: Reducing the initial biofouling is a common strategy, as the adhesion of proteins and cells at the initial stage of FBR reduces sensor performance. The reduction of biofouling is mainly achieved with an antifouling layer on the outermost membrane surface that delays the protein adhesion. Hydrogels, Nafion, surfactants, naturally derived materials, and others have been used with varying degrees of effectiveness [147]. These anti-fouling coatings act by forming a layer of water, thus preventing protein penetration to the surface [151].
2. *Sensor geometry*: Sensor geometry plays an equally important role with respect to collagen encapsulation. The smaller the implanted device is, the faster and the better will be the integration with the surrounding tissue [152]. Also the physical stress imposed by the geometry of the implantable device represents another factor that contributes to the FBR, *i.e.* sharp corners or edges could harm the body from inside, thus creating additional inflammation, or injuries caused by the movement of the implanted material. To avoid physical stresses, more flexible material can be used.
3. *Polymer coatings*: It is well-known that certain polymers elicit a more favorable FBR than others. Polymer coatings are necessary for implantable enzymatic biosensors, as they reduce the diffusion of interferences to the sensor while simultaneously balancing glucose and oxygen diffusion (see the next sections for more details). Among the polymers commonly used for implant applications, Nafion, *polyurethane* (PU), polyethylene glycol (PEG), and hydrogels have been successfully implemented as membranes for glucose sensors implanted in subcutaneous tissues. Nafion is a perfluorosulfonic acid-based polymer that has been implemented as a biocompatible coating. PU has been extensively used as an outer membrane to act as a biocompatible interface with the surrounding host tissue. Moreover, PU maintains sufficient oxygen transport while limiting glucose diffusion to the sensor. Several scientists investigated the use of copolymers blended with PU to enhanced both the stability and the biocompatibility. Yu et al. [153] proposed an epoxy-polyurethane membrane to enhance the biocompatibility of implantable glucose sensors. The authors reported that this membrane was successfully used for glucose sensors implanted up to 56 days with good sensitivity. Surface passivation with polyethylene glycol (PEG) or hydrogels has been a widely studied strategy for resisting biofouling as well as for reducing the collagen encapsulation [44]. Chemical modifications of polymers improve in some extent the tissue biocompatibility, but other parameters also largely investigated are the porosity and young modulus, both showing great influence in reducing the capsule formation [154].
4. *Release of active material*: The most characteristic outcome of the FBR is collagen encapsulation around the implanted device. Some studies showed that immediately after the encapsulation, the glucose concentration is lower due to an insufficient vascularization. However angiogenesis should produce new capillaries and more glucose should reach the sensor surface [155]. Neovascularization can be improved by incorporating an angiogenesis factor such as *vascular endothelial growth factor* (VEGF) or adding a structured

polytetrafluoroethylene (PTFE) membrane on the sensor surface [156]. However, the risk associated with the use of VEGF is its potential role in the growth of cancer cells [147]. Also drugs or small molecules are commonly integrated in the implant for a subsequent release at the sensor-tissue interface, *i.e.* anti-inflammatory drugs [157], or nitric oxide [158, 159].

Oxygen dependence

As previously stated, the electrochemical detection of hydrogen peroxide requires oxygen, a cofactor in the oxidase enzymatic reaction. In interstitial fluids there is an "oxygen deficit", as the concentration of oxygen is approximately 10 times lower than the concentration of glucose. Oxygen deficiency is mitigated by using polymeric outer diffusion controlled membranes, including polyurethane [153], Nafion [160], chitosan [160], silicone elastomer [161], polycarbonate [162], silicone [163], and layer-by-layer assembled polyelectrolytes [164].

Interferences

When using amperometric sensors based on oxidases, the sensor response is oxygen dependent and the hydrogen peroxide is measured at relatively high potential (600-650mV *vs.* Ag/AgCl reference). At similar or lower potentials there is a significant number of endogenous species (*e.g.*, acetaminophen, ascorbic acid, and uric acid) that are oxidized and thus contribute to the measured signal. Although sensor selectivity is of fundamental importance, many reports in literature often neglect to address the problem of interfering species during the sensor characterization [44]. A certain number of methods have been investigated to eliminate the electrochemical interference, mostly applied to glucose biosensors [165]. Here a selection of the most used methods is listed:

1. *Coating with a preoxidizing layer*: a preoxidizing layer can convert the electroactive interfering specie into an inert form before it reaches the electrode. *E.g.* ascorbate oxidase has been used as preoxidizing layer to catalyze the oxidation of ascorbic acid to produce the electrochemically inert dehydroascorbic acid [166]. Other strong oxidants, *e.g.*, PbO_2 , BaO_2 , CeO_2 and MnO_2 , were also employed as preoxidizing coating due to their strong oxidizing ability. However, these oxidants are so strong that they were able to eliminate not only the interferences but also the analytes [167, 168].
2. *Covering the enzyme layer with a permselective membrane*: Different polymers, in multi-layer or mixed layers, have been used for blocking interfering electroactive compounds based on their charge or size. Size exclusion acts through the size and the uniformity of the pores of the membranes. Electropolymerized films, as poly(phenylenediamine), polyphenol and poly(aminophenol) [169, 170, 171], and various substituted naphthalenes [172], have been extensively used to reject interferents based on size exclusion. Electropolymerization coatings can be generated on extremely small surfaces with com-

plex geometries. However, the films formed often have limited stability for *in vivo* applications. Other common coatings based on size exclusion include plasma-polymerized films [173], and cellulose-acetate membranes [174]. Polymeric films that repel the interferences based on electrostatic repulsion mainly are made in Nafion, which is a negatively-charged perfluorinated ionomer able to effectively repel the negatively-charged ascorbic acid and uric acid [175]. Multilayers have been used to combine the properties of different films with different anti-interference properties. For example, alternate depositions of cellulose acetate and Nafion have been used to eliminate the interference of neutral acetaminophen and negatively-charged ascorbic and uric acids [176, 177, 178]. Moussy et al. [179] prepared a needle-type glucose sensor based on a three-layer membranes system, where Nafion was used as the outer layer, poly(phenylenediamine) as an inner coating to reduce interferences by size exclusion, and the enzyme layer (GOx in a bovine-serum-albumin matrix) was placed between the two layers. The use of a permselective membrane is a fast and effective method to block interferences, but also simple to prepare, as the membrane is normally dispersed over the electrode surface by dipping or spin coating. As a result, the membrane thickness is hard to control.

3. *Measuring the reduction current of hydrogen peroxide catalyzed by a mediator*: mediators have been developed in order to lower the applied potential into a window around 0.0V, where few species are electroactive. Examples are the use of a metal-hexacyanoferrate layer [180], metalized carbons, as rhodium or ruthenium on carbon [181], or horseradish peroxidase immobilized with GOx [182]. If a mediator is used, there is always the possibility to oxidize the reduced enzyme by oxygen and this will have a parasitic effect on the substrate signal [147].
4. *Lowering the potential applied by incorporating a mediator for the direct electron transfer between enzyme and electrode*: the main idea is to replace the oxygen with some redox-active mediators to directly shuttle electrons between the active redox center of enzymes and the electrode. In this way the measurements are independent of oxygen, and lower potentials can be applied to the electrode. Examples are metal complexes (*e.g.*, ferrocene derivatives, or ruthenium or osmium complexes) [183, 165], conducting organic salts [184], and organic-dye films [185]. Despite it is a promising approach, it is necessary to include other methods for the filtering of interferences, as it is difficult to use the mediator approach alone.

Stability and degradation of sensor components

Another factor that can determine the sensor failure after the implantation is the enzyme instability and leaching [44]. Enzyme activity begins to decrease immediately due to the polymer entrapment, or to the exposure to acid fluids, hydrogen peroxide and other reactive radicals, during the FBR process. Several effective immobilization strategies to ensure enzyme stability have been investigated so far: cross-linking of the enzyme with glutaraldehyde and/or *bovine serum albumin* (BSA), enzyme entrapment within polymeric matrices (*e.g.*, hydro-

gels), and incorporation of the enzyme into electropolymerized conducting polymers such as polypyrrole [186]. Nevertheless, enzyme suffers of an inherent loss of activity, primarily due to the loss of non-covalently bonded FAD cofactor [187].

All the membranes used as sensing layer, barrier, and biocompatible layer are subjected to degradation from FBR, calcification, and delamination.

***In vivo* calibration**

Despite all the membranes and chemical modification, the analytical performance of an enzymatic biosensor will dramatically change upon implantation, thus methods for assessing sensor accuracy are essential. Traditionally, the *in vivo* accuracy of such devices is evaluated with procedures for calibration during *in vivo* monitoring, by using external analyte measuring devices, as a commercial glucometer [44].

The calibration of the biosensor represents a crucial step, which consists first in the determination of the parameters describing the relationship between the sensor output and the blood analyte concentration, and secondly, in the subsequent use of these parameters to transform the sensor output into an estimation of the blood analyte concentration in real time [188]. These parameters can be determined either through a single blood glucose measurement (one-point calibration), or through two measurements (two-point calibration).

In the one-point calibration procedure [189], the sensor sensitivity S is determined from a single blood glucose measurement, as the ratio between the corresponding sensor current I and the blood analyte concentration G , which is measured with the external device. Subsequently, the analyte concentration can be estimated in real time from the current I as $G(t) = I(t)/S$. Two-point calibration is slightly more complex, as it requires the determination also of the intercept of the calibration line. It is normally used when the intercept is not negligible, but it is more time-consuming and it is more prone to measurement errors. Thus, the one-point calibration procedure is preferred [189]. Repeated calibrations (twice per day), are required as the sensor sensitivity changes over time due to physiological fluctuations [44].

Nevertheless, with an *in vivo* calibration the concentration of the analyte in interstitial fluids should be similar to its blood concentration. There is always a physiological time lag between blood and interstitial fluid analyte concentration that for glucose ranges between 5 and 15 min. Lag depends on glucose uptake by cells, or from blood vessels, blood flow, and permeability of capillaries, as well as on tissue responses to the sensor such as biofouling, and the collagen encapsulation that limits the glucose diffusion to the sensor.

In conclusion, the development of an implantable biosensor presents many issues that are generated by a myriad of causes. Nowadays, many strategies have been proposed to address these issues, but exclusively for implantable glucose sensor. Chapter 5 will show solutions and strategies selected in this thesis to best find a balance among all these constraints.

2.4.2 Electronics and power supply for an autonomous device

Fully implantable devices require an adequate electronic system for the correct sensor actuation for long time. The device should be small, minimally invasive and it contains three main blocks: (i) the sensing platform; (ii) interface electronics to control and readout the biosensor; (iii) a power management unit.

From the point of view of the power management, the main challenge is to strike a balance between the need for a small implant and the need to achieve an efficient power transfer to the implanted system which is planned to be placed in a freely moving mice.

Although batteries have been largely used for supplying power in implantable devices [190], they are not suitable for long-term implants because their limited lifetime necessitates frequent replacement or recharging. Moreover, batteries are difficult to miniaturize, and, if the application demands high currents, the battery lifetime is limited to a few hours [191]. Some recent work showed that supercapacitors and carbon-nanotube based energy stores have great potential to improve battery capacity, but have not yet matured to commercial availability [192, 193, 194]. As alternative approach, percutaneous systems are rather undesirable due to the potential risk of infection and the discomfort for the animal. The best choice is the development of a wireless power delivery system.

For medical implants, several methods for wireless power delivery have been investigated. Far-field coupling delivers power wirelessly in the form of ultra-high-frequency (UHF) radio signals. For biomedical use, it has been applied to power a chip implanted in a flying insect to acquire neural/EMG signals [195]. This method allows power transmission over long distance (10 m), but it has very low transmission efficiency and safety issues [190]. The inductive powering link is an attractive alternative, as it overcomes the low efficiency through the close alignment between two coils. This method has been widely applied to medical implantable devices [196, 197]. High efficiency is assured in the near-field (in the order of cm), but the link efficiency drops rapidly as the distance between the coils increases. Thus, a close alignment of the coils is required [190]. To achieve high efficiency from the wireless power transfer, the coils and the coupling need to be optimized simultaneously.

For the sensor actuation, the readout electronics are generally realized with *integrated circuits* (ICs) that can be easily miniaturized. The main challenge resides in developing ICs that could perform the control and readout of both CA and CV for the biosensor, with low power consumption.

Low power CA readout electronics, for glucose or neurotransmitters monitoring implantable or wearable platforms, have been presented in [198, 199, 200]. In [201, 202, 203] ICs for CV readout are presented with a control part that is implemented using external waveform generators. In [204] an IC for CA and CV control and readout is presented in 0.5 μm technology. However the power consumption is 20 mW from 5 V supply voltage which is not compatible with remotely powering. Thus, for the realization of the final goal of this thesis, the development of customized ICs is required.

Finally, an appropriate communication system must be developed, that could transmit and receive the data in real-time, and visualize the data on a screen.

2.5 Summary

This chapter offered a wide overview on the state-of-the-art concerning the strategies that were chosen in the present research for the realization of a fully implantable device. Electro-analytical techniques were described and reviewed with concern on their application for biosensing. The functionalization of the electrode surface with nanomaterial, was shown as one of the best strategies to enhance high signal-to-noise ratio in biosensors, while the employment of specific enzymes is required to obtain specificity. All issues related to the biocompatibility and to the sensor functionality of the implantable device were analyzed and addressed with different solutions that ensure a correct integration of the device in the body. Finally an analysis of the possible methods to realize an autonomous system with the electronics and power supply completely integrated were discussed. The present chapter can be seen as a reference for all the results that will be presented in the thesis, and the following chapters will show in which extent the present work goes beyond the state-of-the-art.

3 Drug monitoring with screen-printed electrodes

In this chapter we present *screen-printed electrodes* (SPE) based sensors for drug detection mediated by *cytochrome P450* (P450), and for the detection of an electrochemically active drug. Among several drugs we selected four anti-cancer drugs, for single drug detection but also for multiple drug detection, as drugs are normally administered to patients in combinations. We also measured naproxen, a commonly-used anti-inflammatory drug.

This chapter presents an initial investigation on drug detection in biological fluids, by using SPEs with a carbon working electrode. The screen-printing technology allows the mass-production of electrodes by reducing the fabrication costs, thus making the SPEs ideal for a preliminary investigation on biosensors for drugs, based on P450.

3.1 Cytochrome P450-mediated drug detection

The biosensors presented in this section are based on the adsorption of *multi-walled carbon nanotubes* (MWCNT) on SPEs, and on the adsorption of *microsomes containing P450* (msP450) on the nano-structured surface.

This section presents an initial investigation on the protein adsorption on MWCNTs; a study on the voltammetric peaks obtained when msP450 is adsorbed on electrodes; the proof of the improvement of the sensor sensitivity with MWCNTs; single and multiple drug detection, in a normal test buffer and in serum; an investigation on the long-term stability of the biosensor.

3.1.1 Methods

MWCNTs (~ 10 nm diameter and $\sim 1 - 2 \mu\text{m}$ length) with 5% $-\text{COOH}$ groups content, were purchased as a powder (90% purity) from DropSens (Spain). *Microsome containing cytochrome P450 1A2* (msP450 1A2) and *microsome containing cytochrome P450 3A4* (msP450 3A4) were purchased from Sigma-Aldrich (Switzerland), and *microsome containing cytochrome P450 2B6* (msP450 2B6) from BD Bioscience (USA). Microsomal P450s were purchased as isozyme microsomes with recombinant human P450 1A2 (or P450 3A4, or P450 2B6), recombinant

rabbit NADPH-P450 reductase, and cytochrome *b*₅ (0.5 nmole of cytochrome P450 isozyme in 100 mM potassium phosphate, pH 7.4.) and used as received. The preparation of the purified cytochrome P450 and purified cytochrome P450 reductase is reported in [205].

All the drugs, cyclophosphamide, ifosfamide, ftorafur, etoposide, and naproxen, were purchased in powder from Sigma-Aldrich. Cyclophosphamide, ifosfamide, ftorafur were dissolved in Milli-Q water. Etoposide was dissolved in dimethyl sulfoxide, and naproxen in chromatography grade methanol, due to their low solubility in water.

All experiments were carried out in a 100 mM *phosphate buffered saline* solution (PBS, pH 7.4) as supporting electrolyte.

Human serum was purchased from Lonza (Switzerland) and used without any dilution. For measurements in mice serum, male C57BL/6 mice were used to extract serum samples. They were intravenously injected with PBS. After 4 h, mice were euthanized, blood harvested and left 1 h at room temperature. The blood was collected and then centrifuged at 7000 rpm for 10 min at 4 °C; serum and supernatant were stored at –80 °C.

The biosensors were prepared using commercial carbon paste SPEs (model DRP-C110, Drop Sens, Spain) consisting of a carbon working electrode with an active area of 12.56 mm², a carbon counter electrode and an Ag|AgCl reference electrode. A 1 mg/ml solution of MWCNTs, prepared in chloroform, was sonicated for 30 min to obtain a homogeneous suspension. 30 μl of MWCNT solution were gradually deposited by drop-casting onto the working electrode. After each single deposition, the chloroform evaporates and the nanotubes create a 3D porous nanostructure. 9 μl of msP450 solution were drop-cast onto the CNT-electrode surface and incubated at 4 °C overnight, to promote an homogeneous protein adsorption on the CNT-nanostructure. After a 8-h incubation at 4 °C, this procedure was repeated until the nano-structured electrode was covered with three layers of protein. The functionalized electrodes were stored at 4 °C and covered with PBS when not used.

Electrochemical measurements were performed using an Autolab electrochemical workstation (Metrohm, Switzerland). Morphological analysis of the nano-structured electrodes was performed with acquisition of *scanning electron micrographs* (SEM), with a Philips/FEI XL-30F microscope (Philips, The Netherlands). The scanning electron microscope was operated in 1.5–4.2 mm ultra-high resolution mode (UHR). The resolution was 2.5 nm at 1 kV.

The electrochemical response of the biosensor was investigated by CV at room temperature under aerobic and anaerobic conditions, by applying a potential sweep generally between –800 and +600 mV *vs.* Ag|AgCl at a scan rate of 20 mV/s. For experiments under anaerobic conditions, the PBS solution was bubbled with N₂ for 45 minutes before measurements in a sealed electrochemical cell. During the measurements, N₂ was continuously fluxed on the solution surface in order to avoid oxygen contamination and not to affect the measurements. For the sensor calibration, drug samples were added in increasing concentrations. The electrode was covered with 100 μl of 100 mM PBS (pH 7.4) and drug samples were added at a fix concentration. Sensitivity per unit area and *limit of detection* (LOD) were calculated from the peak current, and estimated according to the procedure reported in the Appendix: "Methods for analysis of calibration curves".

For the continuous monitoring of naproxen, an Alzet model 1002 micro-osmotic pump (USA)

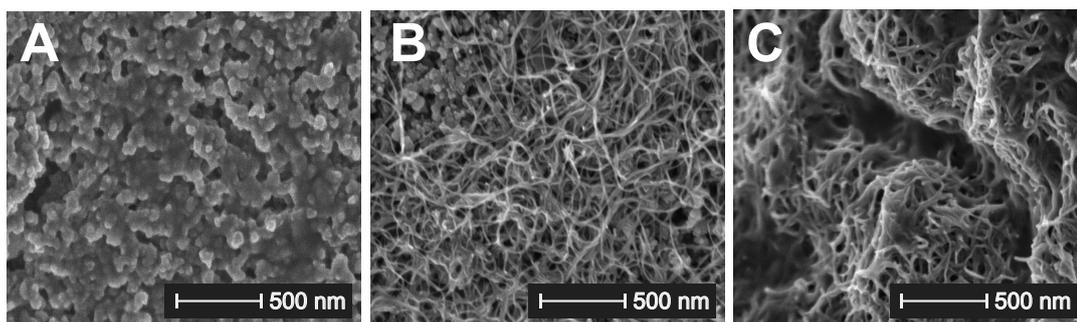

Figure 3.1 – Comparison of typical SEMs of the surface of a graphite SPE before (A), after the deposition of 30 μg of MWCNTs (B), and one layer of a solution of P450 3A4 (C). All images were acquired by using scanning electrode microscope in ultra-high resolution mode at 50'000X magnification.

of 0.6 cm diameter, 1.5 cm length and $90 \pm 10 \mu l$ reservoir volume with a nominal delivery pumping rate of $0.25 \pm 0.05 \mu l/h$ (in isotonic solution at $37^\circ C$), was used to continuously deliver naproxen.

3.1.2 Investigation on Protein Attachment on CNTs

Fig. 3.1 shows typical SEMs of the surface of a graphite SPE (A), after the deposition of 30 μg of MWCNTs (B), and the deposition of one layer of P450 3A4 (C). Fig. 3.1 (B) shows a significant increase of the electro-active area of the electrode after the adsorption of MWCNTs. CNTs tend to create 3D porous structures made by agglomerates, due to their physical properties (see Appendix: "Details on CNTs"). After the deposition of one protein layer (Fig. 3.1C), an increase in CNT-diameter size (of about 10 ± 4 nm) is observed, proving that nanotubes are completely surrounded by a protein mono-layer. This was also demonstrated with an investigation and numerical simulations on the nature of the interactions between P450 and MWCNTs, as it is reported in the following paragraphs.

Crystallographic studies on the binding energy in antigen-antibody complexes [206] revealed that the binding specificity and the physical forces involved in the protein-protein complexes formation can be quantified through an estimation of changes in the Gibbs free energy and in principle, be applied to a wide range of macromolecular systems and protein-surfaces interactions, such as between P450 and CNTs. Similar to studies related to the antigen-antibody interaction, the free energy associated with the protein-CNT complex can be expressed as a function of different sources of interactions [206]:

$$\Delta G = \Delta H_{\Phi} + \Delta H_{EL} - T\Delta S_{CF} - T\Delta S_{TR} - T\Delta S_{ID} \quad (3.1)$$

Eq. 3.1 has different terms related to different sources of the antigen-antibody interaction: ΔH_{Φ} is due to the hydrophobic interactions, ΔH_{EL} accounts for the Van der Waals forces, ΔS_{CF} is the variation of the conformational entropy, ΔS_{TR} is the variation of the entropy

associated with the loss of translational and rotational degree of freedom by the protein P450, and ΔS_{ID} is the variation of the entropy associated with a mole of pure water that stabilizes the P450-CNT interaction. The major contributor in Eq. 3.1 is the term related to the hydrophobic interactions between the two surfaces from two different molecules that participate in the bond (the P450 and the CNT). The term due to the hydrophobic interactions ΔH_{Φ} can be computed as [206]:

$$\Delta H_{\Phi} = \alpha \cdot A_{contact} \quad (3.2)$$

Eq. 3.2 shows that the enthalpy related to hydrophobic interactions is proportional to the contact area between the antibody and the antigen, that is the solvent-accessible surface of the side chains of the two structures forming the complex. Direct experiments have shown that 1 \AA^2 of buried surface corresponds to 104.5 J/mol in case of antibody/antigen hydrophobic interactions. Consequently, the coefficient of proportionality in Eq. 3.2 has been empirically determined as [206]:

$$\alpha = -104.5 \text{ kJ/mol} \cdot \text{nm}^2 \quad (3.3)$$

In order to roughly estimate the bond strength between the P450 and the CNT we compared the enthalpy estimated by Eq. 3.2 with those for the antigen-antibody interactions. Typical contact area in the antigen-antibody interaction ranges from 150 \AA^2 up to 690 \AA^2 . Consequently, Eq. 3.2 and Eq. 3.3 describe a range for the hydrophobic enthalpy from -16 kJ/mol up to -74 kJ/mol . It is known from crystallographic studies that cytochrome P450s have a triangular prismatic shape (Fig.3.2) with approximate dimension of $4.5\text{-}5 \text{ nm} \times 5\text{-}6.5 \text{ nm}$ and a thickness of $3.5\text{-}4.5 \text{ nm}$ [207, 208]. Thus, for cytochrome P450-CNT interaction we can estimate a contact area in the range $272 \text{ \AA}^2\text{-}378 \text{ \AA}^2$, which corresponds to a hydrophobic enthalpy between -28 kJ/mol and -40 kJ/mol . These enthalpies are in the same order of magnitude of antigen-antibody interaction, demonstrating that hydrophobic interactions play an important role in determining the cytochrome P450 attachment onto the CNT surface.

P450 presents on the surface several hydrophobic sites formed by N-terminal domain residues, hydrophobic residues [210], and also by the C-terminal end of the F-G loop [211], whereas other surfaces of the protein are mostly hydrophilic. It is known that cytochrome interacts with the redox partners and with biological membranes, through electrostatic forces and hydrophobic interactions. These hydrophobic interactions lead to a non-specific and random orientation of the immobilized enzymes, even if it has been demonstrated that P450s preferentially adopt a largely uniform orientation that is favorable for a rapid electron transfer [212]. In order to investigate the mechanism of the enzyme adsorption onto CNTs, we performed numerical simulations [209]. With Monte Carlo simulations, we obtained the average diameter of CNTs after the P450 solution has been cast onto CNTs randomly spread on the graphite surface of SPEs. For Monte Carlo simulations, we assumed that a high percentage of CNTs expose their walls for protein adsorption, as illustrated in Fig. 3.1 (B). For protein adsorption, we reasonably assumed that the enzyme generates a self-assembled mono-layer with a random orientation. In this case, the most important contribution to the P450-CNT interaction, is the

3.1. Cytochrome P450-mediated drug detection

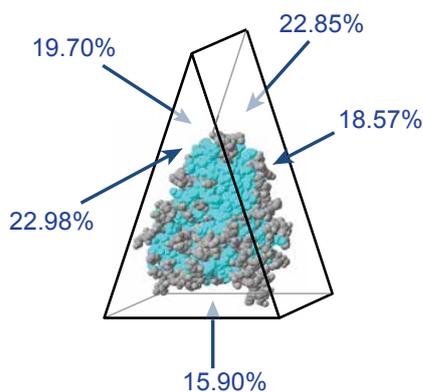

Figure 3.2 – 3D structure of human P450 3A4 (from Protein Data Bank), with its triangular prismatic structure. The percentages of the hydrophobic residues (in light blue) for each face of the enzyme are reported. Adapted with permission from Baj-Rossi, C., et al., *Sensors*, 12(5), 6520-6537 (2012) [209].

hydrophobic effect, which is directly proportional to the contact area of the cytochrome-CNT complex. The contact area depends on the orientation of the protein, *i.e.* on which "face" the protein will be adsorbed on the CNT. Fig. 3.2 shows the 3D structure of cytochrome P450 3A4, with the percentage of hydrophobic sites for each "face" of the protein (the percentage was estimated respect to the total number of the hydrophobic site of the protein). Therefore, we assumed that the probability of attachment of the protein with a specific orientation, is directly proportional to the contact area.

With Monte-Carlo simulations, we simulated different orientations of the cytochrome P450 on the CNT walls, which correspond to different final diameters of CNT, after protein adsorption. We obtained a final diameter of 20 ± 4 nm, which is similar to the diameter estimated from SEM images, 20 ± 3 nm. This simulation proved the capability of this model to describe the physical adsorption of P450 onto CNTs.

Moreover, with these simulations we obtained an average thickness for the enzyme adsorbed on the nanotube between 3 nm and 6 nm. These values are consistent with the size of a P450 molecule [213], also considering the possible different orientations, once it is adsorbed. This thickness range demonstrates that a single protein layer homogeneously covers the carbon nanotube walls, as shown in Fig. 3.1 (C).

3.1.3 Analysis of the reduction current and of the microsomal contributes

As microsomes contain different active proteins (*i.e.* P450, POR, cytochrome b_5), an analysis in *cyclic voltammetry* (CV) can reveal the different contributions as oxidation or reduction peaks. To precisely characterize the peaks obtained for microsomes adsorbed on MWCNTs, we performed an analysis in CV of the reduction peaks, under several experimental conditions: with bare or MWCNT-modified electrodes, in aerobic/anaerobic conditions, with two P450 isoform (3A4 and 1A2), and with purified P450 3A4.

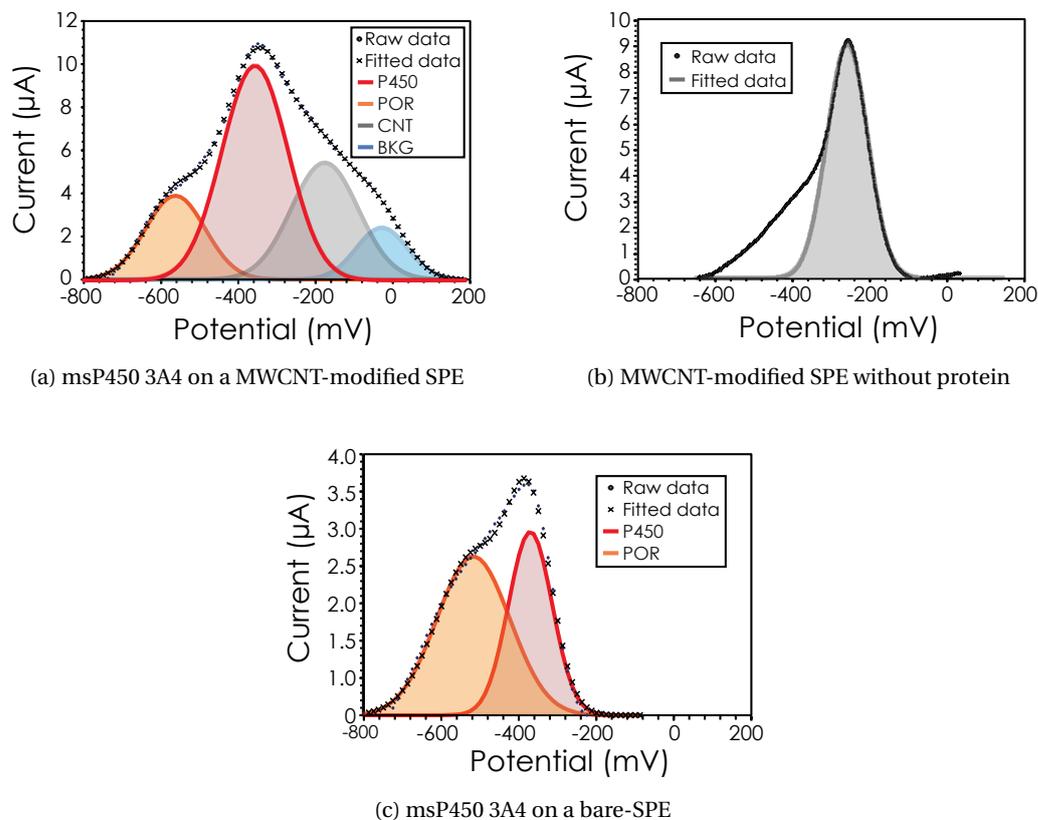

Figure 3.3 – Reduction current peaks from CV after background subtraction, for three cases. CV acquired in a PBS 10X, pH 7.4, with a scan rate of 20 mV/s. Adapted from Baj-Rossi, C., et al., *Electroanalysis*, 27(6), 1507–1515 (2015) [205].

Reduction peaks of msP450 3A4 on MWCNT-modified or bare electrode

Fig. 3.3 shows the reduction current peaks in the potential window +200/-800 mV for three cases: for msP450 3A4 on a MWCNT-modified SPE (a), for a MWCNT-modified SPE without protein (b), and for msP450 3A4 on a bare-SPE (c).

The resolution of overlapping peaks with mathematical functions, is a well-known procedure in literature [214, 215], and can be used to visualize the faradic current generated by the various biosensor components. The basic functions used for the decomposition are the Gaussian, the Hyperbolic cosine and the Cauchy function [216]. More complex functions are usually based on modifications or combinations of these three.

In order to visualize the individual contributes of CNT, P450 and POR, we normalized the reduction current between +200/-800 mV to the baseline obtained with the automatic peak recognition software, and we used the Gaussian functions to describe the different faradic contributes. Gaussian functions represent a good model for the identification of peak from CV with P450-modified electrodes, as already shown in [217]. The peak position of each gaussian was initially centered according to the data obtained from literature and then optimized with

3.1. Cytochrome P450-mediated drug detection

the fitting. After baseline subtraction, the reduction peak region was fitted with Gaussian functions, which were then summed up to fit the current profile of the peaks [217].

In Fig. 3.3 the Gaussian curves in subfigures (a-b-c) present the same color code in order to compare the peaks of the different systems. Fig. 3.3 (a) shows the baseline-subtracted reduction peaks for msP450 3A4 adsorbed on a MWCNT-modified-SPE. We observe four different reduction peaks: at -540 mV, at -360 mV, at -200 mV and at -20 mV. Fig. 3.3 (b) shows the baseline-subtracted reduction peaks for a MWCNT-modified SPE, without P450. In Fig. 3.3 (c), the msP450 3A4 on a bare-SPE show only two reduction peaks, at -540 mV and -360 mV. With both bare and MWCNT-modified electrodes, we observed two reduction peaks in the region -300/-600 mV: one reduction peak at -360 mV and one at -540 mV. The peak at -360 mV corresponds to the reduction of the P450 component of microsome, while the peak at -540 mV is attributed to the reduction of POR. Positions of peak potentials are in good agreement with recent studies on microsomes containing P450 and POR [131, 132]. In particular, the authors in [132] showed for msP450 3A4, a reduction peak at -380 mV for P450, and a reduction peak at -420 mV, for POR. The potential peak for POR was confirmed in another electrochemical study [218].

We attributed the peak at -200 mV to the reduction of the carboxyl groups of carbon nanotubes [219] as shown in Fig. 3.3 (b). In Fig. 3.3 (a), the CNT-peak (gray line) at -200 mV displays a lower current, because the protein covers the MWCNTs. The peak at -50 mV (labeled as "BKG") can be attributed to the reduction of other microsomal components [220]. Fig. 3.3, clearly shows that MWCNTs increase the reduction current for the microsomal component P450: the P450 reduction peak current is significantly larger than the POR peak, for the MWCNT-SPE (Fig. 3.3 a), respect to the bare SPE (Fig. 3.3 c). This effect of CNTs of enhancing the reduction current will be further discussed (Section 3.1.4).

Reduction peaks of msP450 3A4 in aerobic/anaerobic conditions

Voltammetric responses of msP450 3A4 were also performed in aerobic/anaerobic conditions, without substrates. In agreement with previous findings [144, 132, 133], we expected a decrease in the cathodic current peak of the microsomal component P450 upon the depletion of oxygen from the solution.

Fig. 3.4 shows the voltammograms for a msP450 3A4-bare SPE (a) and a msP450 3A4/MWCNT-SPE (b), in aerobic and anaerobic conditions. In absence of oxygen, we can observe the oxidation peak for the microsomal component P450 that otherwise would be completely attenuated, in the presence of oxygen. Fig. 3.5 shows the background-subtracted oxidation and reduction peaks for a msP450 3A4-bare SPE, in anaerobic conditions. This voltammogram reveals that the oxidation peak current is slightly smaller than the corresponding reduction peak, probably due to the presence of traces of oxygen, caused by an imperfect sealing of the buffered solution and to the low scan rate (20 mV/s) that makes the oxidation peak more difficult to observe [133].

Fig. 3.6 shows the background-subtracted reduction peaks for a msP450 3A4-bare SPE in a N_2 -saturated buffered solution (blue dots, labeled as " N_2 "), and in aerobic conditions (black dots,

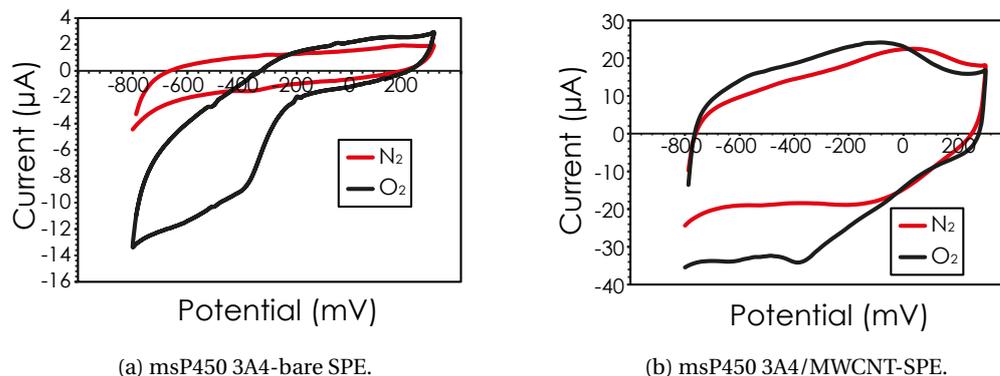

Figure 3.4 – CV acquired in a N_2 -saturated buffered solution (labeled as " N_2 "), and in aerobic condition (labeled as " O_2 "), showing a clear increase of the reduction current when oxygen is added to the solution. Reprinted from Baj-Rossi, C., et al., *Electroanalysis*, 27(6), 1507–1515 (2015) [205].

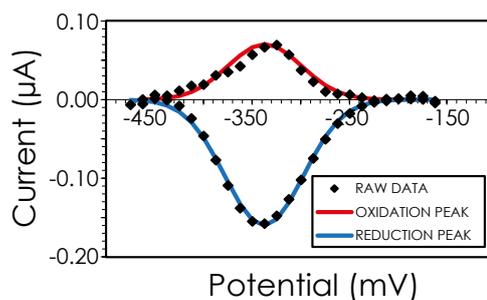

Figure 3.5 – Background-subtracted oxidation and reduction peaks for msP450 3A4 on bare-SPE in anaerobic conditions. Adapted from Baj-Rossi, C., et al., *Electroanalysis*, 27(6), 1507–1515 (2015) [205].

labeled as " O_2 "). A clear decrease of the cathodic current at -360 mV is visible when oxygen is depleted from the solution, with a subsequent increase of cathodic current back to the initial value when aerobic conditions are established again. The increase of the reduction current in presence of oxygen is characteristic for the electrochemical response of heme-proteins, as P450 [132, 133], hemoglobin [221] and myoglobin [219].

We performed similar experiments also with msP450 1A2, obtaining similar results [205].

Purified P450 3A4

To further confirm that the peak at -360 mV corresponds to the reduction of the microsomal component P450, voltammetric measurements on MWCNT-modified SPEs were performed with two preparations of purified proteins: pP450 3A4 (without POR) and pPOR (without P450). Fig. 3.7 shows the background-subtracted reduction peaks for pP450 and pPOR on

3.1. Cytochrome P450-mediated drug detection

Table 3.1 – Concentration (Γ) of electroactive enzyme and percentage relative to the total amount of deposited protein.

P450 isoform	Γ of electroactive P450 (nmol/cm^2)		Electroactive protein (%)	
	BARE SPE	MWCNT-SPE	BARE SPE	MWCNT-SPE
P450 1A2	1.07 ± 0.04	3.2 ± 0.1	27	80
P450 3A4	2.42 ± 0.09	3.77 ± 0.15	61	83

MWCNT-modified SPEs. pPOR (orange dots) presents a reduction peak at -550 mV, while the pP450 3A4 (black dots) shows a reduction peak at -240 mV. It is positively shifted by 100 mV with respect to the msP450 3A4, thus making it overlapping with the reduction peak of CNTs. This might be attributed to the absence of other microsomal components (POR, lipids). However, the potential of this peak is in good agreement with previous studies on purified proteins [142, 145]. Worth to note, is the complete absence of the POR peak (at -550mV), for the pP450 3A4-electrode.

Thus, we can safely assume that the cathodic peak at -360 mV is ascribed to the reduction of the microsomal component P450.

3.1.4 Improvement with CNTs

To investigate the improvement in the electrochemical reactivity of the protein when adsorbed on MWCNTs, we estimated the surface concentration of the electroactive enzyme P450 1A2 and P450 3A4 (Γ , in mol/cm^2) on the electrode. Γ can be estimated as:

$$\Gamma = \frac{Q}{nFA} \quad (3.4)$$

where Q is the charge consumed, in coulombs, obtained from the integration of the reduction peak area after the background correction (divided by the scan rate), n is the number of elec-

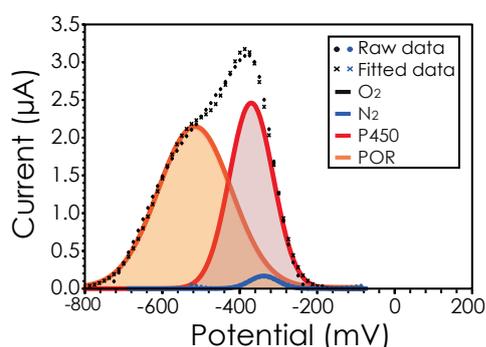

Figure 3.6 – Reduction current peaks from CV after background subtraction, for msP450 3A4 on a bare-SPE in the presence (black points) and absence (blue points) of oxygen. Adapted from Baj-Rossi, C., et al., *Electroanalysis*, 27(6), 1507–1515 (2015) [205].

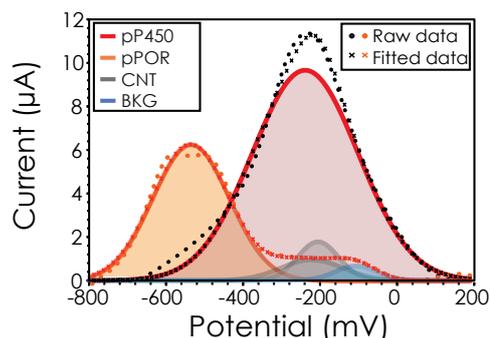

Figure 3.7 – Reduction current peaks from CV after background subtraction, for the purified proteins (pP450 3A4, black dots and pPOR, orange dots) on MWCNT-modified SPEs. Adapted from Baj-Rossi, C., et al., *Electroanalysis*, 27(6), 1507–1515 (2015) [205].

trons exchanged in the redox ($n=1$) [133], A the electrode area (0.1256 cm^2) and F the Faraday constant (in $\text{C} \cdot \text{mol}^{-1}$) [56].

The values of Γ for P450 1A2 and P450 3A4 on bare and MWCNT-modified electrodes are reported in Table 3.1. The values of Q were calculated for a scan rate of 20 mV/s . The percentage of electroactive protein was estimated from the total amount of proteins drop-cast on the electrode, equal to 3.98 nmol/cm^2 (estimation, from vials with a concentration of $\approx 0.5 \text{ nmol}$, on electrodes with area equal to 0.1256 cm^2). Table 3.1 shows that the fraction of electroactive P450, over the total adsorbed protein on the MWCNT-modified electrode, is 80% for P450 1A2 and 83% for P450 3A4. These values are in the same order of magnitude of the percentage obtained for hemoglobin immobilized on a Nafion-CNT electrode [221], and other heme-proteins immobilized in surfactant or polymers [222], proving that MWCNTs are effective in promoting the activity of P450, as has already been found in [219, 220]. This is also confirmed by the smaller fractions of electroactive msP450 obtained for bare electrodes, which is 27% for P450 1A2 and 61% for P450 3A4. We observed a large variation in the fraction of electroactive P450 on bare electrode (*i.e.* a larger differences between the fraction of electroactive P450 1A2 and P450 3A4 on bare electrodes) due to the unstable immobilization of the protein on the electrode surface.

MWCNTs have been recognized as promising nanomaterials for facilitating electron transfer in biosensing [76, 83]. MWCNTs enhance the electrochemical reactivity of proteins or enzymes probably due to the presence of some oxygen-contained groups (*e.g.* carboxyl groups) [221] on the carbon-nanotube surface. Moreover, MWCNTs create a hydrophobic and highly electroactive surface when they are drop-cast on electrodes [217, 223]. We obtain higher value of Γ with MWCNTs than for bare-SPE, for the increase in electroactive area of the electrode due to MWCNTs that creates a 3D-porous structure with a larger effective surface area available for protein deposition.

The MWCNT-enhancement in msP450 reduction current was demonstrated with a comparative experiment for msP450 1A2/MWCNT-SPE and msP450 1A2-bare SPE, for the detection of the anti-inflammatory drug, naproxen. The addition of the drug results in a further increase

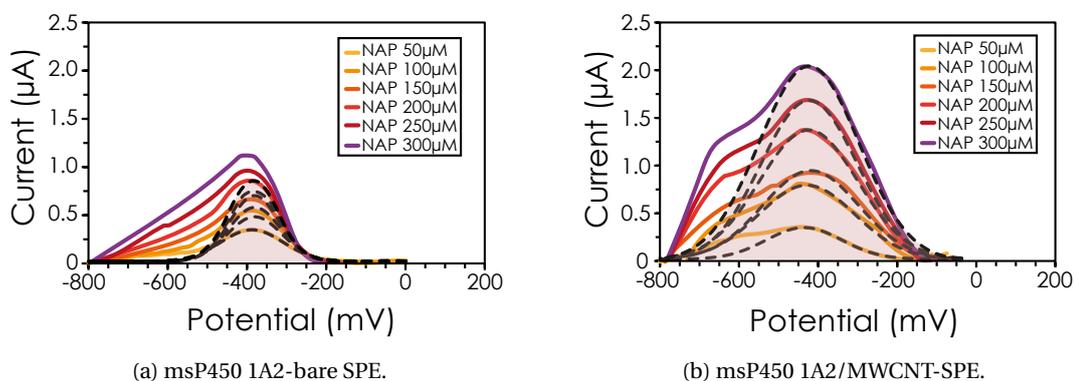

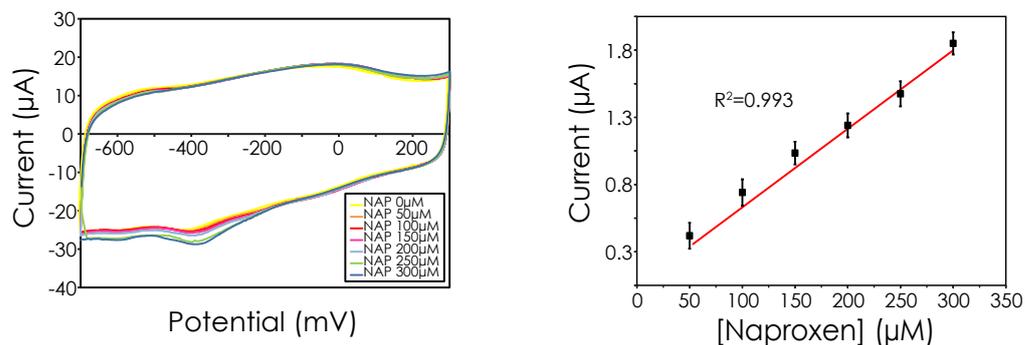

Figure 3.8 – Reduction current peaks from CV after background subtraction, for increasing concentrations of naproxen (NAP). CV acquired in a PBS 10X, pH 7.4, with a scan rate of 20 mV/s. Adapted from Baj-Rossi, C., et al., *Electroanalysis*, 27(6), 1507–1515 (2015) [205].

of the P450 reduction current proportional to the drug concentration. Fig. 3.8 shows reduction currents obtained for msP450 1A2-bare SPEs (Fig. 3.8 a), and for msP450 1A2/MWCNT-SPEs (Fig. 3.8 b) for increasing concentrations of naproxen. Reduction currents obtained are shown after the subtraction of the baseline and normalization with respect to the voltammogram obtained in PBS, in the absence of naproxen. As we expected, the reduction peak current at -380 mV (Fig. 3.8, highlighted in red), linearly increases with naproxen concentration. The increase in current is more evident with msP450s adsorbed to a MWCNT-modified SPE, than to a bare-SPE. In general, with msP450-bare SPEs there is lower sensitivity, higher data variability and noise, resulting in a lower linearity, and higher LOD, than msP450/MWCNT-SPE sensors, as MWCNTs significantly enhance the sensing performance. Also the peak of the POR component shows a slight increase, but less significant. Control experiments were performed with methanol and milliQ instead of drug and we confirmed that the voltammograms for msP450/MWCNT-SPE did not show any significant change (data not shown). The increase of the P450 reduction current proportional to the drug concentration is consistent with other studies in literature, as verified for a number of different P450s immobilized onto electrodes, for several drugs: P450 2C9 [146], P450 2B4 [133, 139], P450 3A4 [142], P450 2B6 [224], P450 2D6 [225], and P450 1A2 [136, 138].

3.2 Drug measurement results

3.2.1 Single and multiple drug detection

We calibrated the msP450/MWCNT-SPE sensors with four drugs: three anti-cancer agents, cyclophosphamide, ftorafur and ifosfamide, and one anti-inflammatory drug, naproxen. These drugs were selected because they are relevant in clinical applications, and because they present sufficiently wide pharmacological ranges, compatible with the detection limit of the

(a) Voltammograms of msP450 1A2 on MWCNT-SPE in aerobic conditions (in 100 mM PBS pH 7.4), at increasing naproxen (NAP) concentrations.

(b) Current response (from the peak current) of the MWCNT/msP450 1A2-SPE sensor to different concentrations of naproxen (confidence interval 95.4%), in PBS.

Figure 3.9 – Calibration of the msP450 1A2/MWCNT-SPE sensor for naproxen. CV acquired in a PBS 10X, pH 7.4, with a scan rate of 20 mV/s, at room temperature. (a) and (b) reprinted from Baj-Rossi, C., et al., *Electroanalysis*, 27(6), 1507–1515 (2015) [205], and from Baj-Rossi, C., et al., *Biosensors and Bioelectronics*, 53, 283–287 (2014) [140], respectively.

biosensors. Three different microsomal P450 isoforms were used, P450 1A2, P450 2B6 and P450 3A4. The calibrations were acquired in PBS (pH 7.4), in human serum, or mouse serum (for naproxen).

Voltammetric responses for each cytochrome-drug pair were firstly acquired in absence of drug (the blank signal), and then in presence of the drug, at increasing concentration within the pharmacological range. As an example, the voltammetric responses to increasing aliquots of naproxen and the calibration curve are shown in Fig. 3.9, while the background-subtracted signals with the reduction peaks, are shown in Fig. 3.8 (b). Naproxen was measured with a msP450 1A2/MWCNT-SPE, in CV, with a potential sweep between -700 and $+300$ mV *vs.* Ag|AgCl at a scan rate of 20 mV/s.

Table 3.2 compares our results obtained in PBS and in serum. As expected, due to the presence of several proteins in the serum, the system exhibits better performance in PBS than in serum, although the limits of detection are within the pharmacological ranges for all the tested drugs, proving the feasibility of P450-based biosensors for measurements in a complex biological fluid. The decrease in sensitivity obtained in serum can be reasonably attributed to the plasma proteins, such as albumin, bilirubin or hemoglobin, which can bind and interact with drug molecules, reducing the free drug concentration at the electrode surface. Plasma proteins can also be not-specifically adsorbed on the electrode surface and partially block the binding site of the enzyme, thus further reducing the signal.

The possibility to simultaneously detect the presence of multiple drugs in the sample was investigated by CV, by measuring a first drug, cyclophosphamide, ifosfamide, or ftorafur, in the presence of a second drug, etoposide, at fixed concentrations. Etoposide is an electrochemically active compound that can be detected without the mediation of a P450

3.2. Drug measurement results

Table 3.2 – Sensitivity and LOD for MWCNT-SPEs with different P450 isoforms for drug detection. Naproxen was measured in mice serum, while the other drugs in human serum.

Drug	Range (μM)	P450	Sensitivity ($\mu\text{A}/\text{mM} * \text{mm}^2$)		Limit of detection (μM)	
			PBS	Serum	PBS	Serum
Cyclophosphamide	3-77	2B6	1.02±0.05	0.3±0.1	2.44±0.02	14±4
		3A4	0.63±0.03	0.32±0.05	4.9±0.3	11±2
Ftorafur	1-10	1A2	8.8±0.7	3.9±0.5	0.7±0.1	0.8±0.1
Ifosfamide	10-160	2B6	1.20±0.02	0.09±0.04	2.8±0.1	40±18
		3A4	1.60±0.02	0.43±0.03	2.02±0.03	7.1±0.5
Naproxen	9-300	1A2	0.54±0.02	0.6±0.2	16±1	33±18

enzyme (see section 3.3). According to the possible chemotherapy regimens administered for the treatment of breast-cancer, three sets of paired drugs were tested (cyclophosphamide-etoposide, ifosfamide-etoposide, and ftorafur-etoposide), as they are metabolized by the same P450 isoform. The results are reported in [209]. A well-defined increase in the sensitivity with etoposide concentration is visible in each case. This behavior is probably due to a partial hetero-activation effect of etoposide on the P450 3A4 and the P450 1A2-mediated metabolism of the other drugs, due to allotropic kinetics of P450 enzymes.

These results proved that, by measuring etoposide with a MWCNT-modified electrode, we could subtract the contribution of etoposide from the current peak measured with the other P450-modified electrode, thus indirectly measuring the concentration of the other drug, *e.g.* ifosfamide [209]. The results presented in this section are one of the first attempts of drug calibration in serum and of multiple drug detection with a P450-based sensor.

3.2.2 Solutions for multiple drug detection

A key step to integrate biosensors for drug monitoring in implantable devices, consists of the immobilization of MWCNTs and msP450s on a sensing platform with an array of micro-fabricated electrodes, for multiple-drug monitoring, as illustrated in Fig. 3.10.

Since P450s can host several molecules in their active site, they can detect two different compounds at the same time. With some drug pairs, P450s will produce multiple peaks in the single cyclic voltammogram [217]. But with other drugs, as reported in [209], we cannot distinguish the contributions of each single drug within a mixture by using only one P450-sensor, because the current peaks are given at the same potential. The solution to this problem is using several P450s in a sensor array, in the right combination. With this strategy, the contribution of every drug present in the mixture can be decoupled. We built a system-level mathematical model [226] based on linear algebra and on a matrix formulation for the decoupling of individual drug contributions in a system containing multiple P450 biosensors. The model, designed to decouple an indefinite number of compounds (in practical clinical cancer, the amount of drugs to be monitored are typically in the range from 1 to 10), has been

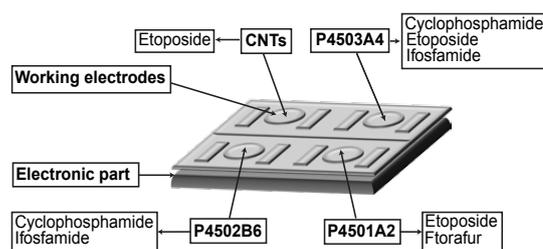

Figure 3.10 – Multiple-spots sensor architecture. Three working electrodes are nanostructured with multi-walled carbon nanotubes (MWCNTs) and a P450 isoform that is specific for a group of drugs (listed inside the boxes), while one electrode is functionalized with only MWCNTs. Reprinted with permission from Baj-Rossi, et al., IEEE Sensors Journal, 13, 4860-4865 (2013) [226].

validated with real experimental data, and it can be used for the design of a biosensor array chip for personalize therapy, as the one illustrated in Fig. 3.10.

The model has the advantage to be based on linear algebra, thus it can be easily implemented to algorithms with low computational costs. A model based on linear algebra can be applied when sensors give a linear response even in presence of multiple drug interactions. For the set of sensors that were analyzed, the linear approximation is justifiable, since all the performance criteria evaluated for the biosensor, such as the sensitivity and limit of detection, are determined within the linear concentration range of the calibration curve.

The contribution of this work reported in [226] is to give a means to assert the accuracy and the limit of detection of the sensor array in case of multiple-drug detection with P450 enzymes.

3.2.3 Sensor stability and continuous drug monitoring

An essential feature of a biosensor for real-time drug monitoring is the stability during continuous measurements. Few literature reports studied P450-biosensor stability [144, 227], with the majority showing the storage stability, *i.e.* the sensor response after 12 h, days or a few weeks of storage. Furthermore no studies have been conducted on the stability of P450-based sensors during continuous measurements.

We investigated at first the stability of the MWCNT/msP450 1A2-SPE sensor over 36 h. The sensor was incubated in 100 mM PBS (pH 7.4) for 36 h and CVs were continuously acquired every 90 min, in order to reduce the scans applied to P450 and saving its catalytic activity. CVs were recorded in aerobic conditions and in the absence of any drugs. The aim was to investigate the decrease of the msP450 1A2 reduction peak due to continuous cycling, thus decoupling any possible kinetics effect attributed to the presence of a substrate that could produce an activation or inhibition effect on P450 activity [119].

Fig. 3.11 (a) depicts the reduction peak behavior for msP450 1A2, in 36 h. Values in the y-axis are the currents of the reduction peaks at -380 mV. The peak shows good stability for the first 16 h, and then starts to gradually decrease, reaching about 70% of its initial height after 22 h,

3.2. Drug measurement results

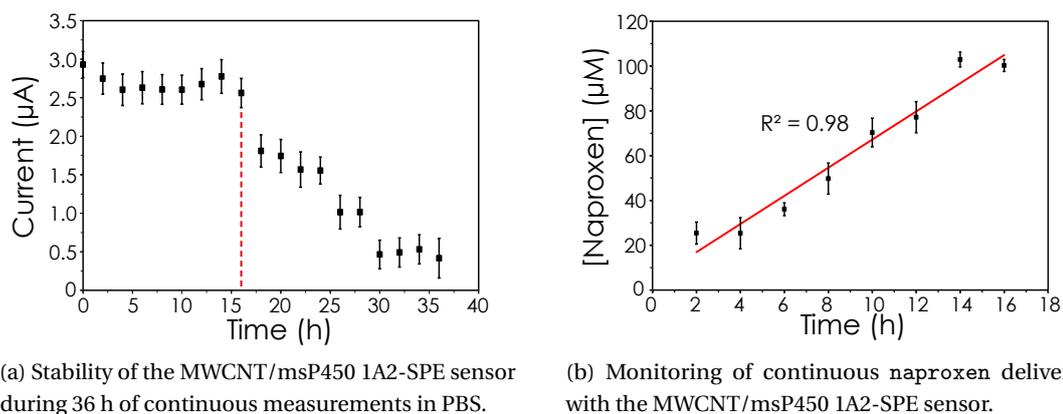

Figure 3.11 – Stability and continuous drug monitoring of a msP450 1A2/MWCNT-SPE sensor, for naproxen detection. CV acquired in a PBS 10X, pH 7.4, with a scan rate of 20 mV/s, at room temperature. Reprinted with permission from Baj-Rossi, C., et al., *Biosensors and Bioelectronics*, 53, 283-287 (2014) [140].

and about 20% after 36 h. A reason for the decrease of P450 activity after 16 h, is the enzyme degradation due to prolonged use, under continuous potential cycling, every 90 min. A similar loss in catalytic activity for immobilized enzyme was already reported in [228], where an enzyme hydrogenase almost completely lost its activity after 24 h under continuous potential cycling.

The ability of MWCNT/msP450 1A2-SPE sensor to monitor naproxen in real-time was further investigated. The sensor was employed to monitor the concentration variations of naproxen, which was continuously delivered in solution by means of a micro-osmotic pump. After the micro-osmotic pump was loaded and its delivery rate reached the steady state, the MWCNT/msP450 1A2-SPE sensor started monitoring in PBS for 36 h, while $5 \pm 1 \mu\text{M}/\text{h}$ of naproxen were constantly delivered. Cyclic voltammograms were acquired under aerobic conditions. As proved by the previous experiment, after 16 h the MWCNT/msP450 1A2-SPE sensor starts losing its activity. Fig. 3.11 (b) shows the monitoring of naproxen, delivered by the osmotic pump for the first 16 h. The reduction current peaks, measured with the sensor every 2 h, were transformed in naproxen concentration (y-axis in Fig. 3.11 b), according to the linear regression function obtained from the sensor calibration (Fig. 3.9 b). A fairly good linearity over a time lapse of 16 h was obtained. The delivery rate of the micro-osmotic pump was compared with the amount of naproxen measured by the MWCNT/msP450 1A2-SPE sensor per hour. The amount of naproxen measured per hour, estimated from the calibration line shown in Fig. 3.11 (b), was $6.2 \pm 0.2 \mu\text{M}/\text{h}$, which confirms the delivery rate of the osmotic pump previously estimated by the supplier, $5 \pm 1 \mu\text{M}/\text{h}$. These results proved that the MWCNT/msP450 1A2-SPE sensor was able to monitor the continuous delivery of naproxen for 16 h [140]. This study represents an absolute novelty regarding the present state-of-the-art of sensors based on P450s, as none of the previous studies in literature reports a long-term evaluation of the P450 stability, neither the continuous measurements of a drug.

3.2.4 Repeatability

The reproducibility of electrochemical signals obtained using three biosensors was evaluated by comparing the peak current on continuous cycling (for 1 h) with a MWCNT/msP450 1A2-SPE sensor. Almost no significant changes were found, as we obtained a *relative standard deviation* (R.S.D.) value of 4.4%.

The repeatability of the biosensing process was evaluated by measuring the responses of a freshly prepared biosensor to 200 μ M naproxen within the first 6 h of preparation at 1 h time interval, while storing in PBS at 4 °C after each measurement. A R.S.D. value of 3.1% was obtained, indicating good repeatability.

The storage stability of the biosensor was investigated by monitoring the response to 200 μ M naproxen with cyclic voltammograms after storing in PBS at 4 °C for 0 h, 12 h, 24 h, 2 days, 4 days and 1 week. The peak current decreased with increase in storage time. Nevertheless the biosensor still retained 75% of its initial response after 1 week of storage, with an R.S.D. value of 11.2%. These results proved that the MWCNT/msP450 1A2-SPE sensor had good reproducibility in the preparation procedure and it can be repeatedly used in voltammetric determination of drugs. For each evaluation, three different samples were employed.

3.3 Detection of electroactive drugs

The redox mechanism of the etoposide, a drug used as breast-cancer treatment, was investigated, as case of study of an electrochemically active drug. Previous studies on the electrochemistry of etoposide at glassy carbon electrodes [229], showed that etoposide is oxidized to orthoquinone, resulting in two anodic peaks: a peak at 300 mV that corresponds to a reversible one-electron process; a peak at 600 mV, which occurs irreversibly. Both current peaks have been proved to linearly increase with the concentration of etoposide. The reversal of the potential scan results in two cathodic peaks (at 250 mV and -50 mV), due to reduction of the orthoquinone.

The voltammetric response to increasing concentrations of etoposide was measured with graphite SPE without P450. Bare-SPE and MWCNT-SPE, were used as working electrodes. The preparation of the MWCNT-SPE is reported in the 'Methods' section (3.1.1). The voltammograms were registered by applying a potential sweep between -600 and +1000 mV and measuring the current in PBS, where etoposide solution was added at increasing concentrations. Fig. 3.12 shows the etoposide common voltammogram, obtained with MWCNT-SPE (a) and with a bare electrode (b), with four characteristic peaks [229]: two oxidation peaks at +250 mV, and +450 mV, and two reduction peaks at 0 mV and 150 mV. The peak at -200 mV corresponds to the reduction of CNT-oxygen moieties [219], as proved by the absence of this peak for the bare electrode (Fig. 3.12 b).

This study further confirms the enhancement in current when the electrodes are nanostructured with MWCNTs, as we obtained much higher current peaks than with bare electrodes. We measured etoposide in the physiological range obtaining a sensitivity (computed considering the anodic peak at 200 mV, calibration not shown), for a MWCNT-SPE of

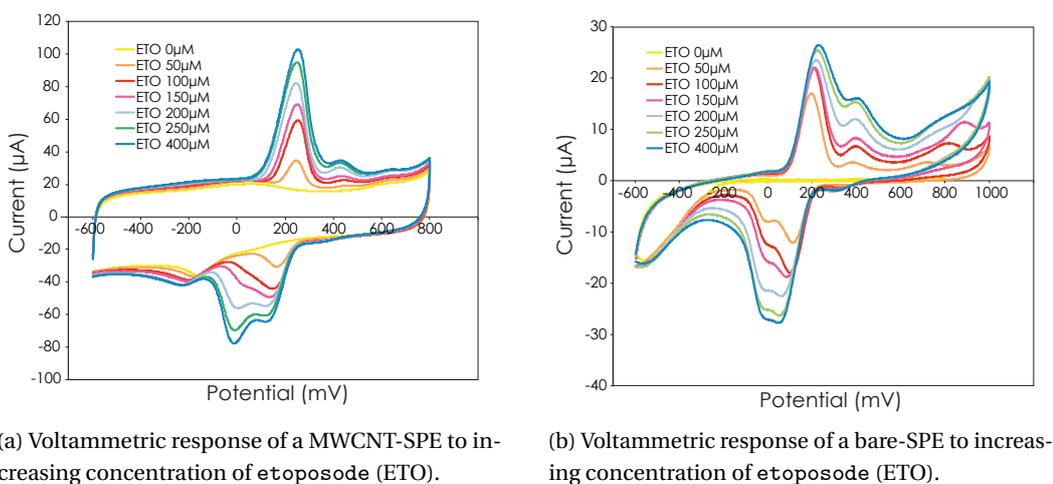

Figure 3.12 – Detection of the electroactive drug etoposide.

$73.7 \pm 0.4 \mu A / mMmm^2$, with a LOD of $5 \pm 2 \mu M$, definitely suitable to match the etoposide physiological range ($34 - 102 \mu M$ [230]). We also measured etoposide with a MWCNT-SPE in human serum, obtaining a sensitivity of $9 \pm 3 \mu A / mMmm^2$ and a LOD of $12 \pm 8 \mu M$.

3.4 Summary

The current state-of-the-art on P450-based biosensors provides an extensive investigation on the P450 electrochemistry. However, the present state-of-the-art is not focused on the development of P450-biosensors as a diagnostic tool. The results presented in this chapter represent a significant step forward respect to the state-of-the-art.

The P450 biosensors presented in this thesis are made on SPEs nanostructured with MWCNTs and functionalized with microsomes containing cytochrome P450. We proved that MWCNTs significantly improve sensor sensitivity and detection limit, as they provide a larger area, more favorable for the P450 adsorption. With MWCNT-nanostructured electrodes we performed detection of several drugs in their therapeutic range, and in complex solutions like human or animal serum.

With an investigation on the P450-biosensor stability in long-term measurements, we proved that the enzyme is active and stable for 16 h. Moreover, the continuous monitoring of a drug with a P450-biosensor has been proposed for the first time. The 16-h limit for enzyme stability is long enough for the study of the pharmacokinetics for many drugs. However it indicates that, at the current stage, our P450-biosensors can be successfully exploited as a disposable sensor, they still present issues to be investigated for implantable applications.

In the next chapter the design, fabrication and characterization of the sensing platform will be presented. We will show that with the micro-fabricated platform we can monitor electroactive drugs, metabolites, pH and temperature.

4 Design and test of the implantable sensor platform

The need for system integration into a small implantable device strongly influences the design constraints for every component of the device. As illustrated in Fig. 4.1, the fully implantable device consists of: 1) a passive sensing platform, 2) *integrated circuits* (ICs) to perform electrochemical measurements and 3) a coil for power and data transmission. As an example, the sensing platform must be capable to monitor multiple parameters, must be realized as small as possible, with biocompatible materials. Moreover, the sensing techniques must be compatible with low-power electronics, and grant at the same time sufficient precision for reliable measurements.

The electrochemical platform was designed to host five independent biosensors, for the simultaneous monitoring of drugs and endogenous metabolites, pH, and a temperature sensor. A sensing platform for electrochemical measurements, combined with the presence of a pH and a temperature sensor, is designed to optimize the sensing performance in different physiological conditions, as changes in pH and temperature can affect the sensor specificity. This chapter presents the design, fabrication and characterization of the electrochemical sensing platform, with respect to the constraints given by the integration with the electronics

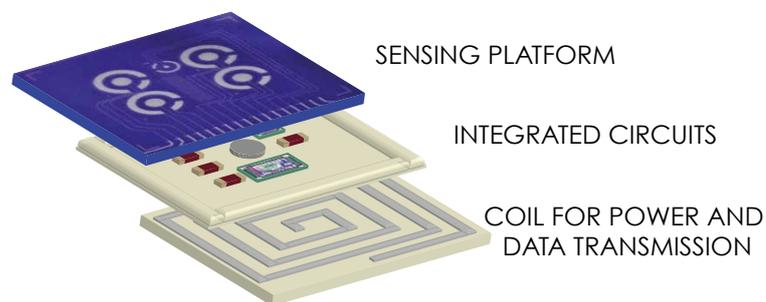

Figure 4.1 – Scheme of the integrated implantable device. Reprinted with permission from Baj-Rossi, et al., IEEE Transaction on Biomedical Circuits and Systems, 8, 5, 636-647 (2014) [231].

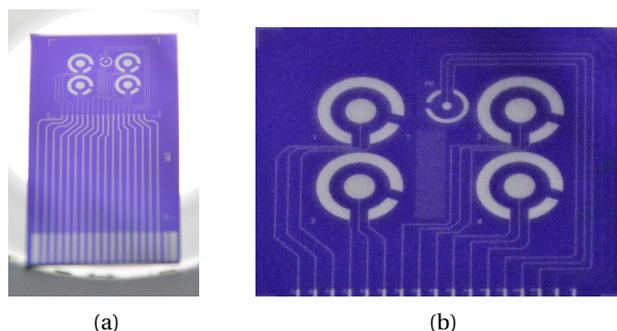

Figure 4.2 – Photograph of the sensing platform in the version for *in-vitro* tests (a), and for implantable applications (b).

that is needed to actuate the sensor, read-out and transmit the data to an external receiving device (the integration with the IC is presented in Chapter 6). The calibration towards drugs, endogenous metabolites, pH and temperature with the micro-fabricated platform is reported, proving the flexibility and accuracy of this platform.

4.1 Platform design and microfabrication

As illustrated in Fig. 4.1, we decided to vertically assemble the device, by placing the platform on the top of the PCB that contains the circuits, the microcontroller and the antenna on the bottom. The platform measures 12x11 mm, to fit the size of the coil (12x12 mm), and to leave some space for the wire bonding between the pads on the platform and the pads on the PCB. For the *in-vitro* characterization with commercial potentiostats, a bigger version of the platform was realized, with larger pads compatible with commercial connectors. Fig. 4.2, shows the two versions of the platform.

For the fabrication we selected biocompatible materials used in standard microfabrication processes (*e.g photolithography, metal evaporation*), available in the clean room facilities in EPFL. **Silicon** wafers were chosen as substrate, with a 500nm SiO_2 layer covering the top, as insulating layer for the metal deposition.

Platinum was selected for its versatility and for its biocompatibility, as it has been widely used for implantable medical applications, ranging from pacemakers, vascular stents, to joint prosthesis [232]. We employed Pt as material for the electrodes, for the pads, and for the temperature sensor. Pt is a common materials for WE and CE, but it can be also used as *pseudo reference electrode* [233, 234]. With a pseudo reference electrode, the potential varies in a predictable manner according to the composition of the solution, but it can be adjusted by adding to the solution a redox compound with well-known potentials, like ferrocene. Moreover, Pt can be employed for the realization of a *resistive thermal device* (RTD), as the Pt resistance linearly varies with the temperature.

Aluminum Oxide (Al_2O_3) was selected as material for the passivation layer, as it is a well-known biocompatible material, widely used for coatings of medical implant [235, 236].

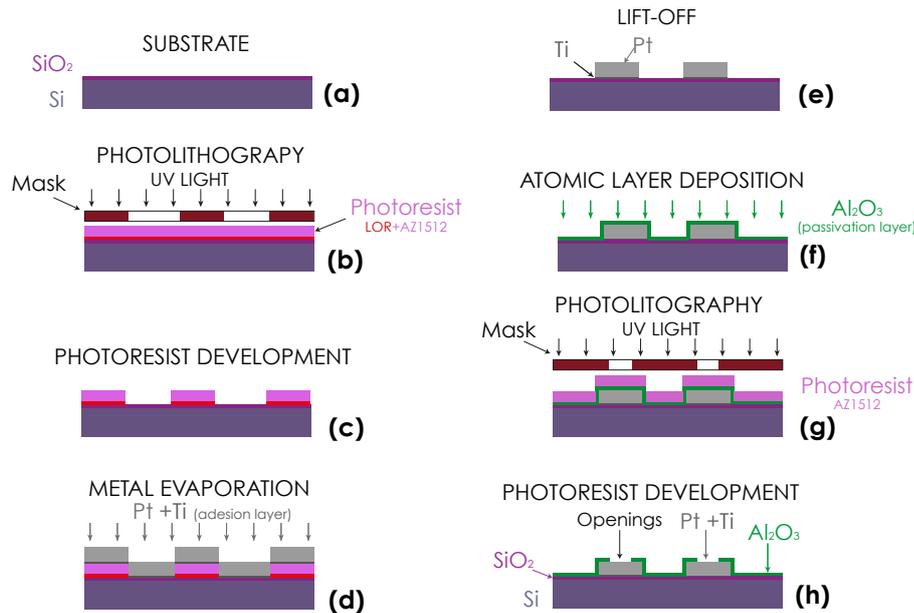

Figure 4.3 – Process flow.

4.1.1 Microfabrication

The microfabrication of the sensing platform was realized in the *Center for Micro- and Nanotechnologies* at EPFL. The required processing steps for the fabrication, *i.e.* the process flow, was designed in our laboratory [237]. As a result of the optimal choice of the materials, the fabrication process requires only two masks and it is efficient, as it can be completed in a few days, with the production of a significant number of platforms (8-12 platform per wafer, for a maximum of 8 wafer that can be fabricated in the same process). The mask fabrication starts with a glass substrate with a Cr/photoresist film on top. Direct laser writing lithography is performed with the *Heidelberg DWL200*, for the mask fabrication. After the laser writing, the photoresist is developed with the *Süss DV10*. The Cr is then etched in a wet bench trough a mixtures of perchloric acid $HClO_4$, and ceric ammonium nitrate $(NH_4)_2[Ce(NO_3)_6]$, and the photoresist is eventually stripped with the remover *Technistrip P1316*. The masks are rinsed with deionized water and dried with a nitrogen flux. Fig. 4.3 reports the steps for the platform fabrication that are described here:

- *Photolithography with the first mask*: the wafers (a), are coated with a double layer of resists, *i.e.* 400nm of *Lift-Off Resist* (LOR) and 1.6 μm of *AZ1512* (b). LOR is a polymer that dissolves in alkaline solutions. It is used before a sputtering or evaporation step, as a sacrificial material that can be etched with standard developers by extending the development time of the top resist (the *AZ1512*). This method, known as the double layer lift-off or bi-layer lift-off, successfully enables the resist dissolution with the subsequent lift-off of sputtered material. The two resists are spin-coated with the *EVG150*. The

coated wafers are exposed using the first mask, with the *Süss MA6/BA* for 2.8 s, and then developed in the *EVG150*, (c). Exposed areas results in open areas after the development. Consequently evaporated or sputtered materials, after resist dissolution, remains only in the exposed areas on the top of the substrate.

- *Metal evaporation*: 10 nm of Ti and 100 nm of Pt are evaporated with the *LAB600H*, through the physical vapor deposition technique (d). Ti is used as adhesion layer for the Pt.
- *Lift-off*: the wafer is dipped in the remover 1165, first in the ultrasound-bath, and subsequently in the normal bath for approximately 7-8 h, depending on the thickness of the metal layer (e). An O_2 plasma cleaning is often necessary to remove the residues of resist.
- *Atomic layer deposition*: *Atomic layer deposition* (ALD) (f) is used for the deposition of 20 nm of Al_2O_3 , as passivation layer. This technique enables the controlled growth of a uniform and pinhole-free passivation layer, with high resistance towards chemical wet etching.
- *Photolithography with the second mask*: to open the passivation layer on the top of the electrodes and the pads, a second step of photolithography is performed with the second mask (g). In this case, mask alignment is required, and only one layer of resist (1.6 μm of AZ1512), is necessary.
- *Argon Ion Milling*: *Argon Ion Milling* (AIM) (h) is used to etch the passivation layer where the resist was removed. To etch 20 nm of Al_2O_3 , 90" of AIM are required. AIM can produce an highly precise anisotropic etching. After the AIM, the resist is removed in the SVC14 bath.

4.1.2 Design

The platform was designed with two different layouts. Fig. 4.4 shows the photograph of the first platform with the main structures. In the first design, the platform hosts an array of four independent cells in the three-electrode configuration: a *working electrode* (WE), a *counter electrode* (CE) and a *reference electrode* (RE), all made in Pt. In this configuration, the WEs are surrounded by a semicircular CE and a small RE. We chose this design to grant that each cell presented the same structure and distance between electrodes. WEs were realized in three different geometries (diameter of 500 μm , 1 mm and 1.2 mm), in order to explore the best configuration. The main advantage behind the design of an array of independent sensors is the possibility to perform multiplexed measurements of drugs or metabolites at the same time. The electrical connections between the electrodes and the pads are ensured by Pt wires, which are 20 μm width in the implantable version, and 100 μm in the longer version for the *in-vitro* tests. In this latter case, the footprint of the pads is designed according to the footprint of the pads inside the commercial connector.

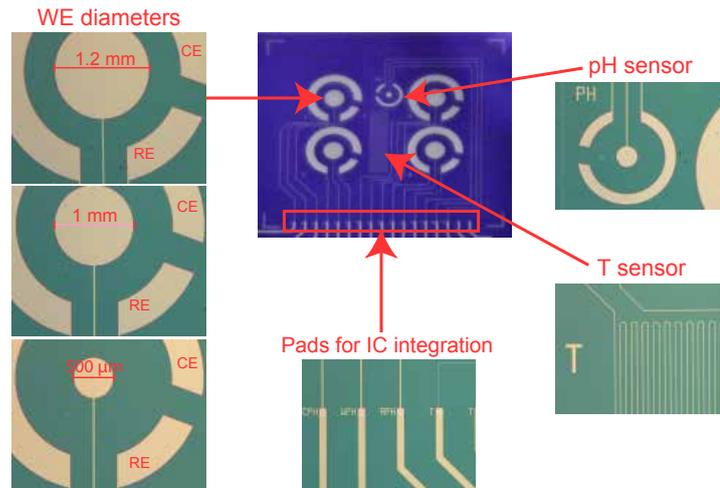

Figure 4.4 – Photographs of the microfabricated platform (center), with the three geometries for the WE, the pads for integration with ICs, the pH sensor and the temperature sensor. Adapted with permission from Baj-Rossi, et al., IEEE Transaction on Biomedical Circuits and Systems, 8, 5, 636-647 (2014) [231].

The platform also contains a fifth cell, which is employed as pH sensor. It has a diameter of $300\ \mu\text{m}$ and it is based on the deposition of an anodic Iridium oxide film. The RTD used as a temperature sensor, consists of a Pt wire, $4\ \text{nm}$ wide and $93\ \text{mm}$ long.

In the second design, the five WEs share a common CE and RE. Fig. 4.5 shows the photograph of the second platform. The CE surrounds the other electrodes and it is designed as large as possible to collect the maximum current flowing from the WEs, as requested from the

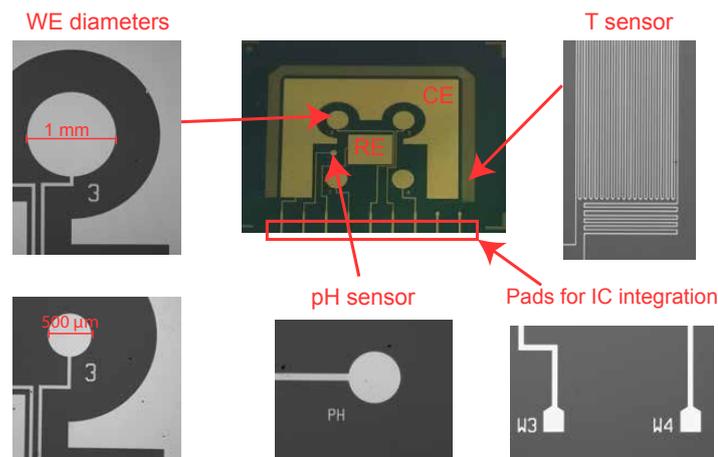

Figure 4.5 – Photographs of the second microfabricated platform (center), with the two geometries for the WE, the pads for integration with ICs, the pH sensor and the temperature sensor.

integrated circuits that need to readout the current, in the implantable device. With the CE of the first design (Fig. 4.4), when measuring the current of the sensor, the voltage of the CE gets saturated. This is due to the high voltage drop between RE and CE electrodes. In order to keep the voltage of CE within the supply voltage range (0 to 1.8 V) we significantly increased the area of the CE in the second design. A bigger CE electrode decreases the equivalent resistance between CE and RE, and consequently the voltage drop between the CE and the RE. Next sections will show a complete characterization of the sensing platform, in terms of different techniques to integrated MWCNTs, and calibration of the sensor towards drugs, metabolites, pH and temperature.

4.2 Sensor Characterization

In this section we initially show the characterization of the bare electrodes of the different electrode geometries and of the different techniques used in this thesis to nano-structure the WEs with MWCNTs. Then we present the calibration of the micro-fabricated platform towards detection of glucose, lactate, drugs, pH and temperature in the physiological ranges.

4.2.1 Methods

Multi-walled carbon nanotubes (MWCNTs, ~10 nm diameter and ~1-2 μm length) with 5% -COOH groups content, were purchased as a powder (90% purity) from DropSens (Spain). For drop-cast deposition, a 1 mg/ml solution of MWCNTs, prepared in chloroform, was sonicated for 3 h to obtain a homogeneous suspension. A 0.7% w/v chitosan solution (pH 5) was prepared by dissolving 700 mg of chitosan in a solution of acetic acid 2%, stirred overnight, filtered, and the pH of solution was adjusted to 5 with concentrated NaOH. For electrodeposition or drop-cast with chitosan, MWCNTs in powder were dispersed in chitosan (0.7% w/v, pH 5) and then sonicated for 3 h to obtain a 8 mg/ml solution. To add the nano-structure to the WEs we investigated different techniques: direct drop-cast of MWCNTs dissolved in chloroform or in chitosan, and the electrodeposition of MWCNTs, dissolved in chitosan. With the drop-cast technique, a 0.2 μl of MWCNT solution (in chloroform or chitosan) were dropped on the WE. After the solvent evaporates, the MWCNTs are adsorbed on the electrode surface. Before the experiments, the electrode was dried in air at room temperature for some time in order to evaporate the solvent. For electrodeposition, the platform was dipped in a 8 mg/ml MWCNT/chitosan solution, with an external CE that was kept parallel to the WE, and a constant potential of 1.5 V was applied for a time interval, which is dependent on the electrode dimension [237].

For the characterization of bare electrodes and nano-structured electrodes, a solution of potassium ferrocyanide was prepared by dissolving *potassium hexacyanoferrate (II) trihydrate* in PBS 1X (pH 7.4).

Glucose oxidase (GOx) from *Aspergillus Niger* and *lactate oxidase* (LOx) from *Pediococcus* species were purchased from Roche in lyophilizate powder and dissolved in a 100 mM PBS (pH

7.4). *D-(+)-glucose* and lithium L-lactate were purchased from Sigma-Aldrich (Switzerland) in powder and dissolved in in PBS, pH 7.4. For the glucose and lactate detection, $2\mu\text{l}$ of a solution 15 mg/ml of GOx and 33 mg/ml of LOx were dropped on the nano-structured WEs, respectively. Electrodes were stored overnight at 4°C . All the samples were freshly prepared and used the same day. When not in use, electrodes were stored at 4°C .

Etoposide, mitoxantrone, and acetaminophen, were purchased as a powder from Sigma-Aldrich. Due to their low solubility in water, etoposide and mitoxantrone solutions at different concentration were prepared by dissolving them in Dimethyl sulfoxide (from Sigma Aldrich), while acetaminophen was dissolved in ethanol, before storage at room temperature. For the pH sensor, a solution of Iridium(IV) chloride hydrate (99.9% metals basis, from Sigma Aldrich), H_2O_2 (30%), oxalic acid dihydrate (98%, from Sigma Aldrich), and potassium carbonate anhydrous (99%, from Alfa Aesar) was prepared for the deposition of the *Iridium Oxide* (IrOx) film, as reported in [238]. A layer of IrOx was created on the electrode surface through galvanostatic deposition, by applying a constant current of $0.9375\ \mu\text{A}$ for 500 s. After a stabilization in PBS pH 7.4 for 2 days to reduce potential drift, the electrodes were tested for pH sensing.

All experiments were carried out in a PBS 1X, pH 7.4, as supporting electrolyte. Electrochemical measurements were performed using an Autolab electrochemical workstation (Metrohm, Switzerland). Electrodes were tested for glucose and lactate sensitivity in CA at +650 mV. The sensors were first dipped in a PBS 1X solution (pH 7.4), under stirring conditions, then conditioned for 1 h at +650 mV and then tested against repeated injections of glucose or lactate. CV was used for the initial sensor characterization, in presence of potassium ferrocyanide 100 mM, and to identify the oxidation/reduction peaks of the drugs etoposide and mitoxantrone. CV was performed at room temperature under aerobic conditions by applying a triangular waveform voltage in the range between -600 mV and +800 mV vs. Pt, with scan rate of 20 mV/s. *Square wave voltammetry* (SWV) was performed by applying a linearly increasing potential between -600 mV and +400 mV, for etoposide detection. After an initial conditioning in PBS, drops of $200\ \mu\text{l}$ of etoposide or mitoxantrone solutions were added at the right concentration. CA was also used to calibrate the bare electrodes for the detection of etoposide and acetaminophen. The pH was computed averaging the *open circuit potential* (OCP) in a time window of around 120" by continuously changing the pH of the buffer solution by means of an external pH meter (from VWR). An external reference electrode (double junction in Ag|AgCl) was used in order to have stable and reproducible measurements. For the temperature sensor, a True RMS Multimeter 37XR (Wavetek Meterman) was connected to our platform to measure the changes in resistivity.

4.2.2 Characterization of bare electrodes

The platform was characterized by CV with potassium ferrocyanide 100 mM, to test differences in current for the WEs with different geometries, and the two designs of the platform. Fig. 4.6 shows the CV in presence of potassium ferrocyanide 100 mM with the comparison between: (a) the three geometries of the WEs in the first platform (Fig. 4.4); (b) the first and second

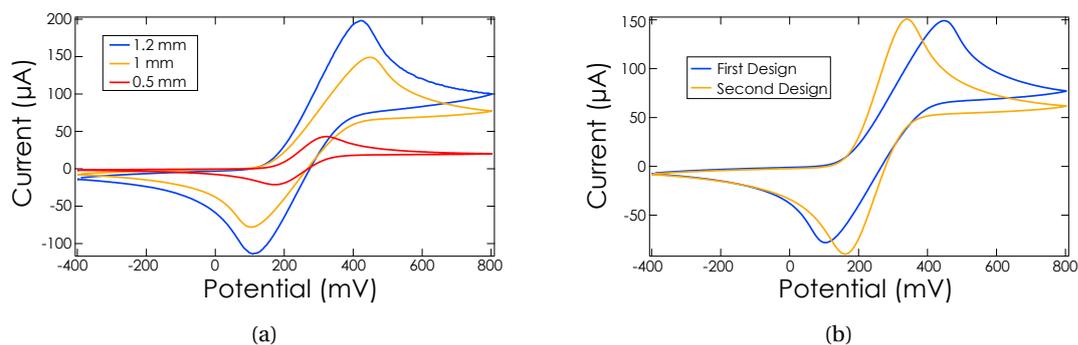

Figure 4.6 – CV in presence of potassium ferrocyanide 100 mM: (a) for the three geometries of the WEs for the first design; (b) comparing the first and second version of the platform, both acquired with a 1 mm-diameter WE.

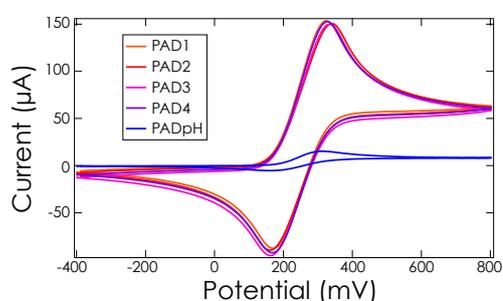

Figure 4.7 – CV in presence of potassium ferrocyanide 100 mM for the 5 WEs (1 mm diameter) of the second platform.

version of the platform, both acquired with a 1 mm-diameter WE. As expected, by increasing the diameter of the WE, we obtain higher currents (Fig. 4.6 (a)). Fig. 4.6 (b) shows some differences between the first and the second platform: with the second platform we obtained more symmetric peaks for the potassium ferrocyanide redox, due to the larger area of the CE. Fig. 4.7 shows the CV with potassium ferrocyanide 100 mM for the four 1 mm-diameter WEs of the second platform. The voltammograms are well overlapped, with small differences in current. The WEs in the second platform, as illustrated in Fig. 4.5, are not surrounded in the same way by the CE, thus we can have small differences as the output current. This result proves that the proposed design grants reproducible results among the different WEs.

4.2.3 CNT deposition techniques

As illustrated in the section 2.1.2 in Chapter 2, several nanomaterials have been investigated in research, to enhance the output signal of the biosensors. Among different promising nanomaterials we focused on carbon-nanotubes due to their electrical properties.

In the present work, we investigated several techniques for the integration of MWCNTs onto the micro-fabricated WEs. As main criteria to evaluate the different techniques we selected the

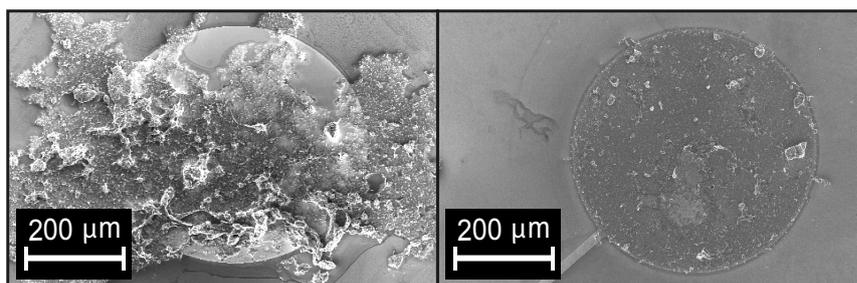

Figure 4.8 – SEM of WEs with $500\mu\text{m}$ diameter, nano-structured with drop-cast MWCNTs (on the left), and electrodeposited MWCNTs in a chitosan matrix (on the right).

efficacy to measure the analyte of interest within the pharmacological range, the simplicity of the technique, and the biocompatibility, taking into account that the final goal of this project is the integration of MWCNTs in an implantable device.

The first technique is the direct drop-cast of a solution of MWCNTs dissolved in chloroform, as illustrated in the previous chapter for the measurements with screen-printed electrodes. With micro-fabricated electrodes, subsequent drops of solutions were drop-cast on the WEs, with a volume of $0.05\mu\text{l} - 0.1\mu\text{l}$, until $0.2\mu\text{g}$ of MWCNTs were adsorbed on the electrode surface. This amount of MWCNTs was optimized by evaluating the performances of the sensor towards glucose detection. Despite the simplicity of this technique, the precision of the deposition and the repeatability is relatively low, as illustrated by the SEM in Fig. 4.8, on the left. A method to control the deposition of MWCNTs and to ensure the repeatability of the deposition on different sensors, is to check the similarity of the voltammogram by running a CV measurement after CNT deposition.

In our group other techniques were investigated to integrate MWCNTs on micro-fabricated electrodes: direct growth through chemical vapor deposition [239], and micro-spotting of MWCNTs dissolved in Nafion [240]. While the direct growth is a very promising method, as it enables the precise growth of CNTs and other nano-structures on electrodes with high density, micro-spotting present a limited precision, as the spot size is fixed and limited by the instrument resolution. As alternative technique, we investigated the electrodeposition of MWCNTs in chitosan. Chitosan is a natural polysaccharide obtained from the deacetylation of chitin, abundant in natural environment with low toxicity. Chitosan offers a unique set of characteristics such as biocompatibility, simplicity of chemical modifications, superior permeability to water, and biodegradability to harmless products, antibacterial properties, gel-forming properties, and good adhesion properties due to hydrophilicity, physiological inertness and affinity towards proteins. Due to its advantageous features, chitosan is one of the most used biopolymers for the immobilization of enzymes and CNTs [241, 242, 243] for biosensing applications [244].

Chitosan undergoes pH-dependent hydrogel formation, at the electrode interface. Carbon nanotubes or other nano-materials can be incorporated in the chitosan solution for realizing subsequent immobilization on the electrode. Fig. 4.9 illustrates the electrodeposition of

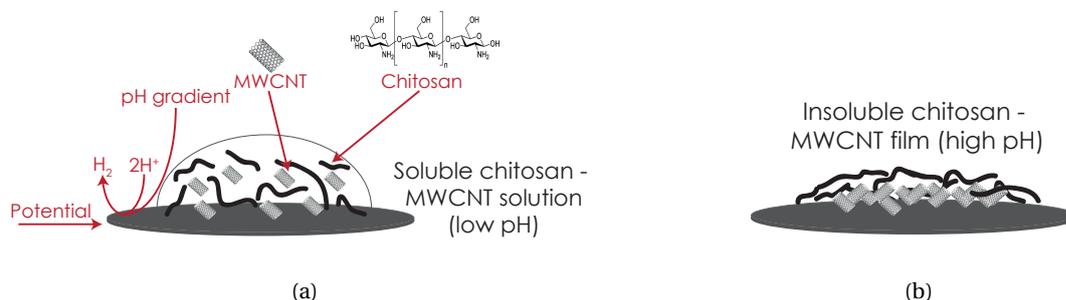

Figure 4.9 – Electrodeposition of MWCNTs in a chitosan matrix: (a) the electrode is immersed in a chitosan-MWCNT solution at pH 5. (b) After the application of a fixed potential, the chitosan create a three-dimensional hydrogel network that entraps the MWCNT on the electrode.

chitosan and MWCNT. Chitosan and MWCNTs are first dissolved in a slightly acidic solution (pH 5), as chitosan is protonated and soluble at low pH (Fig. 4.9 (a)). When the electrode is immersed in the chitosan-MWCNT solution and a voltage is applied to the electrode, a pH gradient is established in the immediate vicinity of the electrode surface, created by the consumption of protons in the solution. The chitosan chains become deprotonated when the localized pH exceeds 6.3, thus creating a three-dimensional hydrogel network that entraps the MWCNTs dissolved in the matrix (Fig. 4.9 (b)). The rate of this electrochemical deposition is proportional to the current density and can be adjusted by changing the applied voltage. Electrodeposition is a versatile and simple technique that enables a spatially controlled deposition of CNTs in a biocompatible hydrogel, and it offers unique opportunities for integration of nano-structures in micro-fabricated electrodes, regardless the electrode geometry or the inter-electrode distance [245, 246]. The extent of the deposition, can be precisely controlled varying the deposition time, and the amount of MWCNTs can be tuned by varying the concentration of the initial solution. Therefore this technique enables reproducible and precise functionalization [246], as shown in the SEM of Fig. 4.8, on the right. We optimized the potential for electrodeposition to 1.5 V, and the concentration of the solution to 8mg/ml of

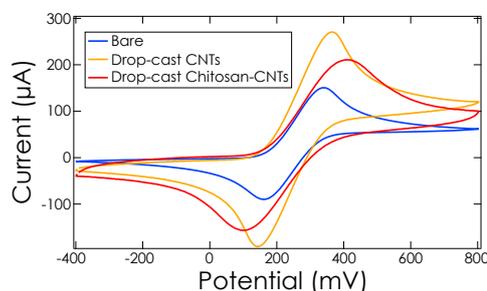

Figure 4.10 – Cyclic voltammety in presence of potassium ferrocyanide 100 mM for a bare electrode (blue line), drop-cast MWCNT modified electrode (orange line), and a drop-cast chitosan-MWCNT modified electrode (red line).

MWCNTs in chitosan, with a deposition time variable according to the electrode size: 600” for the 500 μm diameter, 2000” for the 1 mm diameter, and 2400” for the 1.2 mm diameter [231, 237].

With both drop-cast and electrodeposition of MWCNTs, we succeeded in measuring glucose, lactate and electroactive drugs, as it will be shown in the following subsection. Moreover, in the last part of the present research we also investigated the direct drop-cast of MWCNTs dissolved in chitosan. For the final implantable device, we could not employ the electrodeposition, as the integrated circuits were not able to supply to the platform the correct potential. As we needed to entrap MWCNTs in a biocompatible matrix, we decided to drop-cast the solution of chitosan-MWCNTs. When the solution is in contact with the electrode surface, the solvent evaporates and the chitosan creates a three-dimensional hydrogel network, entrapping the MWCNTs in proximity of the electrode surface [247, 248].

Fig. 4.10 shows the comparison between voltammograms obtained with a 1 mm-diameter bare electrode, a drop-cast MWCNT modified electrode (from a MWCNT-chloroform solution), and a drop-cast chitosan-MWCNT modified electrode, in presence of potassium ferrocyanide 100 mM. The chitosan partially insulate the electrode, as shown in the lower current in the CV in Fig. 4.10, respect to the drop-cast of MWCNTs in chloroform, but it represents a significant improvement with respect to the bare electrode.

4.2.4 Glucose and Lactate

The characterization of the microfabricated sensor toward detection of glucose and lactate was performed in CA. With electrodes modified with drop-cast MWCNTs and enzymes, we initially measured both glucose and lactate with the commercial potentiostat used in the

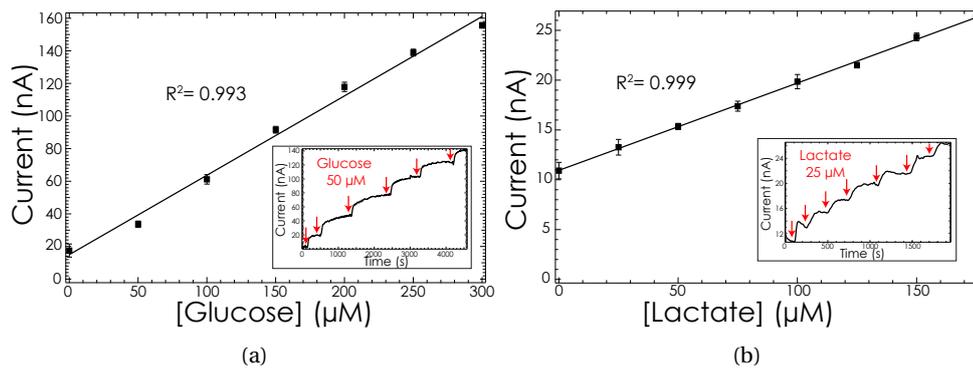

Figure 4.11 – Calibration curve of glucose (a) and lactate (b) detection in CA at +650 mV, after electrodeposition MWCNTs in chitosan, and after the adsorption of GOx and LOx, respectively. The insets report two examples of CA for glucose and lactate detection. Reprinted with permission from from Baj-Rossi, et al., IEEE Transaction on Biomedical Circuits and Systems, 8, 5, 636-647 (2014) [231], and from Baj-Rossi, C., et al., In Engineering in Medicine and Biology Society (EMBC), 2014 36th Annual International Conference of the IEEE (pp. 2020-2023) [249].

laboratory.

With electrodes modified with electrodeposited MWCNTs in chitosan, we performed detection of glucose and lactate in CA at +650 mV, after the adsorption of GOx or LOx. For glucose detection we used a 1.2 mm WE, for lactate a 500 μm WE. The sensors were first dipped in a PBS solution (1X pH 7.4), under stirring conditions, then conditioned for 30 min at +650 mV and then tested against repeated injections of lactate 25 μM , or glucose 50 μM . The CA measurements at +650 mV for glucose and lactate are reported in the insets of Fig. 4.11 (a) and Fig. 4.11 (b), respectively. The arrows correspond to repeated injections of lactate 25 μM or glucose 50 μM . Well-defined current steps are visible after every further injection. The calibration lines reported in Fig. 4.11 (a) and Fig. 4.11 (b), are calculated from the evaluation of the current steps, by measuring the difference between the reached current value and the baseline. For lactate we obtained a sensitivity of $77 \pm 26 \mu\text{A}/\text{mMcm}^2$ and a LOD of $4 \pm 1 \mu\text{M}$, while for glucose we obtained a sensitivity of $63 \pm 15 \mu\text{A}/\text{mMcm}^2$ and a LOD of $8 \pm 2 \mu\text{M}$, which fits with many clinical applications [250]. Many other metabolites of clinical interest (e.g., glutamate, ATP) can be monitored with the sensing platform, by changing the enzyme that is employed for the electrode functionalization.

Calibration of glucose and lactate at higher physiological concentrations will require the adoption of a system of membranes, as will be illustrated in the next chapter.

4.2.5 Drugs

The anti-cancer drug mitoxantrone was monitored to test the performance of the sensing platform in CV. CV has been found to be excellent for the determination of electroactive drugs in different biological fluids. Mitoxantrone, an anti-neoplastic agent for the treatment of secondary progressive sclerosis, can be oxidized at a working electrode, through an irreversible electrode process that gives two oxidation peaks in CV: at 500 mV and 700 mV (*vs.*

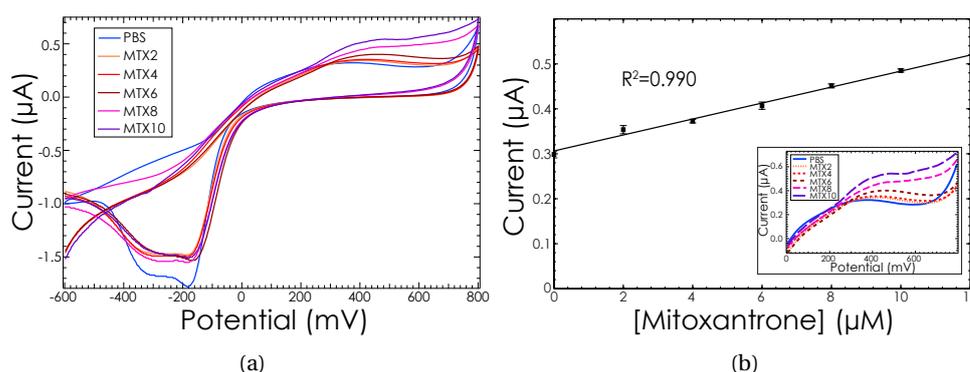

Figure 4.12 – Cyclic voltammograms of a bare 1.2 mm WE in PBS and in presence of increasing concentrations of mitoxantrone (MTX in the legend) (a). Calibration curve for mitoxantrone within the physiological range in PBS (b). Reprinted with permission from from Baj-Rossi, et al., IEEE Transaction on Biomedical Circuits and Systems, 8, 5, 636-647 (2014) [231].

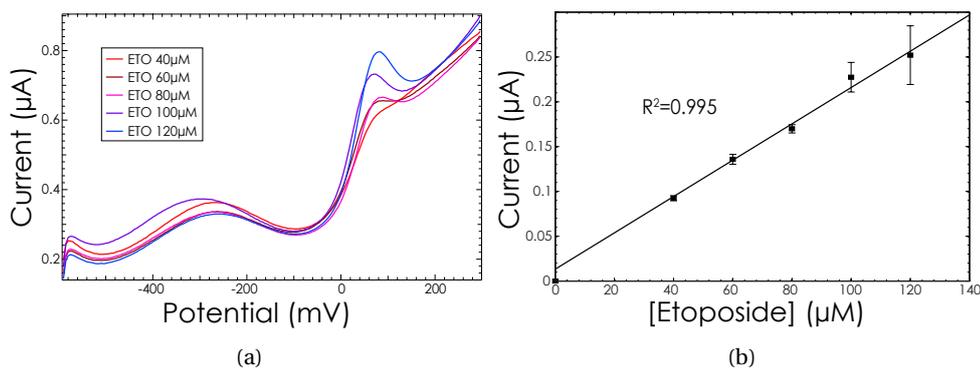

Figure 4.13 – Square wave voltammograms for a bare 1 mm WE, in presence of increasing concentrations of etoposide (ETO in the legend), (a). Calibration curve for etoposide within the physiological range in PBS (b).

Ag|AgCl] [251]. Fig. 4.12 (a), shows the cyclic voltammograms of a bare 1.2 mm WE in PBS, and in presence of increasing concentrations of mitoxantrone. According to the literature, the voltammograms show a well-defined oxidation peak at 400 mV (*vs.* Pt), while the other oxidation peak at 200 mV (*vs.* Pt) is not visible at such low concentrations. Fig. 4.12 (b) shows the dependence of the peak current on mitoxantrone concentrations. The y-axis values are the oxidation current peaks centered at 400 mV. The inset in Fig. 4.12 (b) shows the linear increase in current of the oxidation peaks. From the linear range of the calibration curve for mitoxantrone we obtained a sensitivity of $392 \pm 72 \mu A / mM \cdot cm^2$ and a LOD of $1.8 \pm 0.3 \mu M$, which is compatible with the physiological range ($1.8\text{--}3.3 \mu M$). Similar curves were obtained also for etoposide (data not showed).

To investigate other techniques, SWV was employed to calibrate bare electrodes for the detection of the drug etoposide, an anti-cancer drug, normally used in combination with other chemotherapeutic agents in the treatment of refractory testicular tumors and as first line treatment in patients with small cell lung cancer. Fig. 4.13 (a), shows the square-wave voltammograms of a bare 1 mm WE in presence of increasing concentrations of etoposide. The voltammograms show well-defined oxidation peaks at 150 mV (*vs.* Pt). Fig. 4.13 (b) shows the linear dependence of the peak current on etoposide concentrations. From the linear range of the calibration curve we obtained a sensitivity of $258 \pm 45 \mu A / mM \cdot cm^2$ and a LOD of $21 \pm 10 \mu M$, which is compatible with the physiological range ($34\text{--}102 \mu M$ [230]).

CA was also employed to calibrate bare electrodes for the detection of the drugs etoposide and acetaminophen. Acetaminophen is a widely used over-the-counter analgesic and antipyretic drug. It is known from literature that acetaminophen is an electro-active compound that in voltammetry shows an oxidative peak at around 470 mV (*vs.* Ag|AgCl).

The CA measurements at +450 mV for etoposide and at +650 mV for acetaminophen, are reported in the insets of Fig. 4.14(a) and Fig. 4.14 (b), respectively. The arrows correspond to repeated injections of etoposide $30 \mu M$ or acetaminophen $50 \mu M$. Well-defined current steps are visible every further injection. The calibration lines are calculated from the evaluation

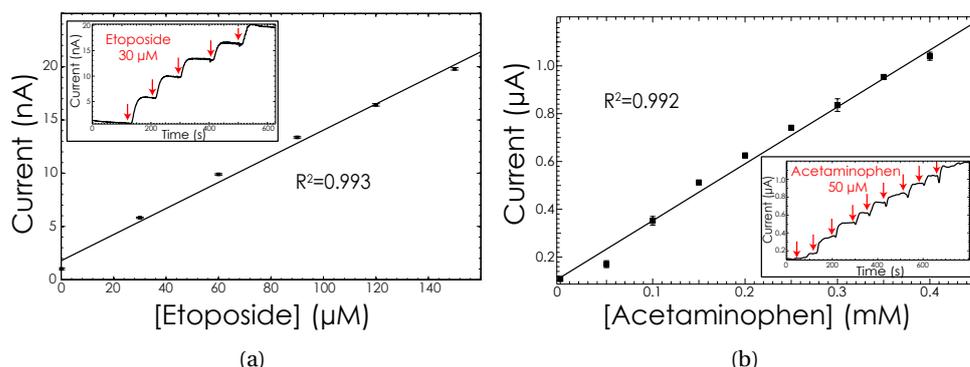

Figure 4.14 – Calibration curve from CA at +450 mV and at +650mV, for detection of etoposide (a), and acetaminophen (b), respectively. For etoposide detection we used a $500\ \mu\text{m}$ WE, for acetaminophen a 1 mm WE. The insets show the variation of the current *vs.* time, after injections of increasing drug concentration.

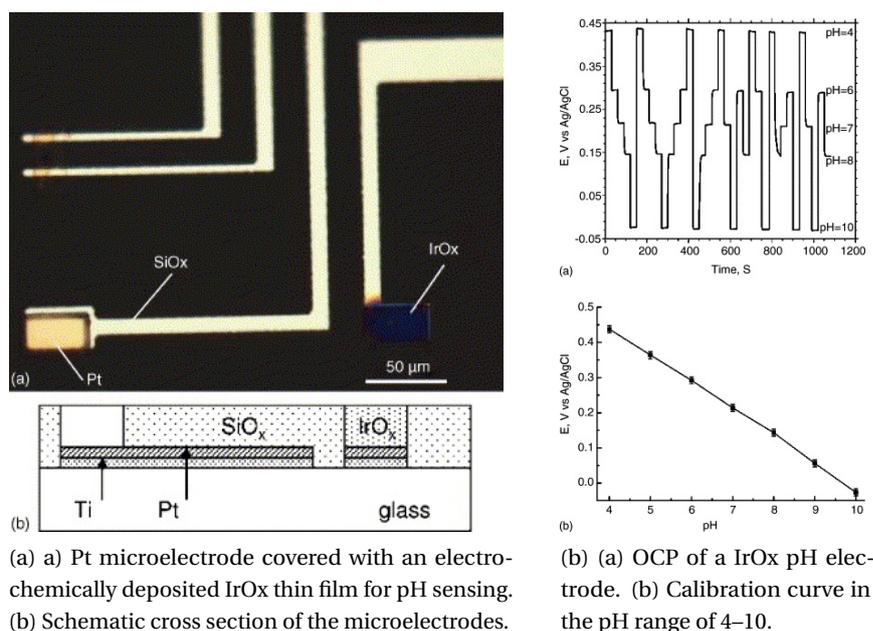

of the current steps, by measuring the difference between the reached current value and the baseline. For etoposide, we obtained a sensitivity of $58 \pm 5\ \mu\text{A}/\text{mM} \cdot \text{cm}^2$ and a LOD of $17 \pm 4\ \mu\text{M}$, which is compatible with the physiological range ($34\text{-}102\ \mu\text{M}$ [230]). We measured acetaminophen in both the human physiological range ($0.05\text{-}0.2\ \text{mM}$ [252]), and in the mice physiological range ($0.3\text{-}1.6\ \text{mM}$ [253]). As presented in the next chapters, we decided to measure acetaminophen in experiments with mice. For acetaminophen at higher concentrations, we obtained a sensitivity of $171 \pm 15\ \mu\text{A}/\text{mM} \cdot \text{cm}^2$ and a LOD of $0.26 \pm 0.12\ \text{mM}$, which is compatible with the physiological range in mice ($0.3\text{-}1.6\ \text{mM}$ [253]). For the lower concentration range, we obtained a sensitivity of $269 \pm 32\ \mu\text{A}/\text{mM} \cdot \text{cm}^2$ and a LOD of $0.034 \pm 0.014\ \text{mM}$, which is compatible with the physiological range in humans ($0.05\text{-}0.2\ \text{mM}$ [252]).

These results prove that the sensing platform is capable to monitor drugs and metabolites within their therapeutic ranges.

4.2.6 The pH sensor

In-vivo pH measurements are of considerable clinical interest, since at the microscopic scale, local pH drastically affects the vital activities of cells and cellular organelles. Enzyme activities depend on pH as well. Moreover, according to Nernst equation, changing the pH of the solution would alter the concentration of one of the species involved in the reaction and result in a shift in the redox potential [254]. Thus it is fundamental to monitor pH in case of enzymatic amperometric biosensors.

To achieve small sizes and robust design of a pH sensor that could be integrated in a small implantable device, several technologies have been proposed including *ion-sensitive field-effect transistor* (iSFET) pH sensors [255], hydrogel film pH sensors [256], optical fiber pH sensors [257], and solid-state metal pH sensors [258, 259]. For *in-vivo* applications, iSFET sensors have power consumption concerns due to the FET operation requirements. Optical pH

Figure 4.15 – Example of electrochemical IrOx-based pH sensor, Reprinted with permission from [238].

sensors also have power consumption problems due to the use of light sources, while optical devices could be unsuitable for long-term implantations. Hydrogel film pH sensors have the limitation of a complex and expensive design and a fabrication process for polymer layer, with an usually slow electromechanical response [256]. Several solid-state metal oxides have been investigated as the pH sensing films, including PtO_2 , $IrOx$, RuO_2 , OsO_2 , Ta_2O_5 , RhO_2 , TiO_2 and SnO_2 [259]. RuO_2 , SnO_2 , and $IrOx$ have been proved more advantages in sensor performance compared to others [260]. However, RuO_2 and SnO_2 presented hysteresis and drift problems leading to unstable responses. As proved in many studies [261, 260, 238, 262], *iridium oxide* (IrOx) film has performed outstanding stability over wide pH ranges, rapid responses, less potential drift and high durability over wide time and temperature ranges. There are different fabrication methods of iridium oxide film including sputtering deposition [263], electrochemical deposition [238, 261, 264], thermal treatments [265, 266], and sol-gel [256] processes. The sputtering iridium oxide film deposition process produces uniform films with good quality, however, it is costly due to the fabrication costs and complexity [263]. Thermal treatments include thermal decomposition of an iridium salt [265], and thermal oxidation of an Iridium-carbon film [266]. These thermal processes require a high temperature ranging from 500 to 800 °C, thus creating cracking problems in the film. Moreover high temperatures also limit the materials and reagents used for the sensor fabrication. The sol-gel deposition is based on dip coating followed by heat treatment techniques, which could provide a simpler and economical fabrication approach [259]. Anodic iridium oxide thin film deposition is based on the electrolysis of a solution containing iridium complexes and represents one of the easiest and cheapest techniques for IrOx thin film fabrication.

These solid-state metal pH sensors are all potentiometric sensors that consist of two electrodes: one of them is fabricated from an inert metal and is used as a reference electrode (usually made from $Ag|AgCl$), while the other electrode has the pH-sensitive layer deposited onto it. When the sensor is in contact with a test solution, metal oxides adsorb hydrogen ions at the surface sites, changing the valency of the oxygen atom. As a result, a potential difference is generated between the two electrodes, called *open circuit potential* (OCP). OCP magnitude is proportional to the pH of the solution. Fig. 4.15 shows a pH sensor based on an anodic IrOx film. The main issue of potentiometric metal oxide pH sensors is the potential drift, resulting in poor accuracy and need of frequent calibration [267].

In our sensing platform we decided to fabricate an anodic IrOx thin film for pH sensing. For an optimal galvanostatic deposition, we placed in the beaker containing the IrOx solution, an external screen printed electrode with a WE in Pt, which was used as CE for the deposition. The external CE was placed parallel to the WE of our platform, in order to have a current density constant all over the surface of the WE. For the galvanostatic deposition, the optimized parameter for our electrode were a constant current of $0.9375 \mu A$ for 500 s. Fig. 4.16, (a), shows the microscope image of Pt WE coated with a electrochemically deposited IrOx thin film for pH sensing. The image is in white/black, otherwise we could observe the pale blue color of the IrOx film, as in Fig. 4.15 (a).

In order to characterize the IrOx electrodes we performed calibration experiments in PBS by changing the pH. An external reference electrode double junction in $Ag|AgCl$ was used to obtain stable and reproducible measurements. The OCP of an IrOx film changes in a predictable manner according to the solution pH. Fig.4.16 (b) shows the calibration of the pH sensor in the pH range from 5 to 9. The pH of the buffer solution was continuously controlled with an external pH meter and we measured the corresponding OCP for the forward scan (pH from 5 to 9) and for the backward scan (pH from 9 to 5). The inset of Fig.4.16 (b) reports the OCP measurements *vs.* time. In the considered range, the potential changes linearly with increasing pH, with a sensitivity of of -74 ± 3 mV/pH for the forward scan, and -75 ± 5 mV/pH for the backward scan. These sensitivity values are quite close to the values reported in [238, 268, 264], showing a near super-Nernstian response. The response of anhydrous IrO_2 films to pH, can be explained with one of the two following equations:

and the redox potential is determined by

$$E = E^0 - 2.303 \frac{RT}{F} pH = E^0 - 0.05916 \cdot pH \quad (4.3)$$

where E^0 is the standard electrode potential with a value of 926 mV for the SHE or 577 mV for a $Ag|AgCl$ reference electrode. RT/F is equal to 25.688 at $25^\circ C$. Thus, the response of the sensor to pH, changes with a slope of approximately -59 mV/pH (Nernstian response) [259]. Hydrated iridium oxide films exhibit super-Nernstian responses, described by the mechanism

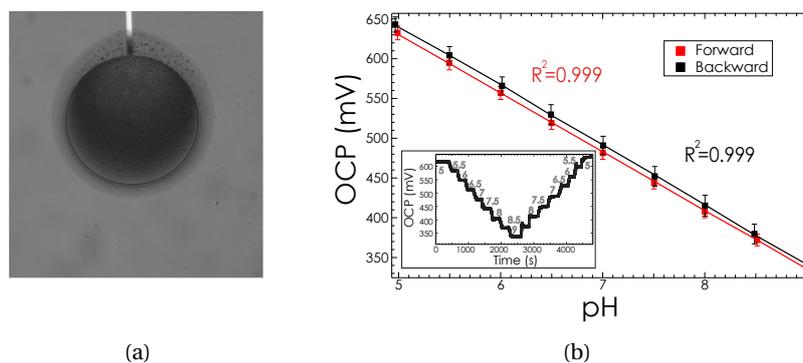

Figure 4.16 – Microphotograph of the WE with the IrOx film (a). OCP of the IrOx coated electrode to different pH. Error bars correspond to the standard deviation for 9 different measurements (confidence interval 95.4%). Reprinted with permission from from Baj-Rossi, C., et al., In Engineering in Medicine and Biology Society (EMBC), 2014 36th Annual International Conference of the IEEE (pp. 2020-2023) [249].

of one transferred electron per $1.5H^+$ ion, resulting in a slope of approximately -90 mV/pH:

Our IrOx film shows near-super-Nernstian response, thus suggesting the prevalence of a hydrated form of iridium oxides [238, 268, 264].

Despite the promising results, we faced some issues with IrOx-based pH sensors. First of all, in different experiments we observed a difference in the open circuit potentials at the same pH level. This phenomenon is called hysteresis, and may be due to different factors, as different oxidation states and the degree of hydration on the film surfaces, which may establish a new equilibrium of ions at different times of testing. Hysteresis commonly exists in IrOx-based pH sensors, and other metal oxide pH-sensing films [259]. In the inset in Fig. 4.16 (b), the hysteresis could be identified by comparing the potentials at the same pH levels. The differences were in the range 3-10 mV. The potential drift phenomenon is common in ion selective pH sensors and the 3–10 mV drift is considered small [269].

However, we obtained more differences in the potential level (at the same pH level), between different electrodes. We obtained differences in the range of 10-150 mV, even if the sensitivity was always similar, close to -75 mV/pH. A more accurate study on the deposition process and its variables could in the future explain these differences among different electrodes.

The last issue is the use of an external RE that is a limit if the goal is to produce a miniaturized implantable sensor. The Pt pseudo-RE was discarded as it showed important instabilities in potential. It is known that the sensing performance of currently available solid-state pH sensors is not as reproducible or stable as the conventional system with internal filling solution, due to imperfect solid-state REs [260]. A reported in literature, most of the thin films Ag|AgCl electrodes, fabricated with electrochemical deposition, typically show large potential drift in long term stability studies, and dissolution of AgCl into the solution. One of the best plain

Ag|AgCl thin films REs, without semi-permeable membrane, achieved stable potentials only over 7 h, in KCl 3M [270]. A promising approach is the employment of a nanoporous Pt with polyelectrolyte (PE) junction, as RE for pH-sensor [260].

4.2.7 The temperature sensor

There are a number of ways to measure temperatures microscopically, including infrared thermography, liquid crystal thermography, thermistors, resistive temperature device, and thermocouples, and many others [271]. Among the devices that can be miniaturized to be integrated in a sensing platform, thermistors, resistive temperature device, and thermocouples guarantee the best sensing performances and the most economic fabrication processes.

Thermistors consist of a semiconductor whose resistance is sensitive to temperature. Modern thermistors are usually mixtures of oxides of nickel, manganese, iron, copper, cobalt, magnesium, titanium, other metals, and doped ceramics. They are manufactured by sinterization of particles in controlled atmospheres. Thermocouples consist of two different conductors connected together to form a circuit. When a temperature difference is created between their junctions, a small current flows around the circuit, proportional to the difference in temperature. A basic thermocouple consists of two metallic wires, such as copper and iron, which are soldered together at one end and connected to a voltmeter at their other ends. Advances in microfabrication techniques have allowed for the development of thin film thermocouples [272]. A RTD works by measuring the resistance of a conductive material whose resistance changes predictably as a function of the temperature. The resistance of a conductor is related to its temperature because the motion of free electrons and of atomic lattice vibrations is also temperature dependent. Copper, gold, nickel, platinum, and silver are the most widely used materials. The resistivity of platinum is six times that of copper, it is relatively unreactive and because it has a well-established temperature coefficient of resistance it is a common

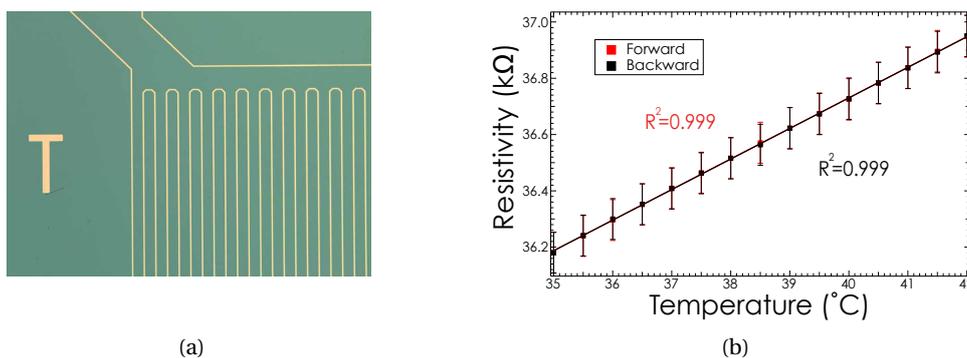

Figure 4.17 – (a) Microphotograph of the RTD in Pt. (b) Calibration curve for the temperature sensor. Error bars correspond to the standard deviation for 9 different measurements (confidence interval 95.4%). Reprinted with permission from from Baj-Rossi, et al., IEEE Transaction on Biomedical Circuits and Systems, 8, 5, 636-647 (2014) [231].

choice for temperatures between -260 and 962 °C [271]. RTDs can be highly accurate and are also widely used in industrial applications [273]. RTD is best suited for lower temperature applications, when high linearity is needed, and its fabrication can be easily implemented within the microfabrication process of an electrochemical platform.

The RTD integrated in our platform consists of a Pt wire of 4 nm width and 93 mm length, with an average resistivity of 34 kΩ at 20°C. Pt is commonly used in the production of resistive thermal devices and it was chosen because, among other metals employed in RTDs such as Cu and Ni, Pt represents the best trade-off between linear behavior, biocompatibility, and higher metal resistivity, which allowed reducing the sensor sizes [271]. Moreover Pt was already used for the realization of the other electrodes. Fig. 4.17 shows the response of the Pt-RTD upon different temperatures in PBS. The temperature was first increased from 35°C to 42°C (forward scan) and then was inversely changed (backward scan). The Pt-RTD shows a linear behavior in the physiological temperature range with an average sensitivity of $0.108 \pm 0.001 \text{ k}\Omega/\text{°C}$, which is comparable with the theoretical value of $0.13 \text{ k}\Omega/\text{°C}$ (that can be calculated from the temperature coefficient of resistivity for Pt, $\alpha = 0.003729\text{°C}^{-1}$ at 20°C). High error bars are due to the low accuracy of the instrument used to measure the resistivity.

4.3 Summary

The sensing platform was designed and realized considering biocompatibility, performances and the constraints given by the integration with the electronics and by the final application. Carbon-nanotubes are integrated on WEs to improve the sensitivity and the chitosan is employed to entrap them on the electrode surface, providing a biocompatible coating.

With various functionalization of the WEs, we performed calibration of glucose and lactate, and of different drugs: acetaminophen, etoposide, and mitoxantrone.

We also showed the realization and the performances of a pH sensor and a temperature sensor. In conclusion, so far, the complete integration of a pH and a temperature sensor within an amperometric multi-panel platform that monitors glucose and drugs, still represents a complete novelty.

5 Membrane and packaging

The key aspect for an implantable biosensor is the assessment of the biocompatibility and the biostability. The implant must be well tolerated by the host, in terms of both the materials and the shape of the device, in order to reduce the consequences of the foreign body reaction and to achieve a proper integration with the surrounding tissue. The sensor electronics must be protected by the corrosive action of body fluids and finally strategies to preserve the sensor functionality must be adopted. The biocompatibility and biostability can be promoted by the design of an effective membrane system and of a proper external packaging.

Other important aspects that should not be neglected are the constraints that come from the integration of the sensing platform, presented in the previous chapter, with the custom-made electronics that enables an autonomous powering and actuation of the device. The biosensors must produce currents that fit the range established by the electronic system that read-out and activate the sensors. The minimum current step detectable by our integrated electronic is 12.5 nA and the circuit saturates at a current of 2 μ A. Another limitation is the technique available for the electrode functionalization: only a fixed potential of 650 mV can be applied to the sensor with the customized ICs, thus electrodeposition of MWCNTs in chitosan or the deposition of electropolymerized films are not feasible for the realization of our implantable device, as 650 mV is often not enough to trigger the polymerization in many electropolymers [246, 170]. Furthermore, we want to implant the device in the peritoneum of mice and monitor for 30 days glucose and drugs in the physiological range, which is for glucose equal to 6-9 mM for normal mice, and 12-15 mM for diabetic mice [274]. Finally, the sensors must selectively detect glucose even in the presence of interfering compounds from the biological fluid the device is in contact with, that might affect the sensor functionality.

In this chapter we first show the *in-vitro* characterization of the membranes used to filter the interfering substances, such as ascorbic acid and uric acid, and a characterization only of the outer biocompatible membrane in polyurethane. Then we show the *in-vitro* characterization of the complete system of membranes for detection of glucose and the drug acetaminophen. A long-term study of 30 and 50 days is presented to prove the stability of the sensor. The last section of this chapter is dedicated to the assembly, packaging and *in-vivo* biocompatibility tests obtained by implanting the device in mice for 30 days.

5.1 Membrane

5.1.1 Methods

For the electrode functionalization with MWCNTs, we employed the direct drop-cast of MWCNTs dissolved in chloroform, and a covering in MWCNT/chitosan. The procedure is reported in Methods of the previous chapter. *Glucose oxidase* (GOx) from *Aspergillus Niger* was purchased from Roche in lyophilizate powder and dissolved in PBS (1X, pH 7.4). Bovine serum albumine and *D*-(+)-glucose were purchased from Sigma-Aldrich (Switzerland) in powder and dissolved in in PBS, pH 7.4. For the glucose detection, 2 μ l of a solution 15 mg/ml of GOx were dropped on the nano-structured WEs. Electrodes were stored overnight at 4 °C.

Acetaminophen, etoposide, ascorbic acid and uric acid were purchased as a powder from Sigma-Aldrich. Due to their low solubility in water, acetaminophen and ascorbic acid were dissolved in ethanol, while etoposide in DMSO. A H_3BO_3 buffer solution (0.02 M, pH 9.0 at 25 °C), was employed to prepare 3.57 mM UA stock solution. Solutions of ascorbic acid, uric acid and acetaminophen were freshly prepared before each measurement. All the dilutions were carried out in a PBS (1X, pH 7.4) solution. H_2O_2 was purchased from (Reactolab SA, Switzerland) and was diluted in DI water.

Cellulose acetate (CAc) (average Mn ~ 50,000) was purchased from Sigma Aldrich in powder. A solution 5% (w/v) was obtained by dissolving 500 mg of CAc in 50% ethanol and 50% acetone (5 ml each). The solution was stirred for 15' with a speed of 250 rpm, to obtain a homogeneous solution. The CAc membrane was transferred on the electrode by dip-coating: the lower part of the platform (where the sensors are located), was dipped into 5% CAc for 10" and was withdrawn slowly. It was then exposed to the vapor above the CAc solution for 5" and was dipped again into the solution for 10". The platform was removed and dried in air at room temperature for 1 min and then placed in deionized water for 6 h to permit the dissolution in water of entrapped solvent in the membrane pores [177]. A layer of Nafion 0.5 % or 5% was added by drop-casting of 1 μ l of Nafion solution on the top of the cellulose acetate membrane, and then dried for 10' in air at room temperature [176, 178]. After this step, the enzyme layer was deposited, first by drop-casting the solution of MWCNTs (first of a chloroform/MWCNT solution 1m/ml and then of a chitosan/MWCNT solution 8 mg/ml), and the solution of GOx (15 mg/ml). Before drying the enzyme, a 1 μ l drop of glutaraldehyde (from Sigma-Aldrich) 0.25% is added on the enzyme solution and left at room temperature for drying. For detection of acetaminophen, a layer of *bovine serum albumin* (BSA) was adsorbed on the CAc membrane, before the deposition of the outer membrane, to facilitate the diffusion of the drug to the electrode surface.

For the biocompatible outer membrane, a homogeneous solution was obtained by mixing 125 mg of an epoxy adhesive (EP42HT-2Med system), purchased by Master Bond (Hackensack, USA) as a certified biocompatible two-components adhesive, 112.5 mg of *Polyurethane* (PU, Sigma Aldrich), 12.5 mg of the surfactant agent Polyethylene glycol ether (Brij[®] 30, Sigma Aldrich), for 10 ml of Tetrahydrofuran (Sigma Aldrich) used as solvent [153].

The deposition method of the biocompatible membrane is known as dip coating and it con-

sists of a quick immersion of the sensor in the membrane solution. Subsequent depositions were applied at 1 h intervals and then the sensors were stored overnight at room temperature. A fast curing at high temperature (2 h at 80°C) is needed to ensure the biocompatibility of the resin. After this process the sensors were again kept overnight at room temperature, and then stored in PBS one day for membrane swelling.

All experiments were carried out in PBS 1X, pH 7.4, as supporting electrolyte. For measurements in biological fluids, human serum from human male AB plasma, USA origin, sterile-filtered was purchased from Sigma Aldrich. It was kept at 37°C until use. Electrochemical measurements were performed using an Autolab electrochemical workstation (Metrohm, Switzerland). Electrodes were tested for glucose and acetaminophen sensitivity in chronoamperometry at +650 mV. The sensors were first conditioned for 1 h at +650 mV and then tested against repeated injections of glucose or acetaminophen.

5.1.2 Need for membranes

Fig. 5.1 (a) shows the calibration in chronoamperometry for glucose in the physiological mice concentration (6-9 mM). The calibration presents a quite linear response upon glucose injection, but with a clear saturation after a concentration of 8-9 mM. From the regression analysis of the calibration line we obtained a sensitivity of $47 \pm 2 \mu\text{A}/\text{mM cm}^2$ and a LOD of $0.6 \pm 0.1 \text{ mM}$. As the device will be employed for *in-vivo* measurements in mice, an analysis of the selectivity for glucose over interfering species during characterization is therefore necessary. Indeed, a significant number of interfering substances (*e.g.* ascorbic acid, uric acid, and acetaminophen) can affect the sensor response as they are electroactive at the electrode potential used to oxidize hydrogen peroxide (in the window range of 200-650 mV). Fig. 5.1 (b) shows how relevant the interference of uric acid, ascorbic acid and acetaminophen is, in comparison with the current signal obtained upon the injection of glucose 1 mM, on a GOx-MWCNT-modified electrode. The current signal due to the interfering substances is higher than the current step due to glucose addition. In all measurements presented in this

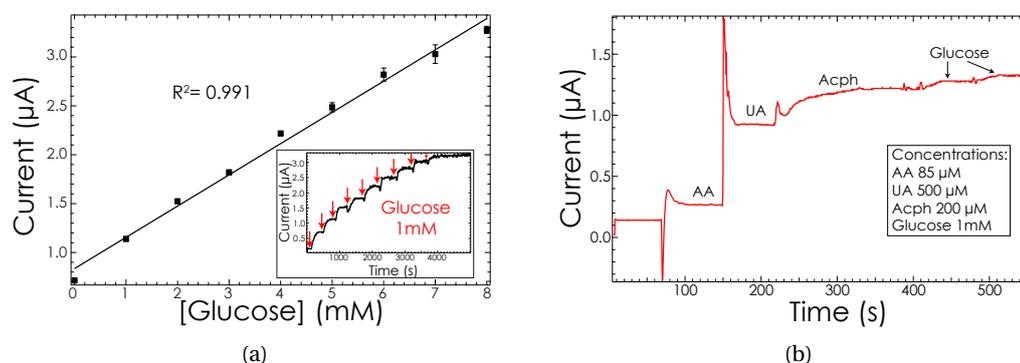

Figure 5.1 – Chronoamperometry at 650 mV on a MWCNT-GOx-modified electrode (1 mm WE): at increasing glucose concentrations (a), and in presence of interfering substances (b).

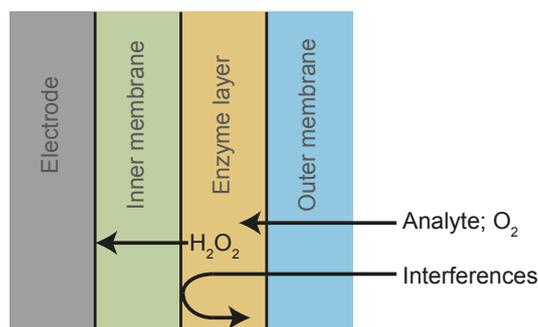

Figure 5.2 – Schematic of the sensor membranes.

study, we tested the interference of ascorbic acid and uric acid at their maximum physiological concentrations: $85 \mu\text{M}$ and $500 \mu\text{M}$ for ascorbic acid and uric acid, respectively [44]. The drug acetaminophen is not considered an interfering substance in mice, unless it is administered on purpose to mice in some pharmacological or toxicological studies [275, 276]. For our purposes, we needed to meet the following requirements: filtering the interference from ascorbic acid and uric acid; reducing the current steps upon glucose injection, to fit the current range (from 12.5 nA to $2 \mu\text{A}$) imposed by the specifications of the IC that will be used with the sensing device in the implantable version; extending the linear range of the glucose sensor up to 15 mM , or up to 30 mM in case of glucose monitoring in humans.

What we need is a system of membranes as illustrated in Fig. 5.2: a permselective layer (the "inner membrane" in Fig. 5.2) is normally used to eliminate interferences such as uric acid and ascorbic acid, which defines the selectivity of the sensor. An intermediate enzyme layer is used to specifically detect glucose. Finally, the electrode should be coated with an outer layer (the "outer membrane" in Fig. 5.2) that controls the glucose and oxygen fluxes and that provides at the same time a biocompatible interface, necessary for any implantable devices [163, 177, 178].

In this study, a double layer membrane made by cellulose acetate and Nafion 5% is employed to retard interferences like ascorbic acid and uric acid. Glutaraldehyde is used as cross-linker to improve the immobilization of the enzyme GOx on a layer of drop-casted MWCNTs. Finally, an epoxy-enhanced polyurethane outer layer is applied to control glucose and oxygen fluxes in order to optimize the linearity of the sensor response, and also to provide a biocompatible interface with the surrounding environment. In the next sections we will first show the characterization of the inner permselective membrane, then we will show an innovative epoxy-enhanced polyurethane membrane, and finally we will present the combination of the inner and outer membrane for the selective detection of glucose in physiological ranges for mice.

5.1.3 Permselective membrane

The simplest strategy to eliminate the problem of oxidizable substances as ascorbic acid and uric acid, which can interfere with the detection of H_2O_2 produced by the reaction between

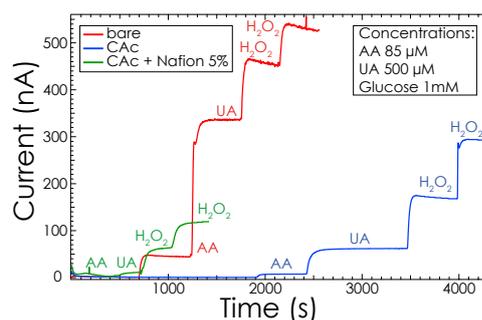

Figure 5.3 – Comparison in chronoamperometry at 650 mV, between a bare electrode, an electrode with the CAC membrane and an electrode with a CAC/Nafion (5%) membrane, towards the screening of the interferents, acetaminophen, and etoposide, and in presence of H_2O_2 .

the GOx and glucose, is the use of a permselective membrane [44]. In some cases, such membranes also protect the surface from biofouling, by excluding surface-active macromolecules (*i.e.*, proteins and platelets).

The range of polymeric materials that have been evaluated as effective permselective membranes includes CAC, Nafion, and electropolymerized films. Electropolymerized films are an attractive choice, because they offer the possibility to carefully control the deposition even on complex electrode shapes and on very small electrodes. Previous studies proved that these films present low stability in the permselectivity property with repeated use [170, 44]. We could not select electropolymerized films as we can only apply to the electrode (in the implantable version), a fixed potential of 650 mV, which is often not enough to trigger the polymerization in many electropolymers [246, 170].

Other common coatings based on size exclusion include plasma-polymerized films [173], and CAC membranes [174]. Polymeric films that repel the interferents based on electrostatic repulsion are mainly made in Nafion, which is a negatively-charged perfluorinated ionomer able to effectively repel the negatively-charged ascorbic acid and uric acid [175]. Nafion is also commonly used as anti-fouling layer [44]. Multilayers have been used to combine the properties of different films with different anti-interference properties. For example, alternate deposition of Nafion and CAC has been used to eliminate the interference of neutral acetaminophen and the negatively-charged ascorbic and uric acids [176, 177, 178]. Permselective membrane is a fast and effective method to block interfering substances, but also simple to prepare, as the membrane is normally dispersed over the electrode surface by dipping or spin coating. The main drawback is the difficulty in controlling the membrane thickness. As the dip-coating fits our requirements, we selected a combination of CAC and Nafion as permselective inner membrane.

We performed an initial membrane characterization on the inner membrane layer, with a bare electrode, in presence of H_2O_2 . Fig. 5.3 shows the comparison in chronoamperometry at 650 mV (with a 500 μm diameter electrode), between a bare electrode, an electrode with the CAC membrane and an electrode with a CAC/Nafion 5% membrane, towards the screening of the

interferents, and in presence of H_2O_2 . The CAC/Nafion 5% membrane resulted in excellent permselectivity, with respect to the bare electrode but also with respect to the use of the CAC membrane alone. With the CAC/Nafion 5% membrane, the interference from ascorbic acid is completely eliminated and from uric acid is drastically reduced. Acetaminophen gives a significant response with respect to the hydrogen peroxide. If this membrane system is used for glucose monitoring in humans, another method to filter the interference of Acetaminophen is necessary, *e.g.* the employment of an electropolymerized film [170] or the employment of a second working electrode for the differential subtraction of the interference [277]. As expected, the addition of the CAC membrane and later of the Nafion layer results in a significant reduction of the current response.

Fig. 5.4 shows the performance of the permselective membrane in presence of the enzyme layer of GOx, in chronoamperometry at 650 mV, in presence of increasing glucose concentrations. MWCNTs and GOx were immobilized on the top of the permselective membrane made by CAC and Nafion. In implantable biosensors, the enzyme activity begins to decrease immediately due to polymer entrapment, or to the exposure to acid fluids, hydrogen peroxide and other reactive radicals, during the foreign body reaction process. Several effective immobilization strategies to ensure enzyme stability have been investigated so far: cross-linking of the enzyme with glutaraldehyde, enzyme entrapment within polymeric matrices (*e.g.*, hydrogels), and incorporation of the enzyme into electropolymerized conducting polymers such as polypyrrole [186]. Nevertheless, the enzyme suffers of an inherent loss of activity, primarily due to the loss of noncovalently bonded FAD cofactor [187]. In our sensors, glutaraldehyde was employed on the GOx, as many studies showed that glutaraldehyde plays an important role in stabilizing the activity of the immobilized enzyme [177, 178, 278, 44]. Fig. 5.4 (a) also reports the comparison between the use of a layer of Nafion 0.5% and Nafion 5%. From the analysis of the permselective ability of the membrane (the zoom reported in Fig. 5.4 (b)), we can conclude that a high Nafion concentration (5% instead of 0.5%) is necessary for a complete filtering of uric acid and ascorbic acid. We also tested the ability of the membrane to filter the presence of another drug, etoposide: Fig. 5.4 (b) shows that etoposide does not give any response with the CAC/Nafion 5% membrane.

A lower Nafion concentration (0.5%) mitigates the saturation of the response upon glucose injection, but it is less efficient in screening the interfering substances, as clearly shown in Fig. 5.4 (b). With Nafion 5% the current response upon glucose injection is significantly higher, but it saturates after the second injection of glucose 1 mM. As previously stated (chapter II), the electrochemical detection of hydrogen peroxide requires oxygen as a cofactor in the oxidase enzymatic reaction. However in interstitial fluids there is an "oxygen deficit", as the concentration of oxygen is at least 10 times lower than the concentration of glucose, thus making oxygen the rate-limiting substrate. And this is also the reason of the low linearity of the sensor response upon glucose addition. This oxygen deficiency is mitigated by using polymeric outer diffusion controlled membranes, including polyurethane [153], Nafion [160], chitosan [160], silicone elastomer [161], polycarbonate [162], silicone [163], and layer-by-layer assembled polyelectrolytes [164]. From the sensor response to glucose reported in Fig. 5.4 it is reasonable to assume that the enzyme quickly saturates due to the lack of oxygen, thus

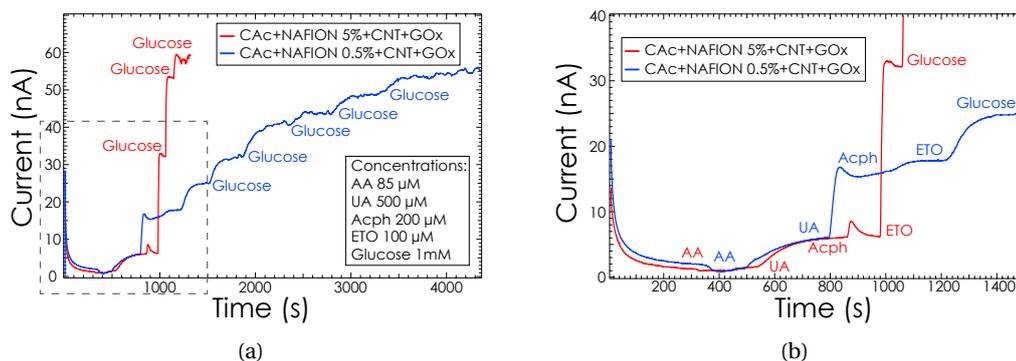

Figure 5.4 – Comparison in chronoamperometry (650 mV) between the use of a layer of Nafion 0.5% and Nafion 5% with a CAC-membrane modified MWCNT/GOx electrode, in presence of glucose and in presence of interfering substances (a). Zoom (in the region of (a) delimited by the dashed square) on the signal generated by the interfering substances (b).

resulting in an extreme non-linearity in the sensor response. With an outer membrane, the income of glucose to the enzyme layer is limited, but the enzyme layer is thin enough that the hydrogen peroxide produced from the reaction between GOx and glucose, can be efficiently re-converted to oxygen at the electrode surface. This effect due to the reduced thickness of the films results in both a rapid sensor response and an extended linear range. The presence of the outer membrane is essential for *in-vivo* measurements because of its ability to extend the linear range of the sensor, while excluding other oxidizable interfering substances at the electrodes and providing a biocompatible coverage.

The next section will focus on the characterization of the outer membrane made by an epoxy-enhanced polyurethane alone, while in the subsequent section we will show the combination of the perm-selective and the outer membrane.

5.1.4 Outer membrane: epoxy-enhanced polyurethane membrane

In the first part of this section, we present a study on the outer membrane, from the point of view of the evaluation of the influence of the membrane on the activity on the enzyme, that will be reflected on the sensitivity of the sensor. In the second part, the characterization of the complete system of membrane is presented, with a study on the beneficial effects of the outer membrane for oxygen-control and extension of the linear range.

In-vitro characterization of the epoxy-enhanced polyurethane membrane

In-vitro characterization of the epoxy-enhanced polyurethane membrane was initially performed on carbon-paste SPEs, in order to assess the optimized number of membrane layers and to understand the membrane effect on the enzyme activity. After the functionalization with MWCNTs and GOx, electrodes were covered with 1-2-3 layers of the membrane, and

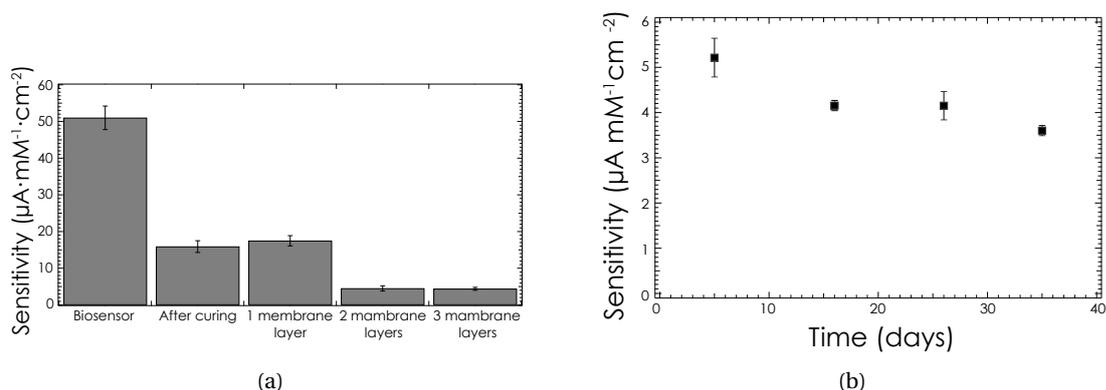

Figure 5.5 – Heat and membrane thickness effects on the sensor sensitivity (Error bars: standard error of three different SPE-based biosensors) (a). Long term stability of a biosensor coated by 2 membrane layers (Error bars: standard error of two measurements on each day) (b). Reprinted with permission from C. Baj-Rossi, et al., *Biomedical Circuits and Systems*, IEEE Transactions on, 8(5): 636–647, 2014 [231].

finally tested for glucose sensitivity with CAC at +650 mV, with injections of glucose 50 μM . Fig. 5.5 (a) reports the effect of the curing temperature (2 h at 80°C) and membrane thickness on the sensor sensitivity. The high temperature effect on biosensors without any membrane was investigated, showing a decrease in sensitivity probably due to a partial enzyme denaturation. However LOD was lower after the curing ($18 \pm 1 \mu\text{M}$) compared to the case of a SPE-MWCNT/GOx biosensor ($73 \pm 8 \mu\text{M}$), due to a reduction of the standard deviation of the background signal (data not shown). The last columns in Fig. 5.5 (a) show that the deposition of one membrane layer does not significantly affect the sensor performances, probably due to a non-homogeneous coating. Two and three layers decrease the sensor sensitivity and increase the LOD ($90 \pm 23 \mu\text{M}$ and $72.0 \pm 0.7 \mu\text{M}$ respectively), but are the best trade-off between the decrease of sensitivity and a homogeneous cover. We also performed chronoamperometry with the microfabricated sensing platform. Working electrodes of 1.2 mm diameter, modified with MWCNTs in chitosan and GOx, were covered with 2-3 layers of the membrane. All the chips were tested for glucose sensitivity with chronoamperometry at +650 mV, and the sensitivity was then compared. Without any membrane we obtained a sensitivity of $63 \pm 15 \mu\text{A}/\text{mM}\cdot\text{cm}^2$ and a value for LOD of $8 \pm 2 \mu\text{M}$. With 2 layers of the membrane we obtained a lower sensitivity ($28 \pm 4 \mu\text{A}/\text{mM}\cdot\text{cm}^2$) but a value for LOD ($6 \pm 4 \mu\text{M}$), which does not statistically differ from the value obtained without membrane. Similarly to the SPE-based sensors, the addition of a third membrane layer does not significantly affect the sensor performances: with 3 layers we obtained a sensitivity of $29 \pm 1 \mu\text{A}/\text{mM}\cdot\text{cm}^2$ and a LOD of $7 \pm 4 \mu\text{M}$. The long term stability of the coated biosensor was evaluated in chronoamperometry for glucose sensitivity on SPEs for 40 days. The work in [279] reported a long term stability of 24 days using the same SPE and GOx immobilized by adsorption onto MWCNT-working electrode. Fig. 5.5 (b) shows that with two layers of epoxy enhanced polyurethane membrane the sensitivity slightly decreases with respect to time; the relative variation is equal to 28% after 35 days. The decrease of the

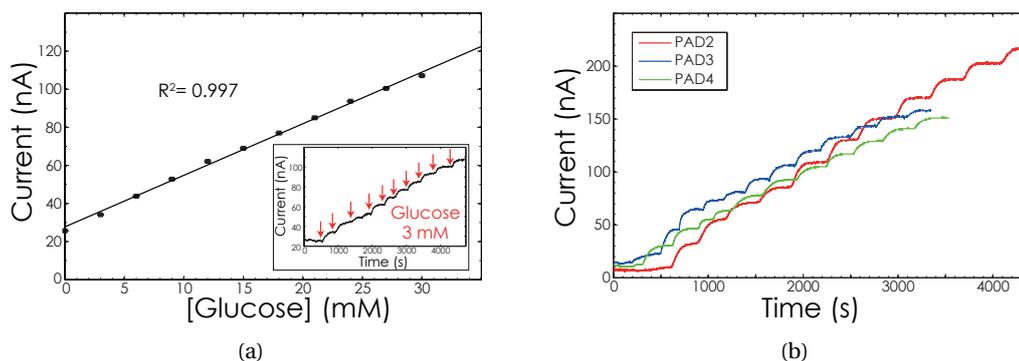

Figure 5.6 – Calibration in chronoamperometry (650 mV) with injections of glucose 3 mM obtained with electrodes with the complete membrane system: CAC/Nafion 5% membrane on a MWCNT/GOx 1 mm-electrode, with the outer epoxy-enhanced PU membrane, (a). Comparison between chronoamperometries at 650 mV, between three electrode pads, with the CAC/Nafion membrane, CNTs, GOx and the PU-epoxy membrane, in presence of the interfering substances and towards monitoring of glucose up to 30mM (b).

sensor sensitivity is mainly due to the partial degradation of the enzyme activity over the time, and it represents the major challenge in the development of a long-term implantable sensor. However, as reported in [188, 44], it is possible to take into account the decrease in sensitivity with a one-point or a two-points calibration method, thus increasing the sensor accuracy during long-time measurements.

***In-vitro* characterization of the complete system of membranes**

Fig. 5.6 (a), shows the calibration in chronoamperometry (650 mV) upon injection of 3 mM glucose obtained with electrodes with the complete membrane system: CAC/Nafion 5% membrane with the layer composed by MWCNT/GOx, with the outer epoxy-enhanced PU membrane. From the calibration reported in Fig. 5.6 (a), we obtained a sensitivity of $0.4 \pm 0.1 \mu\text{A}/\text{mM}\cdot\text{cm}^2$ and a LOD of $0.6 \pm 0.2 \text{ mM}$. The linear range was tested up to 42 mM of glucose (data not shown). As expected, by adding the outer polyurethane membrane, we obtained a vast linear range, quick sensor response, higher signal stability and an optimum filtering of the interfering substances: ascorbic acid is completely filtered (0%) and uric acid is detected as 2% of the current step related to the glucose injection (3mM), which are acceptable values for *in-vivo* applications [44]. Moreover, we obtained the same LOD as for glucose detection without any membrane ($0.6 \pm 0.1 \text{ mM}$), but with a wider linear range. We also obtained current steps and a current range compatible with the constraints given by the integration with the IC, for the implantable device (current steps bigger than 12.5 nA and a maximum current lower than $2 \mu\text{A}$).

The main problem that we encountered was that the inter-electrode reproducibility showed a non-ideal behavior: as shown in Fig. 5.6 (b), PAD 3 and 4 shows similar current steps, while PAD2 has higher current values. Nevertheless, in general we got similar sensitivities and LOD,

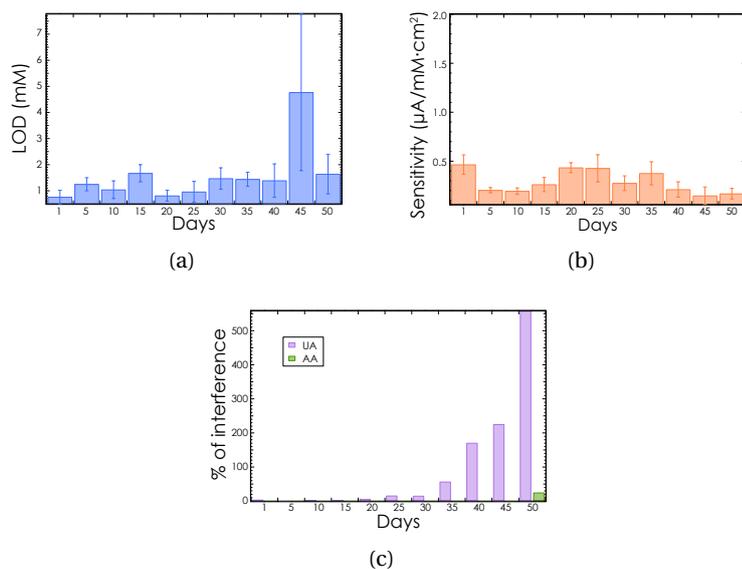

Figure 5.7 – Long term stability in 50 days of biosensors with the CAC/Nafion membrane, CNTs, GOx and the PU-epoxy membrane, towards the detection of glucose in the range 3-30 mM: LOD (a), sensitivity (b), and in presence of the interfering substances AA and UA, (c). The percentage in (c) are the error created by the interfering compounds with respect to the response to 3 mM glucose.

between the 6 different electrodes tested for this study. These inter-electrodes differences are probably due to low precision in the electrode functionalization with MWCNTs by drop-casting. In future studies, the precision of functionalization with MWCNTs can be improved by other techniques such as the direct growth on the electrode surface, and by increasing the size of the electrodes. However a method to account for the inter-electrode differences is to performed a one-point or two-point calibration with each sensor before and during *in-vivo* measurements.

Finally, we addressed the mostly important problem of the long-term stability of the biosensor. Many studies reported the performance of glucose sensor after storage in PBS at 4°C, and by measuring the response of the sensor to a single glucose concentration [280, 281]. In order to be coherent with real applications, we stored the enzyme electrode in pH 7.4, at 25°C instead of 4°C and measured its stability over 50 days by performing a complete calibration on the extended human physiological range (up to 30mM). A complete calibration instead of a single glucose measurement increases the stress for the enzyme, thus increasing the possibility of loosing enzyme activity, but it represents a more realistic experiment [282].

We repeated the calibration of sensors each 5 days, for 50 days, and we also tested the stability of the permselective membrane for the filtering of the interfering substances. Fig. 5.7 reports the results of 50-days stability study in terms of: (a) LOD (mM), (b) sensitivity ($\mu\text{M}/\text{mA}\cdot\text{cm}^2$), (c) % of the signal due to the interferents respect to the average current step obtained with addition of glucose 3 mM. Fig. 5.7 (a) shows an oscillation of the value of the LOD for the first

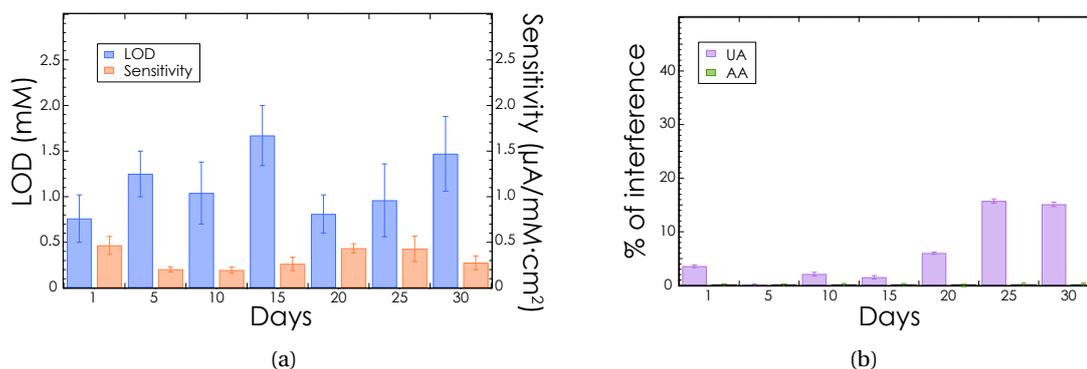

Figure 5.8 – Long term stability in 30 days of biosensors with the CAC/Nafion membrane, CNTs, GOx and the PU-epoxy membrane, towards the detection of glucose in the range 3-30 mM, (a), and in presence of the interfering substances AA and UA, (b). The percentage in (b) are the error created by the interfering compounds respect to the response to 3 mM glucose.

40 days and then the sensor stopped working properly, as resulted from the net increase in the LOD at day 45. The plot of the sensitivity (Fig. 5.7 (b)) confirm this oscillation. Fig. 5.7 (c) shows an optimal filtering of ascorbic acid and uric acid until 20 days. At 25 and 30 days uric acid gives an interference of about 15% respect to the response upon injection of glucose 3 mM. After 30 days the membrane starts loosing its functionality, as proved by the gradual increase of the interference from uric acid. Ascorbic acid is completely filtered until 45 days. It is important to note that the real function of a permselective membrane is to decrease the permeability of the interfering substance, and not to completely filter out the interference [170, 44, 280, 281]. From this study, we can conclude that after 30 days the enzyme activity starts decreasing and that the membranes starts loosing their functionality.

Fig.5.8 (a) reports the variation in LOD and sensitivity, and Fig.5.8 (b) the % of influence due to AA and UA respect to the average current step in 30 days. We observe a fluctuation in the value of LOD and sensitivity but the LOD falls in both human and mouse physiological range. This result is quite acceptable for in-vivo applications [44].

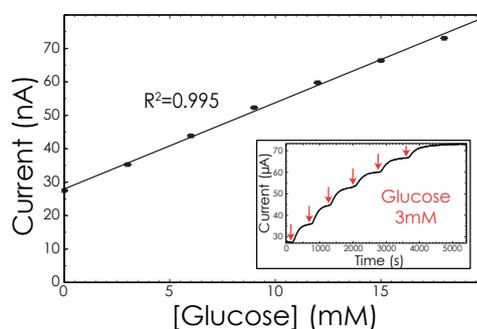

Figure 5.9 – Calibration of glucose (3-18 mM) in human serum at 37°C obtained with sensors with the complete system of membranes.

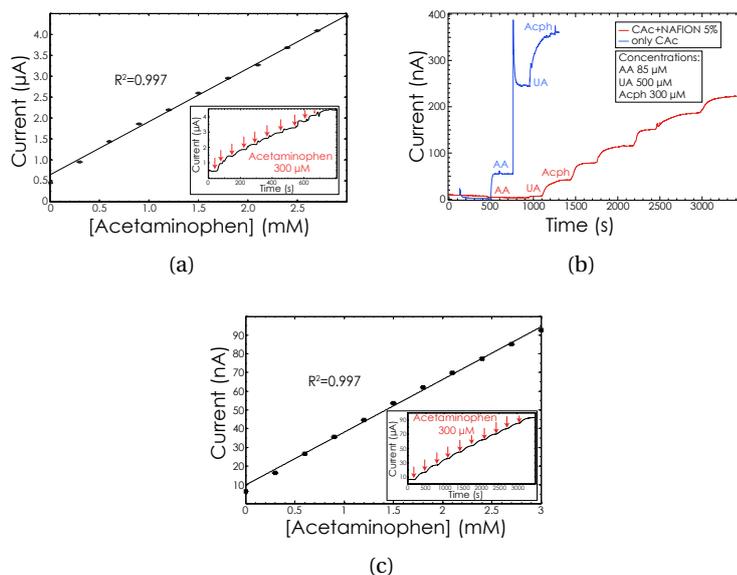

Figure 5.10 – Measurement of Acetaminophen with different systems: (a) with a 1 mm-diameter bare electrode; (b) comparison between an electrode with the CAc membrane only and the CAc/Nafion 5% system; (c) with the addition of BSA and the PU-epoxy membrane.

The biosensors were applied to detect the glucose concentration in human serum at 37°C. Fig. 5.9 shows the calibration curve and the plot of the current *vs.* time (in the inset). The average values of sensitivity and LOD obtained from three different biosensors were $0.42 \pm 0.02 \mu\text{A}/\text{mM}\cdot\text{cm}^2$ and $0.6 \pm 0.2 \text{ mM}$, respectively, which are very close to the values obtained for the first day in PBS: sensitivity of $0.4 \pm 0.1 \mu\text{A}/\text{mM}\cdot\text{cm}^2$ and LOD of $0.6 \pm 0.2 \text{ mM}$. The values in sensitivity and LOD obtained in human serum proved that our biosensors are capable of measuring glucose in human serum without losing sensitivity. The main differences are that the blank current value is higher in serum due to the presence of traces of glucose, and that the current steps are about 1 nA lower than the current steps registered in PBS.

It is thus concluded that the biosensors reported in this study were stable and reproducible enough for the determination of glucose in biological samples. Overall, high sensitivity, excellent selectivity, linearity and long-time stability exhibited by the biosensors presented in this study, make them good candidates for *in-vivo* detection of glucose.

Moreover, the results reported in Section 6.2.1 will show that the membrane system illustrated in this chapter perfectly fit with the limit imposed by the integrated circuits. The chronoamperometry of glucose measured with the custom-made integrated circuit does not statistically differ from the measurements obtained with the commercial potentiostat.

5.1.5 Monitoring Acetaminophen and glucose with the same sensing platform

We finally investigated the possibility to measure a drug, acetaminophen, and a metabolite, glucose, with the same sensing platform. Initially we performed measurement in chronoam-

5.2. Assembly and biocompatible packaging of the final device

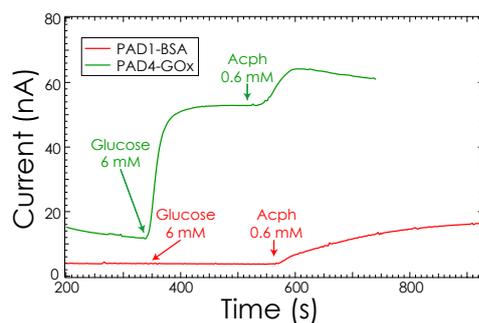

Figure 5.11 – Detection of glucose 6 mM and acetaminophen 0.6 mM added in the same sample. One electrode is functionalized with MWCNTs and GOx (PAD 4), to be specific toward glucose, while on the second electrode (PAD 1), BSA is immobilized. Both electrodes have the complete system of membranes.

perometry of acetaminophen with different systems, reported in Fig. 5.10: (a) with a 1 mm-diameter bare electrode; (b) an electrode with the CAC membrane only and the CAC/Nafion 5% membrane; (c) with BSA and the addition of the PU-epoxy membrane. Bare electrodes show the highest currents, with a sensitivity of $171 \pm 15 \mu\text{A}/\text{mM}\cdot\text{cm}^2$ and a LOD of $0.3 \pm 0.1 \text{ mM}$, which is compatible with the physiological range in mice (0.3-1.6 mM [253]).

Fig. 5.10 (b) shows that the addition of Nafion 5% plays an essential role in screening the ascorbic acid and uric acid, although it significantly lowers the current steps. With the CAC/Nafion 5% membrane we obtained a sensitivity of $15.3 \pm 0.1 \mu\text{A}/\text{mM}\cdot\text{cm}^2$ and a LOD of $14 \pm 4 \mu\text{M}$. By adding the epoxy-enhanced PU membrane, we observed an important decrease in current, as shown in Fig. 5.10 (c). BSA was used to create a space between the inner and outer layer of membranes, to let the drug diffuse to the electrode. However we calibrated the sensor towards addition of Acetaminophen, obtaining a sensitivity of $2.4 \pm 0.6 \mu\text{A}/\text{mM}\cdot\text{cm}^2$ and a LOD of $152 \pm 17 \mu\text{M}$, which is still compatible with the physiological range in mice (0.3-1.6 mM [253]).

Fig.5.11 shows the detection of glucose 6 mM and acetaminophen 0.6 mM present in the same sample. The measurements were performed with a single platform, where one electrode was functionalized with MWCNTs and GOx (PAD 4), to specifically detect glucose, and the second electrode (PAD 1) was functionalized with BSA only. Both electrodes have the inner membrane (CAC/Nafion 5%) and the outer layer (epoxy-enhanced polyurethane). Fig.5.11 shows that only the PAD 4 is selective for glucose, and that acetaminophen creates interference on the PAD 4, but it can be monitored with the PAD 1.

5.2 Assembly and biocompatible packaging of the final device

To reduce the effects of the foreign body reaction, an external biocompatible packaging is needed to ensure a correct integration with the surrounding tissue once the device is implanted. Polyurethane, among many other polymers, has been extensively used as an outer membrane to act as a biocompatible interface with the surrounding host tissue.

In this section we will present two different solutions for the implantable device, that consists of the integration of the sensing platform, the ICs and the powering antenna.

5.2.1 Methods

Integrated device assembly

The epoxy adhesive (EP42HT-2Med system) was used to assemble the electronic components and the sensing platform in the integrated device. The sensing platform was placed on the top of the PCB containing the ICs and the microprocessor. The interconnections between the pads of the sensing platform and electronic components were realized with Al wire bonding and were protected with a glob top protection of 0.3 mm. In the first version of the implantable device, all the edges of the device were rounded with a milling machine. Two subsequent 5 μm layers of Parylene C were deposited by chemical vapor deposition using a Comelec C-30-S Parylene Deposition System. Parylene C was used to cover the whole device but not the electrode array that needs to be in contact with fluids. Finally, the electrodes were functionalized with MWCNTs and the device was covered with three layers of the biocompatible membrane made by epoxy-enhanced polyurethane. The preparation and deposition of this membrane is described in the Section 5.1.1.

In the second version of the implantable device (see the next Chapter), the edges of the device were not rounded with a milling machine, and a certified biocompatible elastomer silicone (Nusil MED 6033) was used to cover and round the edges and the bottom of the device. The sensing part was only covered with the epoxy-enhanced polyurethane membrane. The overall weight and volume of the implantable device are 0.61 g and 0.4 cm^3 , respectively.

In-vivo biocompatibility

For biocompatibility tests, the animals were bred and treated in accordance with the Swiss Federal Veterinary Office guidelines and were kept in specific pathogen-free animal facility. Experiments were approved by "Dipartimento della Sanità e Socialità" with authorization number TI-19/2010. Microchips were cleaned and disinfected with ethanol 70% and placed in sterile PBS (Gibco) for 24 h to stabilize the membrane. An *Air Pouch* (AP) was created by subcutaneous injection of sterile air in the back of male C57BL/6 mice at day 1 (5 mL) and day 3 (3 mL): this procedure creates a cavity of 1.5 cm diameter and 0.5 cm height. At day 6, mice were anesthetized with isoflurane 4%, shaved and locally sterilized with Betadine solution; the sterile microchips were implanted and the cavity sutured with Vicryl 6.0 (Provet AG). As a control of local inflammation, bacterial *lipopolysaccharide* (LPS, 50 μg /mouse, from LabForce AG) was injected daily into the cavity for the last 2 weeks of the 30 days of the experiment. As negative control APs were generated in the absence of any surgical procedure. As further control commercial chips (DATA MARS) were injected through sterile needle. After 30 days, the microchips were removed. The cavity was rinsed with 0.5 mL of PBS (Gibco) and the liquid collected and centrifuged at 7000 rpm for 10 min at 4°C. The concentration of

5.2. Assembly and biocompatible packaging of the final device

adenosine triphosphate (ATP) was determined in the supernatant with ATP determination kit (Invitrogen). For polymorphonuclear neutrophils detection, the pellet was resuspended in 0.2 mL RPMI 10% fetal bovine serum (Gibco) and analyzed at flow cytometer (FACS Canto, Becton Dickinson) with antibodies specific for CD11b and Gr1, labelled with allophycocyanin (APC) and fluorescein isothiocyanate (FITC, BioLegend), respectively.

5.2.2 Final external packaging: epoxy-enhanced polyurethane

In a previous work of our group [283], the cytotoxicity and biocompatibility of each component of the implantable device were tested: the chitosan/CNT matrix was tested for its resistance to corrosion in different solutions, and for its cytotoxicity; Parylene-C efficacy was evaluated by elution tests and cytotoxicity using the copper receiving coil as test substrate. The efficacy of the parylene barrier, as well as the toxicity of carbon nanotubes, has been assessed with *in vitro* cytotoxicity tests conform to the ISO-109931 standards.

In this thesis we performed an evaluation of the *in-vivo* biocompatibility of the assembled device with the packaging by implanting it in mice for 30 days.

Biocompatibility tests

Potential sources of inflammation for implantable devices are attributed to the materials, shape and sizes of the devices [44]. MWCNTs were entrapped in a chitosan matrix to prevent toxicity due to the nano-particle nature of the MWCNTs and residues of the catalysts as well. To prevent leaking of potential hazardous substances and the corrosion of electronic components in contact with biologic fluids, a coating of Parylene C was employed [237]. For an implantable sensor, the development of a biocompatible packaging is essential for a correct wound healing, and ensuring prolonged sensor functionality. Most of biocompatible packaging from literature [284] require a mold (*e.g.* for packaging in PDMS) or the application of an additional membrane (*e.g.* polycarbonate membrane) that results in many manipulation steps that could affect the final biocompatibility grade. In the present thesis a biocompatible packaging made by epoxy enhanced polyurethane membrane was developed and employed for *in-vivo* applications.

Fig. 5.12 (a) shows the photograph of the first version of our device (the first version of the packaging) after the mechanical milling, the deposition of Parylene C, the electrode functionalization and the membrane dip-coating.

In order to investigate the *in-vivo* biocompatibility of the implantable sensor, we subcutaneously implanted four prototypes in mice for 30 days. At the end of the period, the implant site was washed with PBS, and levels of ATP and neutrophils in the elution liquid were quantified to follow the local inflammatory response. Changes in ATP concentration and changes in neutrophils percentage give information on the local cell death and on the status of tissue inflammation, respectively. Fig. 5.13 reports ATP and neutrophil variations in the liquid collected from the implant site. ATP and neutrophil levels were also evaluated for a commercial chip (DATA MARS), in case of artificial inflammation introduced by the injection of bacterial

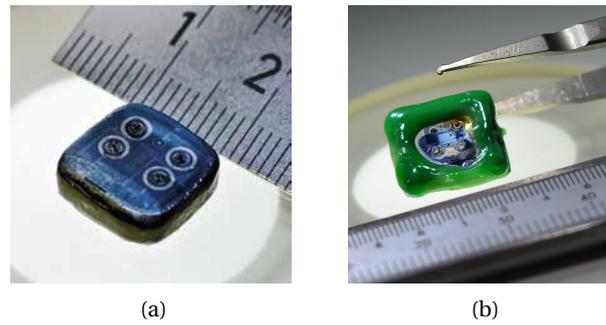

Figure 5.12 – Photograph of the final assembled device. Reprinted with permission from C. Baj-Rossi, et al., *Biomedical Circuits and Systems*, IEEE Transactions on, 8(5): 636–647, 2014 [231] (a); photograph of the final assembled device, (b).

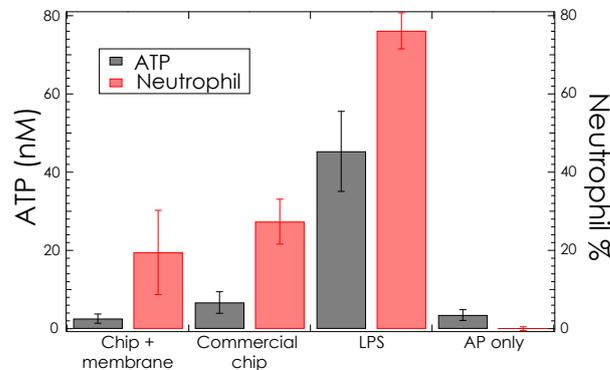

Figure 5.13 – ATP concentrations (nM) and percentages of neutrophils recovered from APs treated as indicated. Reprinted with permission from C. Baj-Rossi, et al., *Biomedical Circuits and Systems*, IEEE Transactions on, 8(5): 636–647, 2014 [231].

lipopolysaccharides (LPS) and for the negative control (mice with AP). In flow cytometry, for the negative controls, the neutrophils level is barely detectable, while there is still a small amount of extracellular ATP due to mechanical stress created by fluid collection. Data from both neutrophil infiltration and ATP concentration suggest that the membrane provides a quite good biocompatible coverage. Furthermore, only in case of induced inflammation (LPS), local redness and swelling were visible. After 30 days, ATP and neutrophil levels are comparable with the negative control (AP), as well as for the commercial chip, and significantly lower than the positive control (LPS), proving that after 30 days the host seems to accept the implant. Unfortunately, after 30 days, a cell layer covered the surface of the sensing platform. Future steps will be the evaluation of the effect of this cell layer on sensing performances and the application of an anti-fouling agent on top of the membrane in order to reduce the cell adhesion.

We also performed *in-vivo* biocompatibility tests with the second version of the packaging, made by the epoxy enhanced polyurethane membrane and a biocompatible silicone, by implanting for 30 days four prototypes in the peritoneum of mice. Fig. 5.12 (b) shows the

photograph of the second version of our device. Unfortunately, the level of neutrophils was still high after 30 days, proving that the host does not tolerate this implant. From these tests we can conclude that the peritoneum is probably not the best place to implant our device, as the mouse can easily scratch the suture and increase the level of the inflammation. Moreover in a previous study from our group, a similar packaging (same materials but different shape) was used for the same study and it showed after 30 days a significant reduction of the inflammatory response in time, suggesting normal host recovery.

5.3 Summary

In this chapter we first presented the realization and the complete *in-vitro* characterization of a system of membranes that consists of: an "inner" permselective layer, designed to filter the signal generated by the oxidation of interfering substances present in biological fluids, such as ascorbic acid and uric acid; and an "outer" layer made by an epoxy-enhanced polyurethane film, that regulates the passage of glucose and oxygen to the electrode surface and provides a biocompatible layer for a correct integration with the surrounding tissue. This system of membrane was employed in a glucose sensor and it successfully monitored glucose in both the human and mice physiological range, in PBS and in human serum at 37°C. The sensor showed good stability for 30 days at 25°C, and the permselective membrane effectively filtered out ascorbic acid and uric acid. Moreover, with the same system of membrane we developed a biosensor for detection of the anti-inflammatory drug acetaminophen.

In the last section of this chapter we showed the assembly of the sensing platform with the electronic components into the implantable device. The external packaging was tested to assess the *in-vivo* biocompatibility by implanting the device in mice for 30 days. The tests proved that the material used for the fabrication of the device and the external packaging generated an inflammation level comparable to a commercial implantable chip, thus proving that the device, after 30 days, is well tolerated by the host.

6 The implantable device

Fully implantable devices require an adequate electronic system for the correct sensor actuation, power management and data transmission. At the same time the device should be small and minimally invasive. From the point of view of the power management, the main challenge is to find a balance between the need of a small implant and the need to achieve an efficient power transfer to the implanted system. Although batteries have been largely used for supplying power in implantable devices [190], they are not suitable for long-term implants because their limited lifetime necessitates frequent replacement or recharging. The best choice is the development of a wireless power delivery system. For medical implant, several methods for a wireless power delivery have been investigated so far in literature. We opted for a battery-less inductive powering link system¹, designed to continuously transfer the power to the implantable device according to the position of the animal.

For the sensor actuation, the readout electronics were realized with miniaturized *integrated circuits* (ICs)². The main challenge resides in developing ICs that could perform the control and readout of both chronoamperometry and cyclic voltammetry for a biosensor, with low power consumption. Finally, an appropriate communication system was also developed, that could transmit the data in real-time, receive and visualize the data on a screen³.

In this chapter we present the final integration of the implantable device into a working system. The device consists of three main blocks: *(i)* the sensing platform; *(ii)* an interface electronics to control and readout the biosensor; *(iii)* a power management unit. We decided to vertically assemble the device, placing the platform on the top of the *printed circuit board* (PCB) that contains the dedicated IC, a microcontroller and the antenna on the bottom. The platform measures 12x11 mm, to fit the size of the coil (12x12 mm), and to leave some space for the wire bonding between the pads on the platform and the pads on the PCB (as illustrated in Fig. 4.1).

We show that the system can be autonomously powered, can effectively actuate the sensors that are located on the sensing platform and can transmit the data to an external device, like a

tablet, to show the measurement in real-time. The first section gives an overall description of the system. We show some preliminary *in-vitro* measurements and then tests with the miniaturized device. At the end of this chapter the validation with preliminary *in-vivo* experiments in mice is also presented.

6.1 System description

Since the stress level changes the measurement result, the animal needs to be in a natural environment and to move freely. Therefore, the animal must be monitored in a living space and the power must be transferred to the implantable system continuously. We decided to monitor the animal inside a cage used in laboratory. An intelligent remote powering system is proposed for the continuous long-term monitoring and to efficiently deliver the power through an optimized inductively coupled power link. Fig. 6.1 shows the scenario of the implantable sensor system for the freely moving animal. The powering system consists of a servo-controlled wireless power transfer system with detection and movement blocks [285, 286]. The detection block is used to find and track the animal in the living space. A permanent magnet is placed in the implantable system. The magnetic field sensors are used to find and track the permanent magnet which is implanted in the animal. The movement block has X and Y rails to move the powering coil to concentric position with the implanted coil where an efficient power transfer is assured. The rails move at maximum speed of 30 cm/s which is sufficient to track a mouse in a living space.

6.1.1 Readout electronics and remote powering system

Fig. 6.2 shows the block diagram of the implantable biosensor system. The power is transferred over an optimized remote powering link which is driven by an efficient class-E power amplifier. The overall power efficiency of the inductive link is 21% including the drain efficiency of the power amplifier. The induced voltage at the implantable system is proportional to the remote powering frequency. On the other hand, the penetration depth of the power in the

body decreases with frequency. Therefore, an optimal frequency is necessary [288]. An ISM band which is 13.56 MHz is chosen for the wireless power transmission. A second channel is preferred for a reliable data transmission due to the moving animal. When the animal moves, the coupling between the coils changes and the received power at the implant changes. Using the same inductive link for power and communication does not allow a reliable data transmission. Accordingly, the data is transmitted over a second channel at 869 MHz by an *on-off keying* (OOK) transmitter and a dedicated antenna.

The induced voltage is converted to a DC voltage with more than 80% of power efficiency by a passive full-wave rectifier. A *low-drop out* (LDO) voltage regulator follows the rectifier to create 1.8 V supply voltage for the bio-sensor system. The *power supply rejection ratio* (PSRR) value of the voltage regulator is more than 60 dB at 27.12 MHz. The reference voltage for the voltage regulator is generated on chip by a fully CMOS voltage generation circuit.

The regulated voltage is given to the waveform generator and the readout and control circuits as the supply voltage. The waveform generator is a mixed-mode circuit to generate different voltage waveforms to control cyclic voltammetry and programmable constant voltage levels to enable chronoamperometry, by using a single mixed-signal circuit. The control and readout circuit applies this waveform to the biosensor and measures the resulted sensor current as shown in Fig. 6.2. This block controls and reads out the sensor array as well as pH and temperature sensors for calibration purpose. It consists of programmable gain amplifiers and a second-order sigma delta analog to digital converter as well as a temperature readout circuit. An on-chip multiplexer decides which sensing site should be connected to the readout circuit. The digital output of the converter goes through an 8b/10b encoding for DC-balancing and to prevent long sequence of similar logic in communication. It consumes 500 μA from a 1.8 V supply voltage. The IC also implement another type of chronoamperometry and cyclic voltammetry readout circuit based on current to frequency conversion [289]. A sample timing schedule for the measurements is shown in Fig. 6.3. The control and readout circuit has been designed to run the measurements according to this schedule. It can measure three different drugs out of three different sensing sites by cyclic voltammetry and a single metabolite by chronoamperometry on the fourth sensing site. Prior to these measurements, pH and the temperature of the solution are measured. It is well-known that changes in pH or temperature could affect the current response in both cyclic voltammetry and chronoamperometry measurements [56]. Thus, the control over pH and temperature enables to correct eventual changes in the current response, during the data post-processing. A detailed description of the IC is out of the scope of this thesis, and more information about the design of the readout and control IC can be found in [290, 289].

Transmitter is one of the most power hungry blocks in a system. Therefore, a low-power transmitter is essential to reduce the power consumption. *On-off keying* (OOK) transmitter is a well-known method for data communication in implantable biomedical systems [291]. Although the transmitter saves energy during transmitting bit "0", the transmitter still consumes high power due to the power amplifier. Accordingly, the proposed OOK transmitter excludes the power amplifier for short range communication and consists of a free running LC oscillator which reduces the overall power consumption of the biosensor system. In addition, the transmitter's inductor is designed as a loop antenna for short-range communication. The data is received by a custom design receiver at 869 MHz, 40 cm away. The transmitter consumes 180 μA at 1.8 V supply voltage, and it allows a reliable data communication with a data rate of 1.5 Mbps.

An optimized inductively coupled power link is designed for an efficient power delivery. The load of the biosensor system can vary. Therefore, the required power at the implantable system can change. Moreover, the coupling between the powering and implant coils may change due to the movement of the animal and hence the received power at the implantable system can change. Accordingly, a power adaptation technique is used to transmit sufficient power to the implantable system: the power level at the implantable system is transmitted to the external unit. The supply voltage of the power amplifier is adjusted and hence the transmitted power changes according to the power feedback data. Fig. 6.4 shows the remote powering signals and

power feedback data for power adaptation. When the implant coil moves closer to the center of the powering coil, the received power by the implantable system increases. Therefore, the rectifier voltage increases. The transmitted power level is adjusted by tracking the rectifier voltage and transmitting power feedback data to the external base station. The implantable circuits have been designed and realized in 0.18 μm technology. A detailed description of the IC is out of the scope of this thesis, and more information about the power management and transmitter can be found in [292, 293]. The overall power consumption of the system is less than 1.6 mW. In the Table 6.1, the performance of the presented inductive-link system are compared with other similar system existing in literature.

The coupling of the coils is a critical parameter to increase the power transfer efficiency especially when the distance between the coils is large. After the optimization of the geometric parameters of the coils in order to obtain the optimal remote powering link [288], finally, the coils were produced on PCB for reliability and reproducibility and characterized for operation frequency. The materials used were copper on a FR4 substrate. Fig. 6.5 shows the optimized inductively coupled power link, where the receiving coil is showed on the top of the powering coil for a better comparison. The powering coil will be placed under the cage, on the servo-mechanic system, while the implanted coil will be integrated in the implantable device. The sizes of the powering and implanted coils are 80x80 mm and 12x12 mm, respectively, and the power transfer efficiency is limited over 30 mm distance [286].

6.1.2 Short-range data communication & Android interface

The sensor data is received and processed by an external reader. The external reader consists of three main parts: the demodulator, the Bluetooth transmitter and the Android interface. The OOK transmitter is a LC tank oscillator to reduce the power consumption. However, the operation frequency of the transmitter drifts due to the temperature and environment change. Therefore, a custom-designed data receiver is used to compensate the frequency drifts in the transmitter. A detailed description of the data receiver can be found in [297].

The digital signal is sent to another board which is in charge of analyze, validate and transmit via Bluetooth the data to the Android interface. The on-board microcontroller is able to sample each bit of the digital signal, decode it and understand if a transmission error has occurred. When the data has been validated, is sent by the well-known UART protocol to a commercial Bluetooth module as a word of two bytes.

For a continuous monitoring of the concentration of the substances we want to measure, an Android application has been developed on the basis of a previous prototype [298]. The most important improvements are the possibility to zoom the curves and to filter the noise with many filtering techniques (moving average, median value, IIR filter, etc.), while the interface is acquiring and plotting the data in real-time. Reliability and data space occupation have been optimized in order to let the user saving a significant numbers of curves according to the external flash memory of the device, which can be any tablet or smartphone.

6.2 Preliminary *in-vitro* measurements

6.2.1 Platform and IC characterization with the system of membrane

The capability of the integrated CMOS circuit to control and readout the sensors in the sensing platform was tested in the presence of the complete system of membrane presented in the previous chapter. A tiny microcontroller was programmed to send the commands to the IC. The output serial data of the IC is given directly to a blue-tooth transceiver in the external

6.2. Preliminary *in-vitro* measurements

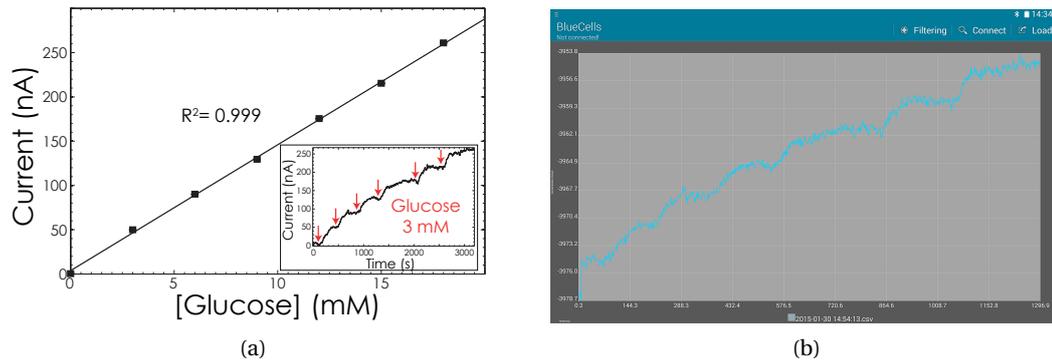

Figure 6.6 – Measurements acquired with IC on the sensing platform (a), and the display of the tablet after the measurement (b).

receiving station, which send them to an android device. The Android device shows the received data in real-time after filtering it.

The measurements in chronoamperometry (Fig. 6.6) shows that, for glucose monitoring, the average sensitivity and LOD obtained from three different biosensors were $0.7 \pm 0.2 \mu\text{A}/\text{mM}\cdot\text{cm}^2$ and $0.18 \pm 0.06 \text{ mM}$, respectively, which are very close to the values obtained with the commercial potentiostat in laboratory. Fig. 6.6 (b) reports a screen shot of the tablet right after a measurement.

6.2.2 Active chip characterization

Preliminary measurements were performed only on the readout and transmitting system by implementing together in an autonomous system the main building blocks: (i) the inductive coil; (ii) the power management IC; (iii) the interface IC to control and readout the biosensor; and (iv) the biosensor. This active autonomous system was tested in cyclic voltammetry to measure the oxidation peaks of the anti-cancer drugs mitoxantrone and etoposide.

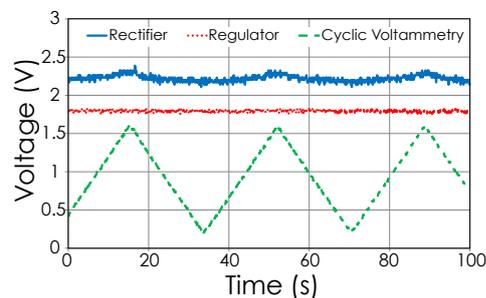

Figure 6.7 – The measured output waveform of the rectifier, regulator and the waveform generator for cyclic voltammetry when the inductive link is used for powering the system. Reprinted with permission from C. Baj-Rossi, et al., Biomedical Circuits and Systems, IEEE Transactions on, 8(5): 636–647, 2014 [231].

Table 6.2 – Comparison of the oxidation peak of etoposide and mitoxantrone measured with the commercial equipment and the active chip. Reprinted with permission from C. Baj-Rossi, et al., Biomedical Circuits and Systems, IEEE Transactions on, 8(5): 636–647, 2014 [231].

Drug	Autolab		Active chip	
	Voltage (mV)	Current (μ A)	Voltage (mV)	Current (μ A)
Mitoxantrone	535	0.81	513	0.86
Etoposide	495	0.45	495	0.43

The measured voltage waveform at the output of the rectifier, regulator and the waveform generator are shown in Fig. 6.7 when the power management unit and the inductive link provides power to the waveform generator and the readout circuits. The readout and waveform generator circuits were used for cyclic voltammetry measurements on mitoxantrone and etoposide, at room temperature under aerobic conditions by applying the triangular waveform with the slope of 82 mV/sec to the WE and a fixed voltage to the RE. Cyclic voltammetry measurements were also performed using an Autolab electrochemical workstation (Metrohm) for comparison. The same triangular waveform slope and range were applied to the sensors. The main oxidation peak position and its location (in voltage) for both measurements are summarized in Table 6.2. The measured oxidation current peak location and value show less than 7% discrepancy between our active chip and the Autolab potentiostat [299].

6.3 *In-vitro* measurements with the implantable device

We finally assembled the miniaturized device to test its performances for metabolites and drug monitoring. Fig. 6.8 shows the setup used for these measurements, with the servo-controlled remote powering system with the X-Y rails and the coil under the cage, and the receiver antenna inside the cage. Fig. 6.9 (c) shows the photograph of the assembled implantable device used for the *in-vitro* characterization. In this version of the implantable device, the edges of the device were not rounded with a milling machine, and a certified biocompatible elastomer silicone (Nusil MED 6033) was used to cover the edges and the bottom of the device. The assembly of the components was realized as described in the previous chapter.

In order to emulate the implantation in the mouse, the implantable device is placed in a Petri dish with a small permanent magnet, which enables the servo-controlled system to track the implantable system inside the cage. In these experiments the magnet was not included in the packaging of the device. For future *in-vivo* measurements, the magnet must be integrated inside the device.

The servo-controlled wireless power transfer system locates the implantable system inside the cage and moves the powering coil to activate the implantable system for a real-time measurement. We proved that, when the implantable system is randomly moved to mimic the movement of the animal, the servo-controlled wireless power transfer system tracks the implantable system and efficiently transfers the power. The data stream in Fig. 6.9 (a) clearly

6.3. *In-vitro* measurements with the implantable device

shows that during the displacement no data are transmitted (the red arrows).

To test the ability of the system for monitoring biomolecules, we injected acetaminophen on the bare surface of the sensing platform of the device, that was placed in a fixed position. The measured current was transmitted from the implantable system to the external reader, thus processed by the microcontroller and finally displayed on the Android interface in real-time. To mimic real animal fluids, a 100 μl -drop of 1X PBS solution (pH 7.4) covered the surface of the sensors, and acetaminophen at 0.5 mM concentration was injected after stabilization of the current.

Fig. 6.9 (b) shows the current generated by two successive injections of acetaminophen 0.5 mM. The current decays quite fast (in less than 10 s), due to the miniaturization of the electrode dimensions. Moreover, the two successive injections of acetaminophen result in a similar current increase with respect to the baseline signal [287].

We also performed calibration of the sensors towards detection of acetaminophen and glucose, in chronoamperometry at +650 mV. For glucose detection, in each of the tested devices we functionalized one electrode with drop-cast of 0.2 μl of MWCNTs (dissolved in chloroform) and 1 μl of GOx 15 mg/ml, as reported in Methods in Chapter IV. For acetaminophen detection, the electrodes were cleaned and used without functionalization. To perform the calibration, the device was placed inside the cage at a fixed position and the chip was covered with 200 μl of PBS at increasing concentrations of glucose or acetaminophen. Calibration lines are calculated from the evaluation of the current steps, by measuring the difference between the reached current value and the baseline (corresponding to the current at 0 μM of glucose or acetaminophen). Sensitivity and LOD were evaluated after linear regression of the data. Fig. 6.10 shows the calibration curves obtained for glucose (a) and for acetaminophen (b). For glucose we obtained a sensitivity of $38 \pm 11 \mu\text{A}/\text{mMcm}^2$ and a LOD of $0.6 \pm 0.3 \text{ mM}$ [300]. For acetaminophen we obtained a sensitivity of $66 \pm 21 \mu\text{A}/\text{mMcm}^2$ and a LOD of $34 \pm 11 \mu\text{M}$, which is compatible with the physiological range for acetaminophen [252]. Although the calibrations are non perfectly linear, we can conclude that our system can autonomously receive power, actuate the sensors to measure glucose and acetaminophen within the physiological

range, read the data and transmit them to an external reader.

In order to test the ability of the powering system to resist to biological fluids after the implant, 30-days measurements were performed in PBS at room temperature. For this test we assembled a device without the passive sensing-platform, as no electrochemical measurements were needed, and we applied the external packaging only on the PBCs with the implant coil and the second layer which houses electronic circuits and off-chip components, as described in the previous chapter: the epoxy adhesive (EP42HT-2Med system) was used to assembly the PCB with the antenna and the electronic component, two subsequent 5 μm layers of Parylene C were deposited by chemical vapor deposition using a Comelec C-30-S Parylene Deposition System, and a biocompatible Silicone (NuSil MED-6233), was used as external cover. The implantable system was continuously immersed in the PBS solution for 30 days at room temperature. The PBS solution is the standard buffer solution that simulates biological fluids and that has the same pH as for the blood (pH 7.4). We monitored the stability of the rectifier output, the regulator output voltages and the supply power of the power amplifier for 30 days. The results showed a good stability of the measured signals, thus proving that the packaging ensures the protection to the implantable system from the corrosion created by the biological fluids [287].

6.4. *In-vivo* measurements with the implantable device

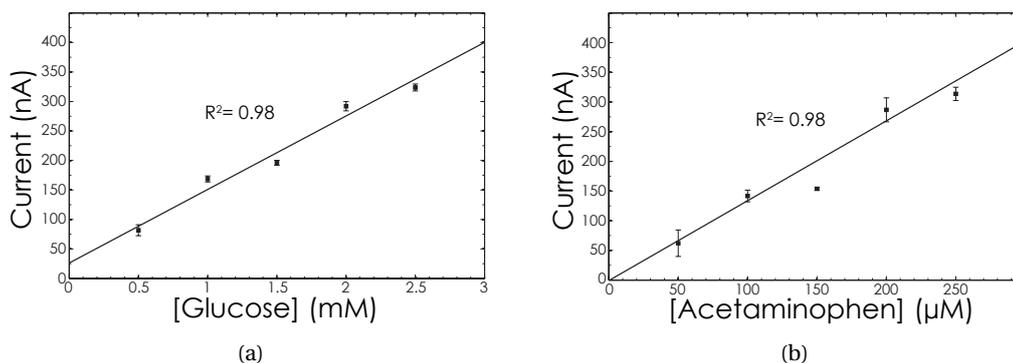

Figure 6.10 – Calibration curves obtained in chronoamperometry with the autonomous microsystem: upon injections of glucose 0.5 mM (a); upon injections of acetaminophen 50 μM (b). 6.4 *In-vivo* measurements with the implantable device

We decided to perform *in-vivo* tests on mice, as it is extremely important to understand what can be done with the present technology and the main limitations. First it is necessary to understand if the system can provide enough power to the device once it is implanted in animals. Even a thin layer of tissue, *e.g.* the skin of mice, could affect the efficiency of the powering link as it increases the distances between the implanted and the powering coil. Then we wanted to investigate the ability of the sensors to measure disease markers and drugs in *in-vivo* applications.

The preparation of the implantable device was described in the previous Chapter (Section 5.2.1). The electrodes were functionalized by drop-cast of MWCNTs in chloroform, followed by the drop-cast of MWCNTs in chitosan. For the glucose sensor, GOx was immobilized on the MWCNTs. For these experiments, only the external membrane in epoxy-enhanced polyurethane was employed. C57Bl/6 male mice (2 months old) were used for the experiments. The animals were bred and treated in accordance with the Swiss Federal Veterinary Office guidelines and were kept in specific pathogen-free animal facility. Experiments were approved by "Dipartimento della Sanità e Socialità" with authorization number TI-09/2013. Microchips were cleaned, placed in sterile PBS (Gibco) for 24 h to stabilize the membrane, and placed under UV light for 1 hour face-down to avoid damages for the enzyme from the UV light. Mice were anesthetized with isoflurane, shaved and locally disinfected with Betadine solution; the sterile microchips were implanted in the peritoneum and the cavity sutured with Vicryl 6.0 (Provet AG). Fig. 6.11 shows the positioning of the device in the peritoneum of the animal (a) and the suture after the surgery (b).

As preliminary tests, the measurements were performed few hours after the surgery, to avoid the inflammation due to the foreign body reaction process that could significantly affect the measurements, due to an increase of the neutrophils and on the release of ATP. Initially the device was intended to be implanted subcutaneously in the back of mice. But as it increased

Figure 6.11 – Positioning of the device in the peritoneum of the animal (a) and the suture after the surgery (b).

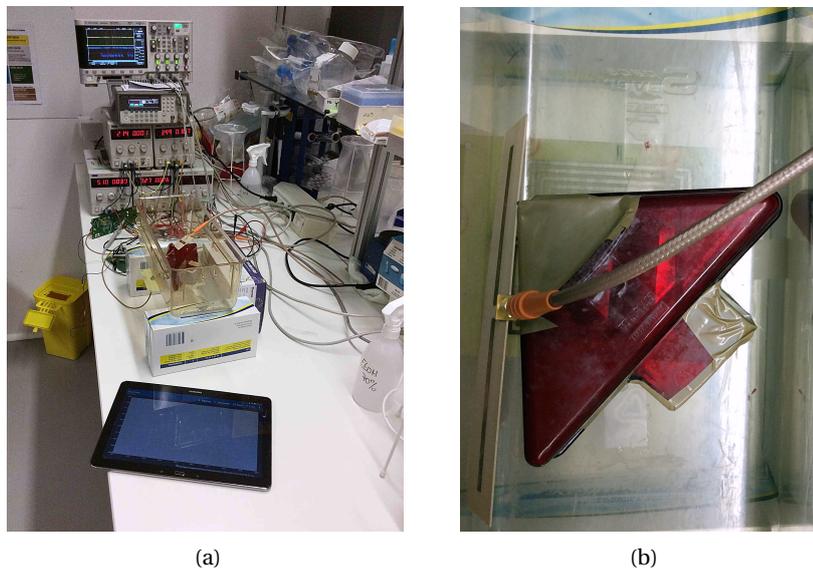

Figure 6.12 – Experimental setup for *in-vivo* measurements (a); the transparent plastic shelter with a red tint, placed inside the cage (b).

too much the distance between the implanted and the powering coil, we decided to implant the device in the peritoneum. After having acquired some measurements from the implanted device, 400 mg/kg of acetaminophen (previously dissolved in ethanol), or a glucose bolus of 2 mg/kg (mouse weight), were injected in the peritoneum and data were acquired for acetaminophen and glucose for 90' and 140', respectively. After the experiments, the animals were sacrificed and the devices were removed by surgery.

Fig. 6.12 (a) illustrates the experimental setup for the *in-vivo* measurements: we used three power suppliers, one frequency modulator, a signal generator, an oscilloscope and the PCBs that receive and transmit via Bluetooth the data to the tablet; the plastic shelter is placed in the mouse cage and the tablet displays the measurement. For sake of simplicity, we did not use the servo-controlled system but we employed a single coil placed under the cage. We selected this configuration in order to reduce the sources of noise, as for this preliminary study the

6.4. *In-vivo* measurements with the implantable device

main goal was to transmit and receive data from the device when the mouse rested in a fixed position. Fig. 6.12 (a) shows the transparent plastic shelter with a red tint normally used in laboratory for mice. As mice do not see red colors, but perceive them as being gray or dark, this design is thought to provide a dark shelter for mice. As humans do see red colors, the red transparent material allows for inspection of the animals while they are inside the shelter, without disturbing them [301].

Fig. 6.13 (a) shows the *in-vivo* real-time monitoring of the drug acetaminophen, after it was injected in the peritoneum of the mouse. The noise from the signal was filtered (with a FIR filter) during data post-processing. Even if the registered noise was quite relevant, due to movements of the mouse, a trend can be recognized, as showed by the fitted curve in red in Fig. 6.13 (a): the signal increases after the injection and it slowly decreases after approximately 30' of measurements. As we are measuring the drug in the peritoneal fluid, we are not expecting to obtain a typical pharmacokinetics curve (as shown in Fig. 1.3), because normally this curve is obtained from measurements in blood, as reported in this study [302] that shows pharmacokinetics curves after the administration of acetaminophen in mice.

Fig. 6.13 (b) on the left shows the *in-vivo* real-time monitoring of the variation in glucose concentration, after the injection of a glucose bolus (2 mg/kg of mouse) in the peritoneum of the mouse. Even if the signal is noisy, a peak of current starting 20' after the bolus injection can be recognized. After the peak, the current start decreasing until it goes back to its original value. The glucose metabolism curve reported in Fig. 6.13 (b) (on the right) was obtained by measuring the glucose concentration in blood with an external glucometer, after 10'-20'-30'-60'-90' the bolus injection. The peak of glucose concentration happens in the first 20' after the injection. Thus we can conclude that we had a lag time of approximately 15'-20', by measuring in the peritoneum that is comparable with values reported in previous studies on subcutaneous glucose measurements [303]. In future studies, it would be interesting to associate the electrochemical monitoring with another quantitative method, *e.g.* with HPLC. These *in-vivo* measurements were an opportunity to investigate the limitations of our system and to think about possible solutions that could, in the future, overcome them:

- The management of the power and transmission of the data should be improved, as a small movement of the mouse made the data transmission interrupted. Moreover in these experiments the mice were alive and awake but they were not totally free to move, as they were confined in the plastic shelter. Future developments on the powering system should find a solution for enabling the system to monitor the mice when they are completely able to move.
- The ICs for sensor actuation were designed for a continuously measure for 3.5' and then to switch to another electrode. However, for *in-vivo* measurements we needed a longer period of time for continuous monitoring of all four biosensors on the sensing platform.
- The noise level should be reduced as much as possible, as it is too high during the measurements (Fig. 6.13), even after the post-processing filtering of the signal.

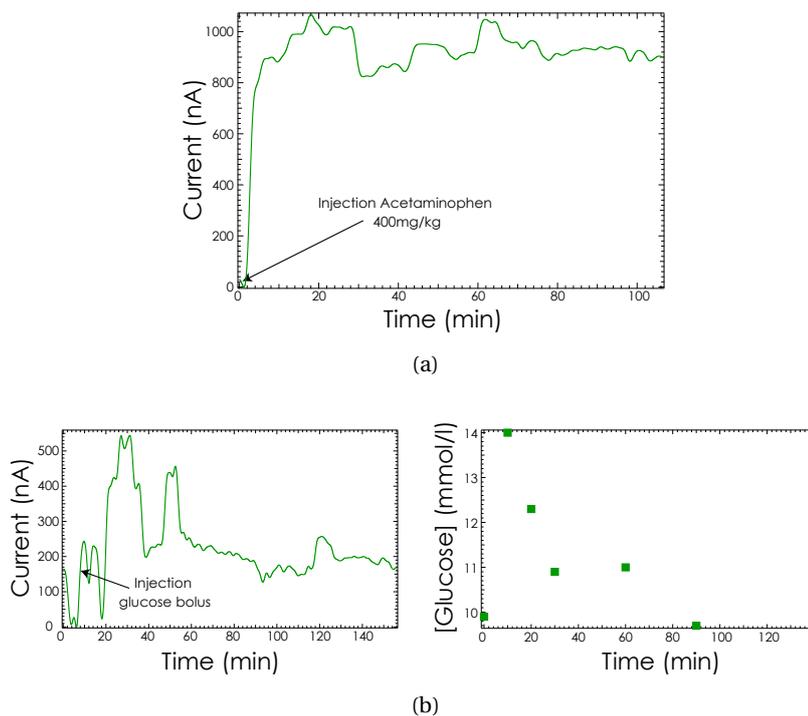

Figure 6.13 – *In-vivo* monitoring of acetaminophen with the implantable system in mice (a); *In-vivo* monitoring of glucose with the implantable system in mice (on the left), and monitoring of glucose in blood with an external glucometer (on the right), (b).

- After an improvement of the system, measurements should be replicated with the complete system of membranes, in order to remove the response from the interfering compounds in biological fluids.
- The sensitivity of the sensor should be improved by fabricating electrodes with a bigger area and the integration of different nano-structures that could effectively increase the signal-to-noise ratio.
- Other strategies to implant the device should be considered, as probably the peritoneum is not an optimal choice: the level of inflammation is still high after 30 days as the animal can scratch the suture and increase the inflammation. Moreover, the level of biocompatibility of the device can be improved, with a different choice of material and the addition of active molecules that can be released from the implant and reduce the level of inflammation.

6.5 Summary

The objective of this thesis is the design and characterization of an implantable electrochemical biosensor for the real-time and continuous monitoring of drug and other parameters, such as endogenous metabolite concentrations, pH and temperature, with fully electronics that

could actuate the device, collect the data and transmit the data to an external user. The final goal is to implant the system in mice that are used in research on animals.

The living conditions of these animals are of primary importance because the stress level can affect the measurement results. This means that the animal must be in a comfortable environment and capable to freely move. Therefore, the final aim of this project is to monitor the animal in a living space, such as a cage, in order to minimize the human intervention. In this chapter we integrated the sensing platform, ICs and the powering system into a working system. The powering system was designed⁴ in a good balance between the need of a small implant and the need to achieve an efficient power transfer to the implanted system that is placed in a small animal. The readout electronics were realized with ICs that can be easily miniaturized. ICs were designed⁵ to control and readout the sensors in both chronoamperometry and cyclic voltammetry, with low power consumption. We showed that the system can be autonomously powered, can effectively actuate the sensors that are located on the sensing platform and can transmit the data to an external device, like a tablet, and displaying the measurement in real-time⁶. My personal contribution to the experimental part reported in this chapter was: the realization of the sensing platform, the integration of the platform with the electronics and the coil into the implantable device, the realization of the biocompatible packaging, the electrochemical measurements, post-processing of the data and statistics. With the miniaturized device, we showed *in-vitro* measurements and calibration of glucose and acetaminophen in the physiological ranges. At the end of the Chapter we showed some promising *in-vivo* experiments in mice⁷, which demonstrated that our system can monitor in real-time the metabolism of drugs (e.g. acetaminophen) and of endogenous metabolites (e.g. glucose) in the peritoneal fluid. These results represent a starting point for future improvements.

7 Conclusions

The objective of this thesis was the design and characterization of an implantable electrochemical biosensor for the real-time and continuous monitoring of drug and other parameters, such as endogenous metabolite concentrations, pH and temperature, with autonomous electronics that can actuate the device, collect the data and transmit the data to an external user. The implantable device was intended to be implanted in mice used in research on animals, and to monitor the animal in a living space in order to minimize the human intervention. The device must be battery-free, autonomous in terms of power supply and readout electronics, biocompatible, stable for long-term measurements, capable of monitoring multiple molecules, and of generating a signal with a high signal-to-noise ratio.

With respect to the current state-of-the-art, that was presented in the first two Chapters, this thesis presents innovative and advanced contributions on:

- *Multiple drug detection.* Selective detection of drugs and drug pairs has been achieved with different strategies, which combined the electrode functionalization with nanomaterials and enzymes. Non-electroactive drugs were monitored with biosensors based on MWCNTs and microsomal *cytochrome P450* (P450) enzymes. As the present state-of-the-art on P450 electrochemistry is not focused on the development of P450-biosensors as a diagnostic tool, the results presented in this thesis represent a significant step forward with respect to the state-of-the-art. We proved that MWCNTs significantly improve sensor sensitivity and detection limit, as they provide a larger area, more favorable for the P450 adsorption. With MWCNT-nanostructured electrodes we performed detection of several drugs in their therapeutic range, and in complex solutions like human or animal serum. With an investigation on the stability of the P450-biosensor in long-term measurements, we proved that the enzyme is active and stable for 16 h, and that it can be employed for the continuous monitoring of a drug. The 16-h limit for enzyme stability is long enough for the study of the pharmacokinetics for many drugs, thus showing the potential of the presented method as a valid alternative in therapeutic drug monitoring practice.
- *Monitoring of multiple parameters.* The electrochemical platform was designed to host

four independent biosensors, for the monitoring of drugs and endogenous metabolites, a pH sensor, and a temperature sensor. The sensing platform was designed and realized considering biocompatibility, performances and the constraints given by the integration with the electronics and by the final application. Carbon-nanotubes are integrated on working electrodes to improve the sensitivity and the chitosan is employed to entrap them on the electrode surface, providing a biocompatible coating. With various functionalization of the working electrodes, we performed calibration of glucose and lactate, and of different drugs: acetaminophen, etoposide, and mitoxantrone. Calibration of a pH sensor based on the Iridium oxide film technology and the calibration of the temperature sensor were also presented. The design of a sensing platform for electrochemical measurement, combined with the presence of a pH and a temperature sensor, is a strategy to optimize the sensing performance in different physiological conditions, since changes in pH and temperature can affect the sensor specificity, and it still represents a complete novelty.

- *Innovative system of membranes, nano-materials and enzyme.* In this thesis we investigated the complex integration of micro-fabricated sensors, nanomaterials, enzymes, a system of membranes and an external packaging, to ensure at the same time measurements with high signal-to-noise ratio, biocompatibility and selectivity against possible interfering molecules in biological fluids. We presented a complete *in-vitro* characterization of a system of membranes that consist of: an "inner" permselective layer, designed to filter the signal generated by the oxidation of interfering substances present in biological fluids, such as ascorbic acid and uric acid; an "outer" layer made by an epoxy-enhanced polyurethane film, that regulates the passage of glucose and oxygen to the electrode surface and provides a biocompatible layer for a correct integration with the surrounding tissue. This system of membrane was employed in a glucose sensor and it successfully monitored glucose in both the human and mice physiological range, in normal buffer solution and in human serum at 37°C. The sensor showed good stability for 30 days at room temperature, and the permselective membrane effectively filtered out ascorbic acid and uric acid. Moreover, with the same system of membrane we developed a biosensor for the detection of the anti-inflammatory drug acetaminophen.
- *System design, fabrication, characterization, integration, biocompatibility and in-vivo tests.* The present research was focused on the complete design and fabrication of the sensing platform and its integration with a customized electronics and an intelligent powering system for the real-time monitoring of molecules in small animals. In the final chapter we showed the integration of the different components and an *in-vitro* characterization of a working prototype. The external packaging was tested to assess the *in-vivo* biocompatibility by implanting the device in mice for 30 days. The tests proved that the material used for the fabrication of the device and the external packaging generated an inflammation level comparable to a commercial implantable chip, thus proving that the device, after 30 days, is well tolerated by the host. We showed that the system can be autonomously powered, can effectively actuate the sensors that are

located on the sensing platform and can transmit the data to an external device, like a tablet, and showing in real-time the measurement. With the miniaturized device we showed *in-vitro* measurements and calibration of glucose and acetaminophen in the physiological ranges. Finally, we presented some promising preliminary *in-vivo* experiments in mice that proved that our system can follow in real-time the metabolism of glucose and of the drug acetaminophen after its administration in the peritoneal fluid.

The results achieved in this thesis are promising, but they can be further improved by additional research. For instance, a more detailed investigation on the P450 electrochemistry could offer new insights on the P450 behavior, that can be used to optimize the P450 immobilization to achieve improved sensing performances and enzyme stability. Recent studies [127, 128] revealed that a non-controlled P450 immobilization on the electrode may induce conformational changes in the P450 proteins that result in the formation of its inactive form, the cytochrome P420. Moreover, even in the absence of any substrate, the P450 active site may go through abortive reactions or "shunts" that lead the production of intermediary products, e.g. hydrogen peroxide, which can generate misleading signals.

After the fabrication of a sensing platform we investigated the immobilization of msP450s and MWCNTs. While for MWCNTs we found some solutions, as presented in Chapter 4, for the immobilization of msP450 we faced some limitations. We increased five times the concentration of the P450s in the microsomes: the msP450 solution was centrifuged until separation of the protein component from the solvent; the protein component was extracted; the protein components from 5 aliquots were merged in one solution. After the electrode functionalization with MWCNTs, three layers of msP450 were adsorbed on the surface of the electrode, according to the procedure previously explained in Section 3.1.1. With cyclic voltammetry, we could identify the reduction peaks of msP450, however we registered high instabilities in current, for all reduction peaks. The peak current level was not stable between sequential cycles. And this current variation was in the same order of magnitude of the current variation due to the addition of drug in the solution, thus making impossible to detect the presence of drugs. The main reasons of these instabilities are the low concentration of the P450 component in the microsomes, and the small size of the electrodes, which reduces the current levels. Small electrodes are necessary for the platform miniaturization. Moreover, a further increase in the P450 concentration with the centrifuge method, would have made the approach not convenient in terms of costs.

Nevertheless, we can envisage solutions that could be investigated in future projects, *i.e.* the use of a recombinant P450 with additional domains that could improve P450 functionalities, or the use of a more concentrated microsomal P450. Moreover, an additional extensive study of P450 electrochemistry, which is out-of-topic for the present work, could offer new insights on P450 behavior to optimize the P450 immobilization for improved sensing performances. In case of multiple drug detection with P450 enzymes, a detailed study on the atypical kinetics of P450s should be associated with the electrochemical behavior of P450 in presence of two or more drug compounds. Furthermore, the long-term stability study presented in Chapter III

Chapter 7. Conclusions

indicates that, at the current stage, our P450-biosensor can be exploited as a disposable sensor, but not for long-term implantable applications. Thus, new strategies based on nano-particles, to improve the P450 stability, are currently under investigation in our group for long-term applications.

The sensing platform may be employed for measurements of several molecules in parallel: with an appropriate instruments will be interesting to monitor *e.g.* the glucose and lactate variation in a cell medium and to simultaneously monitor the changes in pH and temperature. Another interesting application is the simultaneous monitoring of different drugs in a blood sample. Strategies as a microfluidic device, in combination with membranes, can be envisages to reduce or even eliminate the problem of interferences in case of multiple molecules detection with the same sensing platform.

The pH sensor based on the deposition of the Iridium oxide film should be improved in terms of stability of the measured potential, with the employment of a miniaturized external or an integrated stable reference electrode, and with a study over the stability of the Iridium oxide film.

Concerning the biocompatibility issues, the external packaging and the system of membranes must be further tested to check if they promote an adequate vascularization around the implant to enable the diffusion of the analyte to the sensors, and if they reduce the formation of the fibrotic capsule, caused by the foreign body reaction process. Many strategies can be investigated to ensure a long term biocompatibility: the dimension of the device can be reduced; innovative materials, *e.g.* organic an polymers, can be used instead of Silicon or other metals, for the fabrication of the sensing platform but also of the electronics; the release of active molecules (*e.g.* anti-inflammatory drugs or factors that stimulate the angiogenesis), can be associated with the use of biocompatible membranes to enhance the integration of the implanted device with the host tissue. Moreover, according to the ISO10993 standards, before the final device can be declared safe for implantation, several additional tests are required, *e.g.* hemocompatibility, sensitization and systemic toxicity analysis, or multiple cytotoxicity tests. We finally showed the integration of the sensing platform in an autonomous implantable device with customized electronics and powering system, and *in-vitro* and *in-vivo* experiments. The device was able to transmit power, actuate the sensor and receive data once the device was implanted in a mouse that was awake but confined in a small space to reduce its movements. The electronic part can be also improved both at hardware and software levels, in order to increase the signal-to-noise ratio and to enable the monitoring for long-time of the mouse that is free to move in the cage. Moreover, the design of more complex integrated circuits should be implemented, for the real-time monitoring of other molecules and parameter in parallel.

This thesis demonstrated that with a close collaboration among researchers with different competencies and the optimization of each single part respect to the others, we succeeded in realizing a first working prototype, which represents a significant step forward the present state-of-the-art and a rich source of information for future improvements.

A Appendix: Methods for analysis of calibration curves

The final aim of a biosensor is to detect the analyte of interest in a sample with an unknown concentration. Before that, it is necessary to calibrate the sensor: measure the sensor response (in most of the cases a current), at increasing analyte concentrations; build a calibration curve, *i.e.* the plot sensor response *vs.* analyte concentration; measure the sensor response for the unknown sample; estimate the sample concentration from the calibration curve. Therefore, the calibration curve is the principal result of the biosensor characterization and optimization. The biosensor performance is usually experimentally evaluated based on its sensitivity, limit of detection (LOD), linear range, precision of the response, selectivity and its response to interferences. The two main parameter used to evaluate the quality of a calibration curve are the *sensitivity* and the *limit of detection* (LOD). The sensitivity is the slope of the calibration curve, while the LOD can be generally defined as the lowest concentration that can be detected. This section reports the summary of the methods used in this thesis to carry out statistical analysis on data to obtain the calibration functions, evaluate them and report the main important parameters. The following citations refer to the literature used as reference for this section: [304, 305, 306, 307].

A.1 Experiment planning

The minimum number of calibration standards was fixed to 5. The concentration of each of the calibration standard was chosen in order to make the calibration matches with the physiological range of the analyte of interest, thus to obtain a value of LOD equal or smaller than the lower limit of the physiological range. Each calibration was repeated at least three times, by measuring one replicate at each concentration.

A.2 Regression analysis

After the plot of the sensor response *vs.* analyte concentration, the linear regression was computed. The aim of the linear regression is to establish the equation that best describes

the linear relationship between instrument response y and analyte concentration x . The relationship is described by the equation of the line, *i.e.*, $y = mx + c$, where m is the slope of the line and c is its intercept with the y-axis. The "least squares regression" was used as regression method, to find the line that gives the smallest sum of the squared residuals and that best represents the linear relationship between the x and y variables.

The main assumption made for the linear regression analysis were: the error in the x values was considered insignificant compared with that of the y values; the error associated with the y values is normally distributed; since the magnitude of the error in the y values is not always constant across the range of interest, a weighted regression, which takes account of the variability in the y values, was used.

A.3 Evaluate the regression analysis

Regression statistics and *analysis of variance* (ANOVA) statistics were computed for a confidence interval of 95%. To define the best linear range for that particular sensor, the following criteria were used: a *correlation coefficient square* (R^2) possibly bigger than 0.99, a large value of the sum of squares terms (SS in the ANOVA table) for the regression compared to the residuals; a large F value and small p-value (smaller than 0.05).

The regression coefficient table was used to obtain the value for the sensitivity (the slope) and its error. The error on the sensitivity was calculated as the difference between the upper confidence limit (95%) associated to the value of the slope, and the nominal value of the sensitivity. The error can be also calculated from the t-statistic for $n-2$ degrees of freedom, as $e = ts_m$, where t is the 2-tailed Student's value for $n-2$ degrees of freedom (where n is the number of calibration points), and s_m is the standard error for the slope.

A.4 Calculate the LOD

A very general definition of LOD is the "smallest signal that can be distinguished from the background noise associated with the instrumental measurement". Formally, the Limit-of-Detection is defined as the concentration of analyte required to give a signal equal to the background (blank) plus three times the standard deviation of the blank. The limit of detection in terms of current (y_{LOD}), was calculated as the minimum detectable signal, from the IUPAC definition:

$$y_{LOD} = y_B + k \cdot \sigma_B \quad (\text{A.1})$$

where y_B is the mean value of replicates of blank measurements, σ_B is the standard deviation of the blank signal (that can be substituted with the residual standard error), and $k = 3$ ensures, with a confidence level of 99.86%, that the LOD signal is equal or bigger than the background (blank) plus three times the standard deviation of the blank signal. In case of background-subtracted data (corrected by the same blank value), the standard deviation (or the standard

A.5. Reproducibility or precision of the response

error) should be corrected by multiplying for a factor $(\sqrt{\frac{1}{n} + \frac{1}{n_B}})$ that depends on the number of replicate observations (n) and the number of blank measurements (n_B). The LOD in terms of concentration is then calculated from the equation of the regression line ($y = mx + q$). In case of background subtraction and when the value of the intercept (q) does not significantly differ from the mean blank value (y_B), the LOD can be calculated with the equation:

$$LOD = k \cdot \frac{\sigma_B}{m} \quad (\text{A.2})$$

where m is the slope of the regression line (the sensitivity).

To evaluate the error associated with the LOD, we consider the LOD as a derived measurement, as shown in equation A.2. Therefore, its relative error is obtained as the sum of the relative error on the blank signal and the relative error on the slope:

$$\varepsilon_{LOD} = \varepsilon_{y_B} + \varepsilon_m \quad (\text{A.3})$$

A.5 Reproducibility or precision of the response

In some studies the repeatability of the biosensing process was evaluated by measuring the responses of freshly prepared biosensor to a fix analyte concentration within the first 6 h of preparation at 1 h time interval, or, in alternative, by comparing three consecutive calibrations curve. *e.i.* by comparing the sensitivities. In some other studies the storage stability of the biosensor was investigated by measuring the sensor response to a fix analyte concentration after 12 h, 24 h, 2 days, 4 days and 1 week or storage. In other studies the long-term stability of the sensors was evaluated, by calibrating the sensor at a certain time interval up to 30 or 50 days. In all these cases, a *relative standard deviation* (R.S.D.) value (in %) was calculated.

A.6 Selectivity and its response to interferences

For the investigation of the permselective membrane against interfering compounds, the sensor response was measured in the presence of the interferences (*e.g.* uric acid or ascorbic acid) and this value was expressed as a percentage of the sensor response to the analyte concentration (*e.g.* glucose).

A Appendix: Details on CNTs

A.1 Electric properties of CNTs

The electronic properties of SWNTs are controlled by the chirality, *i.e.* the angle at which the graphene sheets is folded, which determines the alignment of the π orbitals in the tube. The chirality angle Θ is shown in Fig. A.1: Θ is quantified by the chirality vector $C_h = na_1 + ma_2 \rightarrow (n, m)$, where n and m are the (integer) numbers that quantify the distance in exagon units from an origin, in the two unit-vector directions, a_1 and a_2 , of the graphene lattice. The chirality vector thus describes the way in which the tube is folded. The translation vector, T , is directed along the tube axis and perpendicular to C_h . The chiral angle, Θ , is defined as the angle between the C_h and the $(n,0)$ direction. Among the large number of possible C_h vectors, there are two inequivalent high-symmetry directions: "zigzag" and "armchair" and are designated by $(n,0)$ and (n,n) , respectively.

The chirality vector can be directly related to electronic properties: when the vector is $(n,0)$. *i.e.* zigzag, SWNT is metal when $n/3$ is an integer, otherwise is semiconductor; when the vector is (n,n) , *i.e.* armchair, the tubes are expected to be metal conductors [308]. MWCNTs, because of statistical probability, are usually metal conductors [67].

A.2 Fabrication and integration of CNTs on electrodes

CNTs can be fabricated through several techniques: synthesis through the pyrolysis or thermal decomposition of a carbon source; arc-discharge evaporation of two carbon electrodes; gas-phase catalytic growth from carbon monoxide; chemical vapor deposition from hydrocarbons; or laser ablation [309].

Regarding the electrochemical properties, normally, high-purity CNTs should be electrochemically inert, which results in the absence of voltammetric response. However, due to impurities or defects, such as metal atom, amorphous carbon, and structural defects, which are inevitably introduced during the fabrication processes, CNTs are highly electrochemically reactive. More-

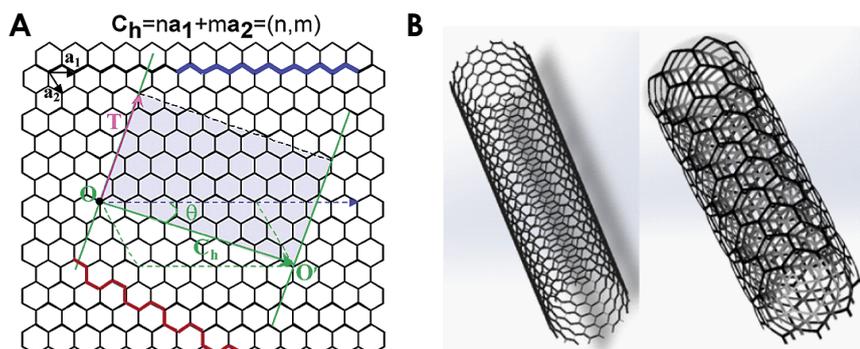

Figure A.1 – (A) Schematic of the roll-up of a graphene sheet to form a SWCNT structure: OO^1 defines the chiral vector $C_h = na_1 + ma_2 \rightarrow (n, m)$ and T is the translation vector. The shaded area represents the unrolled unit cell formed by T and C_h . The chiral angle, Θ , is defined as the angle between the C_h and the $(n,0)$ zigzag direction. $(n,0)$ zigzag and (n,n) armchair SWNTs are indicated in blue and red, respectively. (B) Structure of a SWCNT (on the left) and of a MWCNT (on the right). Adapted with permission from [74].

over, the presence of oxygenated groups, *e.g.* carboxyl groups (COOH^-), at the tips further improves the electroactivity of CNTs [310]. To this purpose, chemical and thermal treatments are used to increase functional oxygenated groups at the nanotube tips and defects along the sidewall. The most common treatments involve solutions of acids that eliminate metallic impurities and create reactive sites on the tubes, which help their further functionalization with oxygenated group. The walls of CNTs are highly hydrophobic, whereas the ends are hydrophilic for the presence of oxygenated species. Therefore CNTs have the tendency to form aggregates in almost all kinds of aqueous solutions, so, they are often dispersed in non-polar organic solvents, surfactants or polymer solutions.

Due to their interesting electrochemical properties, several strategies have been developed for the immobilization of CNTs on electrodes, with the objective to ensure a stable bonding between CNTs and the electrode surface: direct growth on the electrode surface by chemical vapor deposition; covalent bonding through the oxygenated groups, *e.g.* carboxyl groups (COOH^-), on the tubes; direct adsorption of CNTs dispersed in solution; electrodeposition of CNTs entrapped in a polymer; fabrication of CNT-paste electrodes; layer-by-layer assembly. Some techniques can generate aligned CNTs, *e.g.* via direct growth or layer-by-layer assembly. There have been a number of approaches to physically adsorb CNTs on electrodes by dispersing in a binder, *e.g.* Nafion, or by drop casting a solution of CNTs (in solvents like dimethylformamide or chloroform) onto an electrode without any binders. Also chitosan has been used for the dispersion and adsorption of CNTs. With physical adsorption, the resultant electrode had randomly distributed tubes with no control over the alignment or orientation of the nanotubes [76].

Various methods are available for immobilization of proteins and enzymes on CNTs, including adsorption, entrapment, intermolecular cross-linking, covalent binding and affinity, [83, 84, 85]. A detailed description and review on the different technique is out of topic for this

A.2. Fabrication and integration of CNTs on electrodes

work, but we recently reviewed the main techniques for enzyme immobilization for biosensors in this review paper [66].

Camilla Baj-Rossi

Biomedical engineer

Route De Chavannes 68 – 1007 
Lausanne (CH)

+41 76 278 2134 

camilla.bajrossi@gmail.com 

Nationality: Italian 

Born: 1986

Residence permit (CH): B

Experience

École Polytechnique
Fédérale de Lausanne
EPFL

Switzerland

February 2011 – August 2015
(expected)

Ph.D. in Biosensors and Bioengineering
Research Engineer

Innovation: In my thesis I designed and developed an innovative implantable chip for real-time drug monitoring in small animals. I optimized the combination of enzymes and nano-materials, to realize a new and low-cost working device. I realized an optimized biocompatible packaging with multiple functionalities. As a member of a multi-disciplinary team, comprising electronics and biologists, I contributed to the final realization and testing of the implantable chip.

Center for
Biomedical
Engineering, Harvard
Medical School

USA

February 2015 – May 2015

Internship
Research Trainee

Development of a novel biosensor for the real-time monitoring of drugs and metabolites used for in-vitro toxicology tests on cell cultures.

DI.PRO. s.a.s.,
San Mauro
Torinese,

Italy

April 2008 – July 2008

Internship
Research and Development Engineer

Identify the surface modification techniques applicable to the polymeric film of an incisional hernia prosthesis to improve the biocompatibility. The research was applied to a new prototype of prosthesis to reduce the complications after the surgery.

Education

Politecnico di Torino
Italy

2005 – 2008 (B.Sc.)
2008 – 2010 (M.Sc.)

Biomedical Engineering – Bachelor and Master
degree

M.Sc. Grade: 110, *summa cum laude* (top grade in Italian universities)

Expertise: Biomaterials, Biomechanics, Nanobiotechnology

1 award: Optime Award for the "Best Young Graduates of the Year" provided by the Turin Industrial Society, September 2011

Technical

Handling various chemical products: acid solutions, solvents, polymers, nanomaterials, metallic materials for electrochemistry, hazardous substance, biological materials

Chemical modification of surfaces: adsorption, electrodeposition and covalent binding of proteins, nanoparticles and DNA

Electrochemistry analysis techniques: amperometry and voltammetry

Signal processing, fitting and statistics of the electrochemical data

Experience in the basic microfabrication techniques in clean-room CAD design of implantable electrodes and polymeric molds (PDMS, Plexiglas)

Laboratory and electronic measurement instruments

Software

Programming Languages: C/C++

Tools: Matlab (numerical environment) – Comsol (numerical simulation) - Altair Hyperworks (finite elements simulator) - SolidWorks (CAD for 3D-design) - L-EDIT and K-layout (CAD) - Mathematica (Data analysis) - Igor Pro (data fitting)

Analysis – Nova, Versastudio

Graphic Tools: Image J – Adobe Illustrator

Linguistic

Italian	English	French	German
Mother tongue	C1	B2	A1

Additional information

- **Strong experience in public presentations** developed in several international conferences and workshops.
- Skills in **project management and team-leading**, improved by attending different courses (team management, leadership, human resource management, finance and accounting), and by actively participating to the “Venture Challenge” course organized by Venturelab and EPFL “College of Management of Technology”. During this course I attended seminars, prepared business pitches and wrote a business plan that was positively evaluated by experts in entrepreneurship.
- I have been a **committee member** of the IEEE Student Branch at EPFL, helping in organizing several activities for students, related to technology and scientific events.
- In my free time I enjoy trying new sport activities, to challenge my endurance and be in peace with myself. I love tennis, skiing, swimming and dancing salsa. I have been playing volleyball at **professional level** for more than 15 years.
