# Acknowledgements

I have worked on this thesis from October 2002 to April 2007 in the Laboratory of Chemical Reaction Engineering (Group of Catalytic Reaction Engineering, since November 2006). First of all I would like to thank Prof. Albert Renken and MER Liouba Kiwi-Minsker for taking me into your group. I thank you for your advices, encouragement, the freedom and the trust you have given to my work.

Many thanks to Prof. Pierre Vogel for having presided the jury and many thanks to Prof. Frerich Keil, Dr. Benoit Louis and Dr. Gyorgy Foti for having taken the time to examine.

I feel deep gratitude towards Dimitri. Thank you very much for your guidance, inspiration, eternal discussions, availability and the proof reading of my thesis.

Thanks to those who have assisted me in the lab. It would have not been possible to start up the TAP machine without the support of Prof. J.T. Gleaves and Dr. R. Fushimi. Thank you very much for teaching me for one week at your institute in St. Louis, USA. Many thanks also to Dr. G. Yablonsky, Dr. S. Shekhtman, T. Decamp and Dr. Y. Schuurman for your advices on the TAP topic. A big thank you goes to the master students Bryan Bromley and Stéphanie Tissot whose work was very important to complete the experimental part of my thesis.

I am grateful to the technicians Bobo, Jean-Claude, André, the electricians Gaby, Gérard, Supardi, the computer guy PAP and the secretaries Mme Szuman, Mme Anken, Stéphanie, Vida and Sara which always helped in technical and administrative matters and cheered me up when needed.

Special thanks to Chrystèle, Pierre, Pascal, Edi and Sophie for the huge encouragement, for integrating me in Switzerland, teaching me French and the long, long discussions which I appreciated a lot. Edi, thanks a lot for coaching me in alpine sports. Natasha, I owe you a lot for your infinite support and encouragement. Subbu, I always appreciated the inspiring discussions with you and the invitations to your house.

## ACKNOWLEDGEMENTS

I have had the pleasure to be part of a girls evenings community: Chrystèle, Natasha, Sophie, Béa, Ilaria, Justyna and Elena. Thank you very much for the time we spent together, I cherish it.

To my colleagues: Agnieszka, Anne-Laure, Babis, Benoît, Blanca, Carmen, Eric, Erika, Ester, Gabriele, Hao, Igor, Jonas, Kashid, Kim, Lavax, Marie-Agnès, Marina, Martin, Micaela, Michal, Philip, Sébastien and Yves-Alain thanks for the discussions (professional and non-prof.) as well as the coffees and good moments we have shared.

To the people I owe the most: my parents, thanks for your support and trust as well as to my siblings for always believing in me. Thanks to my friends from Germany who came to visit and cheered me up when needed: Christine & Ralf, Florian, Frank, Gisi & Family, Katja, Simone, Susanne and Ute.

Science is organized knowledge.  
Wisdom is organized life.

I. Kant

# Abstract

Nitrous oxide is the third most important gas contributing to global warming and its concentration in the atmosphere is still on the rise. Nitric acid production represents the largest source of  $\text{N}_2\text{O}$  in the chemical industry, with a total annual emission of about 400 kt  $\text{N}_2\text{O}$ . An efficient way to reduce the  $\text{N}_2\text{O}$  is the catalytic decomposition into  $\text{N}_2$  and  $\text{O}_2$ . ZSM-5 zeolites containing iron are known to be effective in this reaction involving Fe(II)-extraframework species as active sites. But the nature of these sites and the reaction network is still under debate. Often the  $\text{N}_2\text{O}$  is in the exhaust together with other gases like  $\text{NO}_x$ ,  $\text{CO}_x$ , oxygen, and water vapor, which may influence the catalyst efficiency towards  $\text{N}_2\text{O}$  decomposition. The effect of these gases on the reaction mechanism is still not understood yet.

The aim of this work is to study the decomposition mechanism of  $\text{N}_2\text{O}$  over isomorphously substituted Fe-ZSM-5 (0.02-0.55% Fe) using transient response methods. Kinetic studies under steady-state conditions give overall information about the reaction, whereas transient experiments lead to information on the individual steps and the possibility to suggest a reaction model. Transient response methods are applied in vacuum using a Temporal Analysis of Products (TAP) setup and at ambient pressure using a Micromeritics AutoChem 2910 analyzer. The influence of different gases such as  $\text{NO}$ ,  $\text{H}_2\text{O}$  and  $\text{NO}_2$  on the decomposition of  $\text{N}_2\text{O}$  over Fe-ZSM-5 is investigated to gain insight into their effect on this reaction.

The TAP multifunctional reactor system is used to perform transient pulse experiments for micro-kinetic analysis of complex heterogeneous catalytic reactions. This setup allows to dose precisely reactants and to monitor product formation with sub-millisecond time resolution implying the absence of external mass or heat transfer. A reproducible low hydroxylation level of the catalyst can be attained in vacuum. The results from the transient responses with the Micromeritics analyzer are obtained under conditions more relevant to “*operando*”.

The mechanism of  $\text{N}_2\text{O}$  decomposition over Fe containing ZSM-5 was studied by transient response methods at ambient pressure with the Micromeritics analyzer and

under vacuum with the TAP setup. Both approaches showed that the mechanism strongly depends on the reaction temperature, but in all cases involves atomic oxygen loading from  $N_2O$  with  $N_2$  evolution as the first reaction step. The surface oxygen,  $(O)_{Fe}$ , formed from  $N_2O$  possesses very high reactivity and oxidizes CO to  $CO_2$  already at 373 K. A complete saturation of the active sites can be reached by the catalyst exposure to  $N_2O$  at low temperatures ( $T < 600$  K in vacuum,  $T < 523$  K at ambient pressure). Under these conditions oxygen is stored and does not desorb. On that basis, the concentration of sites active for the surface atomic oxygen loading from  $N_2O$  is determined by pulse experiments using the TAP setup. The concentration of active sites is found to be the same as in a flow experiment with the Micromeritics analyzer.

The mechanism of surface atomic oxygen recombination and desorption as  $O_2$  depends on the temperature. At temperatures higher than 773 K, the mechanism probably involves direct  $(O)_{Fe}$  recombination. The investigation of the response profiles upon  $N_2O$  pulses at 803 K evidences the  $O_2$  formation is the rate-determining step since the oxygen desorption is found to be slow compared to  $N_2O$  and  $N_2$ . Furthermore, a fit of the oxygen desorption curve corresponded to a first order dependence on the oxygen surface coverage.

In the range of 523 to 773 K, the  $O_2$  formation is facilitated by NO, which is formed on the catalyst surface from  $N_2O$ . The addition of NO to the gas phase confirmed the accelerating effect of NO on the oxygen desorption. NO and  $(O)_{Fe}$  are adsorbed on adjacent, but different sites and are not competing for the same ones. Adsorbed NO accommodates oxygen from  $N_2O$  forming higher oxidized nitrogen oxide species  $NO_2/NO_3$  which decompose back to  $NO_{ads}$  and molecular oxygen. Thus, the recombination of surface oxygen loaded from  $N_2O$  is accelerated by a  $NO/NO_x$  redox cycle whereas adsorbed  $NO_x$  acts as co-catalyst.

Adsorbed NO is oxidized by  $N_2O$  easily as shown also by temperature-programmed desorption (TPD) experiments. Therefore, the interaction of gaseous  $NO_2$  with Fe-ZSM-5 at 523 K in vacuum and at ambient pressure is investigated and demonstrates the formation of two different  $NO_x$  surface species accompanied by the evolution of gaseous NO. These surface species block the sites for oxygen loading from  $N_2O$  whereas the amount of reversible adsorbed  $N_2O$  stays constant compared to the standard pre-treated catalyst. The formation of reactive surface oxygen from  $NO_2$  could neither be evidenced in TPD nor with CO oxidation experiments.

Adsorbed water strongly influences the  $N_2O$  decomposition inhibiting it completely, at least at temperatures  $\leq 673$  K. Water pulses at 523 and 593 K result in partial desorption of the loaded atomic surface oxygen as  $O_2$ , indicating the competition of water for the same adsorption sites. The residual adsorbed oxygen desorbs during TPD experiments at 849 K instead of 715 K for the dry catalyst and it can not oxidize CO to  $CO_2$ . It means that the active sites are transformed into an inactive form in the

presence of water. The oxygen which stays on the catalyst seems to participate in the Fe(II) oxidation to the hydroxylated Fe(III) species. These Fe(III) species are inactive in N<sub>2</sub>O decomposition and could be activated again by high temperature treatment in He or in vacuum.

During TAP experiments only small amounts of water are dosed and the water desorption is facilitated due to vacuum. Therefore, the effect of water could be shown to be reversible at temperatures > 700 K. At 803 K oxygen desorbs significantly faster with increasing water amount suggesting a water assisted O<sub>2</sub> desorption. Simultaneously, the catalyst activity decreases to about a half of the initial activity of the dry zeolite.

To conclude, from the TAP reactor data obtained under vacuum conditions and the results from the transient flow experiments at ambient pressure it follows that the mechanism of the N<sub>2</sub>O decomposition over Fe-containing ZSM-5 depends strongly on the reaction temperature and on the presence of NO, H<sub>2</sub>O and NO<sub>2</sub>. In general, below 523 K only surface atomic oxygen loading from N<sub>2</sub>O takes place with simultaneous evolution of N<sub>2</sub> in the gas phase. The O<sub>2</sub> formation proceeds via direct (O)<sub>Fe</sub> recombination at temperatures above 773 K. In the range of 523 to 773 K, the recombination of the atomic oxygen involves NO<sub>x</sub> adsorbed on the catalyst surface.

# Version abrégée

Le protoxyde d'azote est le troisième gaz le plus important contribuant à l'effet de serre et sa concentration dans l'atmosphère ne cesse d'augmenter. La production d'acide nitrique est la plus grande source industrielle de  $N_2O$  répandue dans l'environnement, avec un total d'émission annuel proche de 400 kt. Une alternative efficace pour réduire cette valeur est la décomposition de ce gaz en  $N_2$  et  $O_2$ . La zéolithe ZSM-5 contenant du fer est connue pour être un bon catalyseur de cette réaction impliquant du Fe(II) hors maille cristalline comme sites actifs. Cependant la nature de ces sites ainsi que le mécanisme réactionnel est encore débattu. Souvent, le  $N_2O$  libéré dans les gaz industriels est mélangé avec d'autres gaz comme les  $NO_x$ , les  $CO_x$ , l'oxygène et la vapeur d'eau qui peuvent avoir une influence non négligeable sur l'efficacité du catalyseur. Les effets de ces gaz sur le mécanisme de décomposition du  $N_2O$  ne sont encore pas bien compris.

L'objectif de ce travail est d'étudier le mécanisme de la décomposition du  $N_2O$  sur de la zéolithe Fe-ZSM-5, substituée de manière isomorphe (0.02-0.55% Fe), par des méthodes de réponses transitoires. Les études cinétiques à l'état stationnaire donnent des informations générales sur la réaction alors que les expériences transitoires amènent des informations sur les étapes individuelles si bien qu'il devient possible de suggérer un schéma réactionnel. Les méthodes de réponses transitoires sont effectuées sous vide à l'aide d'un système TAP (Temporal Analysis of Product) et à pression ambiante avec un analyseur Micromeritics Autochem 2910. L'influence des différents gaz comme le  $NO$ , le  $H_2O$  et le  $NO_2$  dans la décomposition du  $N_2O$  sur la Fe-ZSM-5 est examinée afin de connaître leur effet sur cette réaction.

Le système réactionnel multifonctionnel TAP est utilisé pour effectuer des expériences d'injection transitoire pour une analyse de la micro-cinétique des réactions catalytiques hétérogènes complexes. Cette installation permet de doser précisément les réactants et de mesurer la formation des produits dans une résolution de l'ordre de la milliseconde sans limitation de transfert de masse externe et de transfert de chaleur externe. Un niveau faible d'hydroxylation du catalyseur peut être atteint de manière

reproductible sous vide. Les résultats obtenus par méthode transitoire avec l'analyseur Micromeritics concernent des conditions plus "*operando*".

Le mécanisme de décomposition du  $N_2O$  sur de la ZSM-5 contenant du fer est étudié par la méthode des réponses transitoires à pression ambiante avec l'analyseur Micromeritics et sous vide avec l'installation TAP. Les deux approches ont montré que le mécanisme dépendait beaucoup de la température, mais dans tous les cas, la première étape est la déposition de l'oxygène atomique à partir du  $N_2O$  produisant alors du  $N_2$ . L'oxygène à la surface,  $(O)_{Fe}$ , formé à partir du  $N_2O$  possède une très haute activité et oxyde le CO en  $CO_2$  déjà à 373 K. Une saturation complète des sites actifs peut être atteinte lors de l'exposition du catalyseur au  $N_2O$  à basses températures ( $T < 600$  K sous vide,  $T < 523$  K à pression atmosphérique). Sous ces conditions, l'oxygène s'accumule car il ne parvient pas à désorber. Sur cette base, il est possible de déterminer la concentration des sites actifs à la décomposition du  $N_2O$  en effectuant une série d'injections grâce à l'installation TAP. Cette concentration de sites actifs mesurée est identique à celle estimée lors des expériences avec l'analyseur Micromeritics.

Le mécanisme de recombinaison de l'oxygène atomique à la surface du catalyseur ainsi que la désorption de l' $O_2$  dépend de la température. Aux températures plus hautes que 773 K, le mécanisme implique probablement une association directe des  $(O)_{Fe}$ . L'observation des profils due à l'injection de  $N_2O$  à 803 K met en évidence que la formation de l' $O_2$  est l'étape limitante comme la désorption de l'oxygène est lente comparée à la disparition du  $N_2O$  et la libération du  $N_2$ . En outre, la tendance de la courbe de désorption de l'oxygène correspond à une dépendance du premier ordre en fonction de la quantité d'oxygène à la surface.

Entre 523 et 773 K, la formation d' $O_2$  est facilitée par le NO, qui est formé à la surface du catalyseur à partir de la décomposition du  $N_2O$ . L'addition du NO dans la phase gazeuse confirme l'effet accélérateur de ce gaz sur la désorption de l'oxygène. Le NO et  $(O)_{Fe}$  sont adsorbés sur des sites différents mais adjacents et ne rentrent pas en compétition. Le NO adsorbé permet à l'oxygène du  $N_2O$  de former différentes espèces d'oxyde d'azote  $NO_2/NO_3$  qui se décomposent ensuite en  $NO_{ads}$  et en oxygène moléculaire. Ainsi, l'association de l'oxygène adsorbé à la surface déposé par le  $N_2O$  est accélérée par un cycle redox  $NO/NO_x$  où le  $NO_x$  adsorbé agit comme co-catalyseur.

Le NO adsorbé est oxydé facilement par le  $N_2O$  comme le démontre les expériences TPD (Temperature-Programmed Desorption). Par conséquent, les interactions du  $NO_2$  gazeux avec la Fe-ZSM-5 à 523 K, sous vide et à pression atmosphérique, ont été étudiées et démontrent la formation de deux espèces  $NO_x$  différentes à la surface qui accompagnent la formation du NO gazeux. Ces espèces à la surface bloquent les sites pour la déposition de l'oxygène du  $N_2O$  tandis que la quantité de  $N_2O$  adsorbé de façon réversible reste constante en comparaison avec le catalyseur prétraité de façon standard. La formation de l'oxygène actif à la surface à partir du  $NO_2$

ne peut être mise en évidence ni par les mesures TPD ni par les expériences d'oxydation du CO.

L'adsorption de l'eau influence fortement la décomposition du  $N_2O$  jusqu'à l'inhiber complètement à des températures plus faibles que 673 K. Les résultats de l'injection d'eau à 523 et 593 K entraînent une désorption partielle de l'oxygène atomique à la surface en  $O_2$ , ce qui démontre une compétition pour les mêmes sites. L'oxygène résiduel désorbe lors des mesures TPD à une température de 849 K au lieu de 715 K dans le cas d'un catalyseur sec et ne peut pas oxyder le CO en  $CO_2$ . Cela signifie que les sites actifs sont désactivés en présence d'eau. L'oxygène restant sur le catalyseur semble participer à l'oxydation du Fe(II) à la forme hydroxylée Fe(III). Ces espèces Fe(III) sont inactives à la décomposition du  $N_2O$  mais peuvent être réactivées par un traitement à haute température sous hélium ou sous vide.

Durant les expériences avec l'installation TAP, seule une faible quantité d'eau est mesurée et sa désorption est facilitée par la faible pression interne du système. Par conséquent, les effets de l'eau peuvent être démontrés comme étant réversibles aux températures inférieures à 700 K. À 803 K l'oxygène désorbe sensiblement plus rapidement en présence d'eau ce qui peut indiquer un mécanisme de formation de l'oxygène gazeux assistée par l'eau. Simultanément, l'activité du catalyseur diminue de moitié par rapport à l'activité initiale de la zéolite sèche.

Pour conclure, les résultats obtenus sous vide par le réacteur TAP ainsi que par les flux transitoires sous pression ambiante, il s'ensuit que le mécanisme de la décomposition du  $N_2O$  sur la ZSM-5 contenant du fer dépend fortement de la température ainsi que de la présence de certains constituants dans la phase gazeuse comme le NO, le  $H_2O$  et le  $NO_2$ . En règle générale, à une température inférieure à 523 K, seule la déposition de l'oxygène prend place en même temps que la formation du  $N_2$  lors de la décomposition du  $N_2O$ . La formation de  $O_2$  s'effectue via une recombinaison directe de  $O(Fe)$  aux températures supérieures à 773 K. Entre ces deux températures (523 à 773 K), la recombinaison de l'oxygène atomique implique du  $NO_x$  adsorbé sur la surface du catalyseur.

# Chapter 1

## INTRODUCTION

$\text{N}_2\text{O}$  is a very potent greenhouse gas due to its longevity in the earth's atmosphere and its special adsorption properties for infrared radiation [1-4]. Any concentration perturbation that occurs will last for centuries. One metric ton of nitrous oxide has the same effect in the atmosphere as 310 metric tons of  $\text{CO}_2$ . Nitrous oxide is thus part of efforts to reduce greenhouse gas emissions, such as the Kyoto Protocol [5]. Nitrous oxide is the third most important gas that contributes to global warming behind carbon dioxide and methane. Nitrous oxide also destroys ozone in the stratosphere, aggravating the excess amount of UV light striking the earth's surface in recent decades [6-8].

The recently published Fourth Assessment Report of the Intergovernmental Panel of Climate Change stated that the warming of the climate system is unequivocal [9]. The global atmospheric  $\text{N}_2\text{O}$  concentration increased from a pre-industrial value of about 270 ppb to 319 ppb in 2005 and its concentration is still on the rise. More than a third of all nitrous oxide emissions are anthropogenic and are primarily due to agriculture, but control of these emissions is difficult due to the very diffuse nature of  $\text{N}_2\text{O}$  emissions. However,  $\text{N}_2\text{O}$  emissions that can be reduced in the short term are associated with chemical production and energy industry [10-12]. 35% of the  $\text{N}_2\text{O}$  emission in the European Union is concentrated in a limited number of large  $\text{N}_2\text{O}$  sources, which holds promise for an economic and efficient reduction strategy to fulfill

the Kyoto commitment. Nitric acid production represents the largest source of  $\text{N}_2\text{O}$  in the chemical industry, with a global annual emission of 400 kt  $\text{N}_2\text{O}$  [13].

An efficient way to reduce the  $\text{N}_2\text{O}$  emission is its catalytic decomposition into  $\text{N}_2$  and  $\text{O}_2$ . ZSM-5 zeolites containing iron are known as promising catalysts. The reaction involves iron complexes stabilized in the ZSM-5 matrix and proceeds via surface atomic oxygen and gaseous nitrogen formation from  $\text{N}_2\text{O}$ . This reaction takes place at temperatures lower than 600 K. Oxygen recombines only at higher temperatures indicating the in general accepted rate-limiting step in  $\text{N}_2\text{O}$  decomposition the desorption of oxygen from the catalyst surface [14-16]. The catalyst activity is known to be sensitive to the presence of other gases like  $\text{H}_2\text{O}$ ,  $\text{NO}$ , hydrocarbons,  $\text{CO}$ , etc. The addition of gaseous  $\text{NO}$  enhances the activity of Fe containing zeolites [14, 16-18] while their activity is diminished in the presence of water vapors [14]. Slow  $\text{NO}$  formation on the catalyst surface from  $\text{N}_2\text{O}$  interaction is observed over Fe- and Cu-zeolites [19-23].  $\text{NO}/\text{NO}_2$  [16, 18, 24] as well as nitrite/nitrate [25] redox cycles are proposed for active sites regeneration in  $\text{N}_2\text{O}$  decomposition apart from direct recombination from atomic surface oxygen related to a Fe(II)/Fe(III) redox cycle.

The Fe-ZSM-5 catalyst shows no inhibition by oxygen, since it does not react with the active iron sites [26]. Only  $\text{N}_2\text{O}$  can oxidize the Fe(II) sites to Fe(III) upon formation of so-called " $\alpha$ -oxygen" [27, 28]. The atomic surface oxygen deposited from  $\text{N}_2\text{O}$  on Fe-ZSM-5 exhibits a very high, unusual reactivity. The active oxygen rapidly exchanges with  $^{18}\text{O}_2$  at 523 K, whereas Fe-ZSM-5 that is not treated with  $\text{N}_2\text{O}$  is completely inactive for the isotope exchange at that temperature [26, 29]. It oxidises  $\text{CO}$  and  $\text{H}_2$  even at low temperature ( $\sim 373$  K) [26, 30]. Furthermore, it is shown to insert into C-H bonds analog to the enzyme methane monooxygenase (MMO) [27, 29, 31, 32], converting methane to methoxy species at room temperature [29, 33-36] and oxidising benzene to phenol [37, 38].  $\alpha$ -oxygen possesses a high potential as selective oxidant.

The aim of this work is to study the mechanism of the decomposition of  $\text{N}_2\text{O}$  over isomorphously substituted Fe-ZSM-5 (0.02-0.55% Fe) using transient response methods. Transient experiments have the potential to provide considerably more information than steady-state experiments. Whereas steady-state experiments give an integrated picture of a reaction system, transient experiments give information on individual steps. The elucidation of the detailed mechanism of heterogeneous catalysis serves to establish the underlying elementary steps for reaction models which are very valuable in the catalyst development process.

The Temporal Analysis of Products (TAP) multifunctional reactor system is an apparatus that is used to perform transient pulse experiments for micro-kinetic analysis of complex heterogeneous catalytic reactions. The TAP reactor system was developed in 1988 by John T. Gleaves and co-workers for the advancement of industrial heterogeneous catalysts [39, 40]. It has been extensively applied in experimental studies

on catalytic reaction mechanisms and other surface processes [41-46]. The setup is very suitable to dose precisely reactants, to study product sequences with sub-millisecond time resolution and to dehydroxylate the catalyst in vacuum implying the absence of external mass or heat transfer. Hydroxylation is well known to influence the ZSM-5 activity for  $\text{N}_2\text{O}$  decomposition in a negative way [47-49], falsifying mechanistic observations which can be minimized in TAP studies with vacuum conditions and small amounts of reactants. The influence of different test molecules such as NO,  $\text{H}_2\text{O}$  and  $\text{NO}_2$  on the decomposition of  $\text{N}_2\text{O}$  over Fe-ZSM-5 is investigated to gain supplementary mechanistic aspects.

The transient response method is also applied at atmospheric pressure using a Micromeritics AutoChem 2910 analyzer in order to obtain quantitative results and information on the reaction mechanism under more relevant industrial conditions. Mainly temperature and concentration perturbations are imposed on the catalytic system and useful information on the mechanism is gained from the resultant response.

# Chapter 2

## STATE OF THE ART

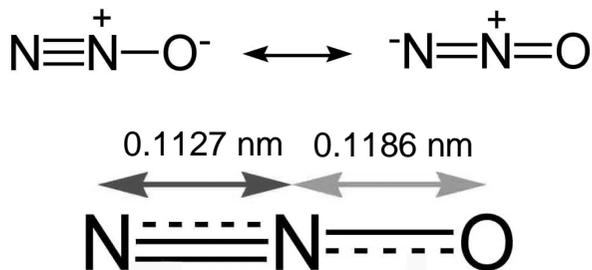

### 2.1. Characteristics of N<sub>2</sub>O

Nitrous oxide (dinitrogen oxide, N<sub>2</sub>O) is a colorless, non-flammable gas with a pleasant, slightly sweet odor under ambient conditions. It was discovered in 1772 by Joseph Priestly, who called it "diminished nitrous air", from the reduction of NO with iron or iron/sulphur mixtures [1]. Sir Humphrey Davy inhaled N<sub>2</sub>O during his medical training in 1799, as part of a study on the physiological effects of several newly discovered gases, and he discovered the ability of N<sub>2</sub>O to promote lightheadedness. It is used in surgery and dentistry for its anesthetic effects, where it is commonly known as laughing gas due to the euphoric effects of inhaling it.

N<sub>2</sub>O is a linear molecule that is isoelectronic to CO<sub>2</sub>. The electronic structure and geometrical structure can be understood in the context of the valence bond resonance forms shown in Figure 2.1. Bond distances determined from rotational spectroscopy measurements are given as well [2].

N<sub>2</sub>O is a very potent greenhouse gas due to its longevity in the earth's atmosphere and its special adsorption properties for infrared radiation [3-6]. The half-life of atmospheric N<sub>2</sub>O is estimated between 110 and 168 years [7, 8]. Thus, any concentration perturbation that occurs will last for centuries. One metric ton of nitrous oxide has the same effect in the atmosphere as 310 metric tons of CO<sub>2</sub>. Nitrous oxide is

thus part of efforts to curb greenhouse gas emissions, such as the Kyoto Protocol. Nitrous oxide is the third most important gas that contributes to global warming behind carbon dioxide and methane, which has 23 times the greenhouse warming potential of carbon dioxide (over 100 years). Nitrous oxide also destroys ozone in the stratosphere, aggravating the excess amount of UV light striking the earth's surface in recent decades [9-11].

**Figure 2.1:** Resonance forms of nitrous oxide and bond distances.

Nitrous oxide is naturally emitted by bacteria in soils and oceans. Agriculture is the main source of human-produced nitrous oxide: cultivating soil, the use of nitrogen fertilizers, and animal waste handling can all stimulate naturally occurring bacteria to produce more nitrous oxide. The livestock sector (primarily cows, chickens, and pigs) produces 65% of human-related nitrous oxide [12]. Industrial sources make up only about 20% of all anthropogenic sources, and include the production of nylon and nitric acid and the burning of fossil fuel in internal combustion engines.

$\text{N}_2\text{O}$  was until recently allowed to be emitted into the atmosphere without restrictions. However, after  $\text{N}_2\text{O}$  was recognized as a relevant greenhouse gas and designated as such in the Kyoto Protocol [13] limitations for  $\text{N}_2\text{O}$  emissions have been set from the legislation of signatory nations. Agriculture is a major anthropogenic source, but control of these emissions is difficult due to the very diffuse nature of  $\text{N}_2\text{O}$  emissions.  $\text{N}_2\text{O}$  emissions can be reduced in the short term with chemical production and the energy industry. The major industrial source of  $\text{N}_2\text{O}$  is the production of nitric acid (400 kt  $\text{N}_2\text{O}$  per year), which is a key bulk chemical in the fertilizer industry [14]. The greenhouse gas effect as well as possibilities to limit the  $\text{N}_2\text{O}$  emission of chemical production plants and combustion processes is discussed in the following sections.

Nitrous oxide is applied in medical and dental use, as food additive e. g. in whipped cream and for filling packages of potato chips as well as oxidiser in rocket engines. There are a number of selective oxidation reactions with  $\text{N}_2\text{O}$  over iron containing MFI type zeolites. An overview is given on studies which target to involve  $\text{N}_2\text{O}$  into organic synthesis as an oxidant in section 2.1.3.

### 2.1.1. The Greenhouse Effect

The natural greenhouse effect raises the temperature of the planet by 33 K, thus making it habitable. On average, 343 W/m<sup>2</sup> of sunlight fall on the earth, roughly 1/3 of which is reflected back into space. The other 2/3 reaches the ground, which re-radiates it as longer wavelength, infrared radiation. Some of this is blocked by greenhouse gases, thereby warming the atmosphere. Naturally occurring greenhouse gases include water vapor, carbon dioxide (CO<sub>2</sub>), methane (CH<sub>4</sub>) and nitrous oxide (N<sub>2</sub>O) [15].

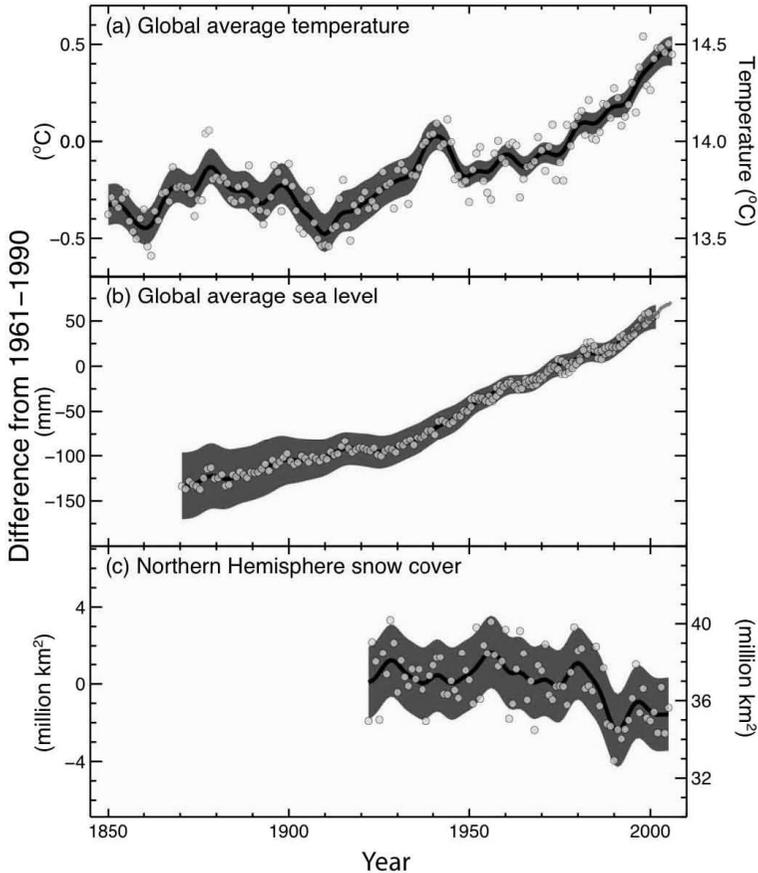

Human activity is emitting extra amounts of greenhouse gases, especially CO<sub>2</sub>, N<sub>2</sub>O, CH<sub>4</sub> and Chlorofluorocarbons (CFCs) which alter the amounts of radiation trapped by the atmosphere and so have an effect on climate. In order to be able to compare the effect of different gases in enhancing the greenhouse effect, a method has been developed of estimating their global warming potentials (GWP). The GWP index is the cumulative enhancement occurring between now and a chosen later time caused by a unit mass of the gas emitted now. It is a relative scale which compares the gas in question to that of the same mass of CO<sub>2</sub>, whose GWP is by definition 1. Some examples of Global Warming Potentials referenced to CO<sub>2</sub> are presented in Table 2.1. The GWP is based on a number of factors, including the radiative efficiency (heat-absorbing ability) of each gas relative to that of carbon dioxide, as well as the decay rate of each gas (the amount removed from the atmosphere over a given number of years) relative to that of carbon dioxide. GWPs have inherent uncertainties, because of the range of assumptions done for their calculation [5].

**Table 2.1:** Global Warming Potentials, referenced to CO<sub>2</sub> [5].

<i>Gas</i>	<i>GWP for various time horizons</i>		
	20 years	100 years	500 years
CO <sub>2</sub>	1	1	1
CH <sub>4</sub>	56	21	6.5
N <sub>2</sub> O	280	310	170
HFC-23	9100	11700	9800
HFC-32	2100	650	200
SF <sub>6</sub>	16300	23900	34900

The recently published contribution of Working Group I of the fourth assessment report of the Intergovernmental Panel on Climate Change (IPCC) clearly stated that warming of the climate system is unequivocal, as is now evident from observations of increases in global average air and ocean temperatures, widespread melting of snow and ice, and rising global average sea level illustrated in Figure 2.2 [16]. Eleven of the last twelve years (1995-2006) rank among the 12 warmest years in the instrumental record of global surface temperature (since 1850). Global average sea level

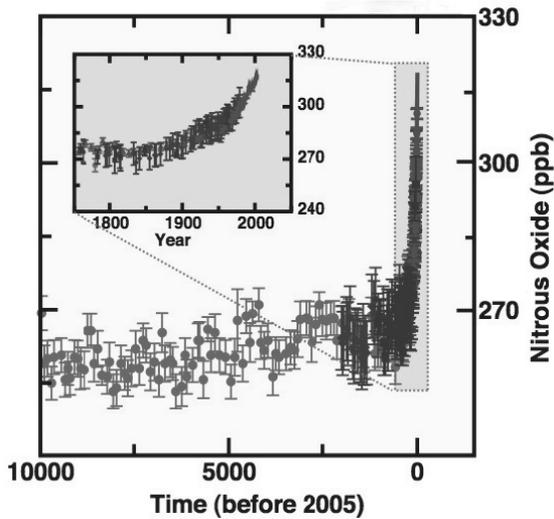

rose at an average rate of 1.8 mm per year over 1961 to 2003. The rate was faster over 1993 to 2003, about 3.1 mm per year. Mountain glaciers and snow cover have declined on average in both hemispheres.

**Figure 2.2:** Observed changes in global average surface temperature (a), global average sea level rise (b) and Northern Hemisphere snow cover for March-April (c). All changes are relative to corresponding averages for the period 1961-1990. Smoothed curves represent decadal averaged values while circles show yearly values. The shaded areas are the uncertainty intervals estimated from a comprehensive analysis of known uncertainties (a and b) and from the time series (c) [16].

Most of the observed increase in globally averaged temperatures since the mid-20<sup>th</sup> century is very likely due to the observed increase in anthropogenic greenhouse gas concentrations. Global atmospheric concentrations of CO<sub>2</sub>, CH<sub>4</sub> and N<sub>2</sub>O have increased markedly as a result of human activities since 1750 and now far exceed pre-industrial

values determined from ice cores spanning many thousands of years. The global increases in  $\text{CO}_2$  concentration are due primarily to fossil fuel use and land-use change, while those of  $\text{CH}_4$  and  $\text{N}_2\text{O}$  are primarily due to agriculture.  $\text{CO}_2$  is the most important anthropogenic greenhouse gas. The global atmospheric concentration of carbon dioxide has increased from a pre-industrial value of about 280 ppm to 379 ppm in 2005.  $\text{CH}_4$  concentration increased from 715 ppb to 1774 ppb and  $\text{N}_2\text{O}$  from 270 ppb to 319 ppb. The atmospheric concentration incline of  $\text{N}_2\text{O}$  over the last 10000 years is illustrated in Figure 2.3. The growth rate of  $\text{N}_2\text{O}$  has been approximately constant since 1980. More than a third of all nitrous oxide emissions are anthropogenic and are primarily due to agriculture [16].

**Figure 2.3:** Atmospheric concentration of  $\text{N}_2\text{O}$  over the last 10000 years and since 1750 (inset). Measurements are shown from ice cores and atmospheric samples [16].

For the next two decades a warming of about 0.2 K per decade is projected for a range of emission scenarios. Even if the concentrations of all greenhouse gases and aerosols had been kept constant at year 2000 levels, a further warming of about 0.1 K per decade would be expected. Continued greenhouse gas emissions at or above current rates would cause further warming and induce many changes in the global climate system during the 21<sup>st</sup> century that would very likely be larger than those observed during the 20<sup>th</sup> century. Anthropogenic warming and sea level rise would continue for centuries due to the timescales associated with climate processes and feedbacks, even if greenhouse gas concentrations were to be stabilized [16].

However, if the rate of climate change can be limited to a low level, then natural and human systems will find it easier to adapt. Therefore, an important way to slow the rate of change is to reduce emissions of greenhouse gases. The second assessment report of the Intergovernmental Panel on Climate Change (IPCC 1996) formed the basis of negotiations over Kyoto Protocol. The Kyoto Protocol to the United Nations Framework Convention on Climate Change is an amendment to the international treaty on climate change, assigning mandatory targets for the reduction of greenhouse gas emissions to signatory nations. The Kyoto Protocol is an agreement made under the United Nations Framework Convention on Climate Change (UNFCCC) [13]. Countries that ratify this protocol commit to reduce their emissions of carbon dioxide and five other greenhouse gases ( $\text{CH}_4$ ,  $\text{N}_2\text{O}$ , HFCs, PFCs and  $\text{SF}_6$ ), or engage in emissions trading if they maintain or increase emissions of these gases. The objective is the stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system [17]. The Kyoto Protocol is an agreement under which industrialized countries will reduce their collective emissions of greenhouse gases by 5.2% compared to the year 1990 - calculated as an average over the five-year period of 2008-12. It should be mentioned that, compared to the emissions levels that would be expected by 2010 without the Protocol, this target represents a 29% cut. National limitations range from 8% reductions for the European Union and some others to 7% for the US, 6% for Japan, 0% for Russia, and permitted increases of 8% for Australia and 10% for Iceland. Possibilities for reduction of  $\text{N}_2\text{O}$  emission of chemical production and the energy industry are presented in the following section.

### 2.1.2. Reduction of $\text{N}_2\text{O}$ Emission from Industrial Sources

The major industrial source of  $\text{N}_2\text{O}$  is the production of nitric acid and contributes with a global annual emission of 400 kt to the global warming [14]. Therefore, the elimination of nitrous oxide from nitric acid plants can make an important contribution to the protection of the Earth's climate.  $\text{N}_2\text{O}$  is also produced during the manufacture of adipic acid, caprolactam, acrylonitrile, glyoxal, and in general organic syntheses using  $\text{HNO}_3$  as the oxidant or reactions involving ammonia oxidation.

The reduction of  $\text{N}_2\text{O}$  emissions from nitric acid plants would effectively contribute or even fulfil the Kyoto commitments of several European countries, which presents an extra motivation for the development of technology. Therefore, promising options to control  $\text{N}_2\text{O}$  emissions in nitric acid plants are pointed out in this section. The production of weak nitric acid is based on the Oswald process and consists of the following basic chemical operations [18]:

- Catalytic oxidation of ammonia with air to nitric oxide:

In a catalytic converter  $NH_3$  is mainly converted to  $NO$  (selectivity about 97%) and water using a platinum-rhodium gauze with a composition of 90% Pt and 10%Rh.  $N_2O$  (typically 1.5-2%) and  $N_2$  are formed as unwanted side-products:

- Oxidation of nitric oxide to nitrogen dioxide:

The nitrous gases are cooled to promote further oxidation to  $NO_2$ .  $NO$  reacts non-catalytically with residual  $O_2$  to form  $NO_2$  and its liquid dimer,  $N_2O_4$ . Operating at low temperatures and high pressures promotes maximum production of  $NO_2$  within a minimum reaction time.

- Absorption of nitrogen dioxide in water to produce nitric acid:

The cooled  $NO_2/N_2O_4$  mixture is introduced into an absorption process to produce weak nitric acid. The tail-gas leaving the absorber column at a temperature of 293-303 K contains  $N_2O$  and traces of  $NO_x$ . Typical values of the tail-gas composition at the outlet of the  $NO_2$  absorber are shown in Table 2.2.

**Table 2.2:** Composition of tail gas at the outlet of the  $NO_2$  absorber ( $N_2$  balance gas) for a nitric acid plant of 1500 ton  $HNO_3$  per day and tail gas flow of  $2 \cdot 10^5 \text{ Nm}^3/\text{h}$  [19].

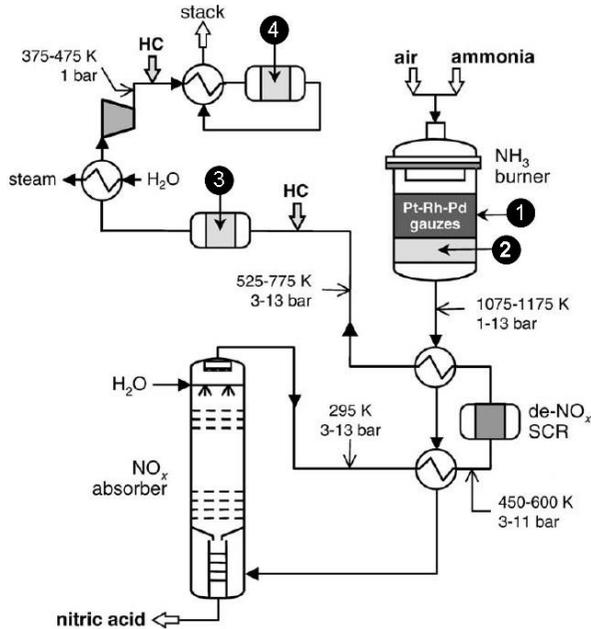

<i>Gas</i>	<i>Concentration</i>	
$NO_x$	100-3500 ppm	(200 ppm)
$N_2O$	300-3500 ppm	(1500 ppm)
$O_2$	1-4 vol%	(2.5 vol%)
$H_2O$	0.3-2 vol%	(0.5 vol%)

The tail gas is heated and used in a tail gas expander for energy recovery. For additional  $NO_x$  abatement a selective catalytic reduction (SCR) facility is in many cases incorporated up- or down stream the tail gas expander. The current technology for  $NO_x$

removal is selective catalytic reduction (SCR) using ammonia as a reductant and in many cases vanadium-pentoxide-type catalysts. Unfortunately, the conventional  $\text{NH}_3\text{-DeNO}_x$  catalysts do not reduce  $\text{N}_2\text{O}$  emissions [20]. The flowsheet of weak nitric acid production according to the dual-pressure configuration is presented in Figure 2.4. Techniques for  $\text{N}_2\text{O}$  abatement can be applied in the following locations in the nitric acid production process [21]:

- Preventing  $\text{N}_2\text{O}$  being formed in the ammonia burner (1)
- Removing  $\text{N}_2\text{O}$  from the  $\text{NO}_x$  gases between the ammonia converter and the absorption column (2)
- Process integrated upstream the tail gas expander (3)
- End-of-pipe downstream the tail gas expander (4)

The above listed locations of the different abatement technologies are marked in Figure 2.4 and will be discussed as follows.

**Figure 2.4:** Flowsheet of a dual-pressure nitric acid plant with the possible locations for  $\text{N}_2\text{O}$  abatement technologies [22].

The emission of  $\text{N}_2\text{O}$  depends exclusively on the ammonia combustions process. Once formed,  $\text{N}_2\text{O}$  passes unreacted through the plant and is not affected by the  $\text{NO}_2$  absorber or the after-treatment for  $\text{NO}_x$  removal of the tail gas. Production of  $\text{N}_2\text{O}$  can be minimized by optimizing the catalytic oxidation of  $\text{NH}_3$  to  $\text{NO}$ . However, the catalytic

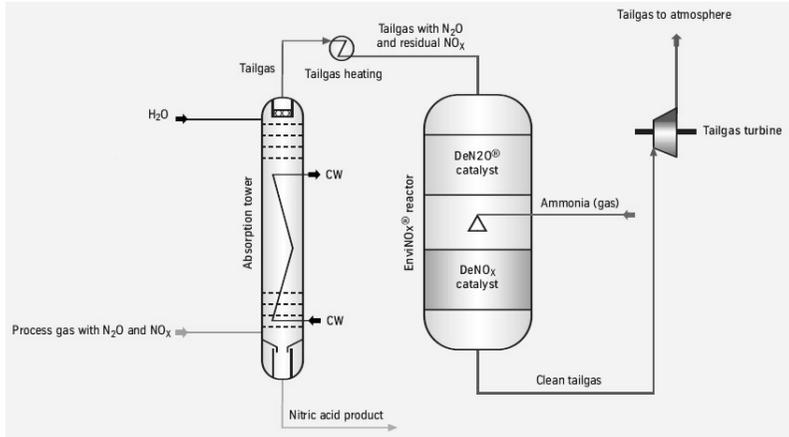

conversion process is already one of the most efficient processes known. An optimized NO yield is expected to be limited by changing any parameter.

The second abatement measure aims on the thermal or catalytic decomposition of  $N_2O$  in the high-temperature zone immediately downstream of the ammonia burner.  $N_2O$  is not stable at elevated temperature and pressure and will decompose if given time. Norsk Hydro, therefore, investigated the possibility to extend the reaction chamber of the oxidation reactor, thus, improving autonomous decomposition of  $N_2O$  [23]. Instead of increasing the reactor chamber, the decomposition of nitrous oxide can be promoted using a catalyst for selective decomposition. Possible drawbacks are that catalyst life may be short due to harsh conditions (temperature of 1075-1175 K and total pressure up to 13 bar) and that the selectivity to NO decreases, since NO decomposition may be also catalyzed. BASF reported 80 and 70% reduction of  $N_2O$  using Cu-based mixed oxide spinel during tests in dual-pressure and atmospheric pressure plants, respectively [24, 25]. Other companies are also investigating this option [26-28].

The third abatement possibility is the implementation of process integrated  $N_2O$  reduction measures upstream the tail gas expander, but behind the nitrogen oxides absorption section, which offers the advantage of not influencing the nitric acid production process. The pressure (3-13 bar) and especially the temperature (500-773 K) of the tail gas are essential parameters to determine the optimal process option. Thermal decomposition of  $N_2O$  in the tail gas is economically unfeasible since its temperature needs to be raised up to 1023-1273 K by external heat supply for the decomposition of only 1500 ppm  $N_2O$ .

At nitric acid plants with high-temperature tail-gases (700-773 K) direct catalytic decomposition of  $N_2O$  over a catalyst without addition of reducing agents is an attractive and economical option to reduce  $N_2O$  emissions. The use of Fe-ZSM-5 seems viable [14]. This catalyst shows no inhibition by oxygen and an improved activity in the presence of  $NO_x$ . However, water severely inhibits the reaction.

Uhde developed a process for the combined reduction of  $N_2O$  and  $NO_x$  emissions from nitric acid plants, called EnviNOx®. As seen in Figure 2.5 the central component is a so-called combi-reactor located between the tail gas heater and the tail gas turbine. It contains two catalyst beds operated at the same pressure and temperature, and a device for the intermediate addition of  $NH_3$ . In the first stage- the so-called De $N_2O$ ® stage-  $N_2O$  decomposition takes place over an iron zeolite under full  $NO_x$  load. In the second stage,  $NO_x$  reduction is effected using  $NH_3$  as a reduction agent, while  $N_2O$  abatement continues simultaneously. The concept requires a tail gas temperature of more than 673 K and was for the first time successfully implemented in a dual-pressure  $HNO_3$  plant in Linz, Austria [29].

**Figure 2.5:** Integration of the EnviNOx® reactor into the HNO<sub>3</sub> process [29].

Furthermore, non selective catalytic reduction (NSCR) has been developed for NO<sub>x</sub> removal and has shown to be capable of reducing N<sub>2</sub>O as well. A reducing agent like hydrogen, natural gas or naphtha is added and oxidised, aided by a Pd catalyst. First, all free oxygen in the tail gas is consumed and thereafter oxygen holding components like NO<sub>x</sub> and N<sub>2</sub>O to levels below 50 ppm, having an efficiency > 98%. The NSCR technology is already applied in the nitric acid industry, commercialized by GIAP especially in Russia and the USA. Disadvantageous is the high fuel consumption levels and high secondary emissions, slip of fuel occurs and when using CH<sub>4</sub> as a reductant, large amounts of CO are produced [21].

The selective catalytic reduction (SCR) of N<sub>2</sub>O with hydrocarbons as reducing agent has been investigated over Fe zeolites [20, 21, 29-32]. The use of hydrocarbons (e.g. propane, propene, natural gas) leads to an increase of the operation costs, due to the high cost associated with the reductant. Reduction of N<sub>2</sub>O with ammonia is also possible, but it generally requires higher temperatures than N<sub>2</sub>O reduction with hydrocarbons [33, 34]. Suppliers of N<sub>2</sub>O removal by SCR technology are ECN and Grande Paroisse [35, 36].

For low-temperature tail gases (500-523 K) a catalyst is required with high activity at low temperatures and stability in the presence of other gases in the feed such as NO<sub>x</sub>, H<sub>2</sub>O, O<sub>2</sub>, SO<sub>2</sub>. None of the catalysts proposed in literature show a good activity and stability in N<sub>2</sub>O conversion under realistic conditions of feed composition and space velocities [37, 38]. Additional extra-heat by a heat-exchanger or the addition of hydrocarbons as reducing agents is necessary.

As a fourth option the N<sub>2</sub>O abatement process can be located end-of-pipe downstream of the tail gas expander. The temperature level is moderate (373-473 K), well below the ignition temperature of all catalysts found. Therefore, in all cases pre-heating is required which makes it a costly and less favourable option. Also the pressure

is about atmospheric, so the volume of the equipment will be larger. However, limitations for retrofit are not so strict for end-of-pipe applications [21].

Combustion processes of fossil fuels, biomass and waste in fluidized-bed combustors (FBCs) also contribute significantly to  $\text{N}_2\text{O}$  emissions [39-42]. The low combustion temperature at which FBCs operate results in low emission levels of  $\text{NO}_x$ , which matches with the optimal conditions for sulphur-capture. Unfortunately, these benefits are connected to a strongly increased emission of  $\text{N}_2\text{O}$  [43]. Options to control  $\text{N}_2\text{O}$  emissions in fluidized-bed combustors are discussed [22]. The major requirement for a working catalyst is the tolerance of the catalyst against deactivation by  $\text{SO}_2$ . Fe-ZSM-5 can be used for direct  $\text{N}_2\text{O}$  decomposition, due to the promotion effect of  $\text{SO}_2$  on the reaction rate.

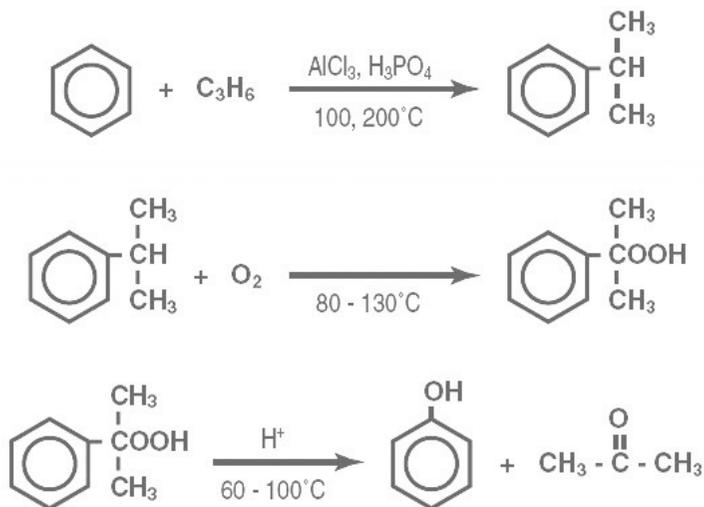

Catalytic and thermal abatement technologies have been successfully developed for adipic acid plants, due to the high  $\text{N}_2\text{O}$  concentrations in the tail gas (25-40 vol%) and the exothermicity of the  $\text{N}_2\text{O}$  decomposition reaction, a large increase in the temperature occurs within the catalyst bed [38, 40, 44]. The adiabatic temperature rise of the gas is considerable and renders a temperature range possible in which a large number of catalysts are effective.

### 2.1.3. $\text{N}_2\text{O}$ as an Oxidant

The selective oxidation of hydrocarbons is one of the most challenging fields of catalytic chemistry. The main difficulty is the creation of selective catalysts, which activate dioxygen generating some catalyst-bound oxygen species of a proper reactivity and activate the organic compound to direct the reaction to the desired products [45, 46]. The optimization of both these parameters simultaneously is a very difficult task, since one cannot tune them independently. For many catalytic oxidation reactions a reasonable selectivity has not been achieved so far and therefore complex multi-step processes are used instead.

$\text{N}_2\text{O}$  which was considered not very toxic but practically useless compound appeared to possess remarkable oxidation chemistry. A brief overview for  $\text{N}_2\text{O}$  as oxidant will be given.  $\text{N}_2\text{O}$  as an oxidant is very interesting in relation to phenol production, which is one of the most bulky chemicals with the annual world production exceeding 6 million tons. Theoretically, the selective oxidation could be done in a single step by adding oxygen to benzene. However, many attempts to accomplish this reaction were unsuccessful. Therefore, at present the cumene technology includes three steps as illustrated in Figure 2.6 [47]:

- Alkylation of benzene with propylene to produce cumene
- Oxidation of cumene to cumene hydroperoxide
- Decomposition of cumene hydroperoxide to phenol and co-product acetone

**Figure 2.6:** Main reactions for phenol and acetone production via cumene.

Despite its great success the cumene process has some disadvantages: a multi-step process, the formation of an explosive intermediate (cumene hydroperoxide), and co-production of acetone in 1:1 stoichiometry.

In 1983 the first use of  $\text{N}_2\text{O}$  for the oxidation of benzene over a vanadia catalyst was reported by Iwamoto et al. [48]:

**Figure 2.7:** Phenol production via benzene oxidation with  $\text{N}_2\text{O}$ .

At 823 K, the reaction selectivity exceeded 70%. This work has stimulated further efforts and in 1988 three groups of researchers [49-51] independently found ZSM-5 zeolites to be the best catalyst for the oxidation of benzene to phenol. The catalysts allowed the reaction to proceed at much lower temperature and with the

selectivity approaching 100%. The oxidation of benzene to phenol using  $N_2O$  as an oxidant has basically two benefits: one-step process and the formation of environmentally friendly molecular nitrogen as a by-product. Based on the direct oxidation of benzene by  $N_2O$ , Solutia Inc. and the Boreskov Institute of Catalysis (BIC) developed jointly a new phenol process, which uses a Fe-ZSM-5 catalyst and was called the AlphOx™ [52, 53].

Two different explanations are suggested for the nature of the catalytic activity of ZSM-5. One approach is based on the acidity of the zeolites with strong Brønsted and Lewis sites [54, 55]. The other one relates to the common oxidation catalysis, which might be provided by the presence of a transition metal. Iron was identified to be present in zeolites at least at the level of a few hundred ppm [56, 57]. Presently it is generally accepted that in the micropore space of the high silica zeolite matrix, iron can form some active sites, which catalyze the reaction and were called by Panov " $\alpha$ -sites" [52].

Furthermore, active oxygen deposited from  $N_2O$  on Fe-ZSM-5 was shown to be capable of converting methane to methoxy species at room temperature [58-62]. Upon heating, the methoxy species decompose without the formation of methanol. Methanol can be formed, however, by hydrolyzing the methoxy groups on the zeolite surface by washing the catalyst with water. The direct conversion of methane to useful chemical products has so far failed due to its severe thermodynamic stability. At present, to produce methanol, methane is first converted to a mixture of  $H_2$  and CO and after that the latter mixture is converted to methanol. However, the partial oxidation of methane to methanol area holds considerable potential for use of the large, worldwide reserves of natural gas.

The surface oxygen deposited from  $N_2O$  on Fe-ZSM-5 exhibits an extremely high reactivity. It oxidises CO and  $H_2$  even at low temperature ( $\sim 373$  K) [63, 64]. Panov et al. [52] gives an overview of data demonstrating the selectivities toward hydroxylation products obtained in the oxidation of various substrates with  $N_2O$  over zeolite catalyst. Quite good selectivities were achieved in the oxidative dehydrogenation of alkanes [65, 66] and in the epoxidation of propylene to propylene oxide [67, 68]. Liquid phase oxidation of alkanes with  $N_2O$  into carbonyl compounds can be applied to a variety of substrates including aliphatic, cyclic, heterocyclic alkenes and their derivatives. These reactions proceed non-catalytically in the temperature range of 423-523 K yielding ketones and aldehydes as the main products and are summarized by Panov et al. [52].

## 2.2. Mechanistic Aspects of N<sub>2</sub>O Decomposition

Mixed oxides, noble metals and transition metal exchanged zeolites [69, 70] are efficient catalysts for the direct decomposition of N<sub>2</sub>O into N<sub>2</sub> and O<sub>2</sub>. An overview of different catalysts is given in section 2.3 whereas more detailed information concerning preparation and activation are summarized for the Fe-ZSM-5 which was the only catalyst investigated in this study.

The decomposition of N<sub>2</sub>O over Fe-ZSM-5 involves iron containing sites, ( )<sub>Fe</sub>, and proceeds via surface atomic oxygen and gaseous nitrogen formation from N<sub>2</sub>O [56, 62-64, 71, 72]:

This reaction takes place at temperatures lower than 573 K. At temperatures higher than 573 K (O)<sub>Fe</sub> can recombine forming O<sub>2</sub>:

It is important that the oxygen formed at low temperatures (T < 573 K), called " $\alpha$ -oxygen" by Panov and co-workers [72, 73], possesses very high, unusual reactivity. The active oxygen rapidly exchanges with <sup>18</sup>O<sub>2</sub> even at room temperature, whereas Fe-ZSM-5 that was not treated with N<sub>2</sub>O is completely inactive for the isotope exchange at that temperature [58, 64]. Oxygen loaded from N<sub>2</sub>O on the catalyst surface converts CO to CO<sub>2</sub> [56, 63, 64, 74]. The most interesting property of  $\alpha$ -oxygen is that it can insert into a C-H bond. It selectively oxidizes benzene to phenol [47, 75], and it even converts methane to methanol [58-62]. The potential of  $\alpha$ -oxygen as selective oxidant is discussed in section 2.1.3.

The structure of the active sites has been much debated. They are Fe(II) sites, but they do not react with O<sub>2</sub> [64]. Only N<sub>2</sub>O can oxidize them to Fe(III) upon formation of  $\alpha$ -oxygen [72, 76]. The active sites were described as binuclear iron clusters [62, 77]. The proposal was partly based on the observation that the ratio of O/Fe was close to 0.5. A second argument made for the notion of a binuclear iron was due to its capability to insert into C-H bonds analog to the enzyme methane monooxygenase (MMO) [58, 72, 77, 78]. The active site of MMO consists of a binuclear iron core. It is interesting to note that the half of the active sites of a Fe-ZSM-5 are blocked by water and another half is still reactive toward N<sub>2</sub>O decomposition militating as well in favor of binuclear iron sites [56]. However, other studies suggested isolated iron sites [79-82] as well as FeO<sub>x</sub> nanoclusters and Fe<sub>3</sub>O<sub>4</sub> particles [82, 83, 79, 84]. In general, it can be stated that iron speciation strongly depends on the method of iron introduction and the subsequent

treatments [79, 83, 85-90]. Furthermore, an exact structural characterization of the active sites is extremely difficult since Fe-ZSM-5 with high Fe loading (1-6 wt%) is a very complex and heterogeneous material while iron zeolite samples with the larger part of active iron (~90%) are generated from a low integral iron loading (~0.01-0.1 wt%).

In literature two possible rate-determining steps for the N<sub>2</sub>O decomposition are discussed. Mechanistic studies have substantiated that O<sub>2</sub> formation is the rate-determining step in N<sub>2</sub>O decomposition over iron containing zeolites [56, 71, 91-96]. On the other side as rate-determining step in N<sub>2</sub>O decomposition over Fe-ZSM-5, the dissociation of N<sub>2</sub>O [97, 98] was suggested and the catalyst reduction by N<sub>2</sub>O [99-101]. The absence of an inverse dependence on O<sub>2</sub> partial pressure for the rate of N<sub>2</sub>O decomposition has led a number of authors to the conclusion that O<sub>2</sub> desorption is rapid and irreversible and consequently not rate-determining [64, 90, 97, 100, 102, 103]. Additionally, if O<sub>2</sub> desorption were rate-determining, the catalyst surface would be saturated with oxygen atoms and the N<sub>2</sub>O decomposition would be zero order in N<sub>2</sub>O partial pressure, in contrast to most experimental findings, which show that the rate of N<sub>2</sub>O decomposition is first order in N<sub>2</sub>O. However, Kiwi-Minsker et al. showed that the reaction kinetics was first order towards N<sub>2</sub>O during the transient period, and of zero order under steady-state conditions at 583 K [104]. This is in accordance with mechanistic studies using transient techniques, which have potential for providing deeper mechanistic insights into complex catalytic reactions and substantiated that O<sub>2</sub> formation is the rate-determining step in N<sub>2</sub>O decomposition over iron containing zeolites [71, 92-95].

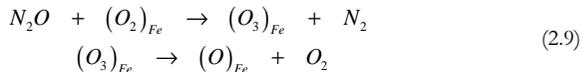

There is no consensus on the reaction pathways leading to gas-phase O<sub>2</sub>. A few authors concluded that O<sub>2</sub> formation occurs via the removal of adsorbed oxygen species by N<sub>2</sub>O [99-101]:

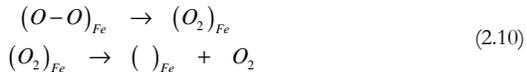

Atomic oxygen species deposited over iron sites can recombine [66, 71, 105] to give gas-phase O<sub>2</sub> according to the following equation.

Detailed mechanistic DFT investigations by Heyden et al. [97, 103] concluded that O<sub>2</sub> is formed via the decomposition of triatomic oxygen species yielding an iron site with monoatomic oxygen species (Equation (2.9)), which further participates in N<sub>2</sub>O decomposition.

Considering this reaction scheme, Kondratenko and Perez-Ramirez [94, 106] proposed upon micro kinetic analysis from transient experiments in the TAP reactor that adsorbed biatomic oxygen species undergo a transformation to another biatomic oxygen species, which ultimately desorbs as gas-phase  $O_2$  as in the following equations:

Evidence was presented that adsorbed NO and  $NO_x$  species are also formed during  $N_2O$  interaction with iron containing zeolites [71, 91, 107-110]:

Adsorbed NO species are slowly accumulated on the surface of Fe-ZSM-5 catalyst with low iron content and strongly affect the dynamics of  $N_2O$  decomposition, leading to an increase of the reaction rate with time [71, 104, 110]. This autocatalytic behavior was related to the facilitation of atomic oxygen recombination/desorption [74]. A considerable increase of the  $N_2O$  decomposition rate upon NO introduction to the reaction mixture was reported by different studies [92, 95, 100, 111, 112]. NO is proposed to act as an intermediate oxygen storage. Adsorbed NO on the catalyst reacts with the oxygen atom that  $N_2O$  deposits on the catalyst surface and forms adsorbed  $NO_2$  (Equation (2.12)).  $O_2$  desorption occurs by recombination of the second deposited oxygen atom with an oxygen atom from  $NO_2$  (Equation (2.13)).

The role of NO in the cycle is purely catalytic. Adsorbed NO may even facilitate the migration of atomic oxygen to enhance their recombination [92, 113]. NO/ $NO_2$  [74, 92, 111] as well as nitrite/nitrate [114] redox cycles are proposed for active sites regeneration in  $N_2O$  decomposition. Surface NO can be further oxidized to adsorbed  $NO_2$  species [91, 92, 95, 110, 115, 116]. They are proposed to participate in the catalytic cycle and function as intermediate oxygen storage.

## 2.3. Catalysts for N<sub>2</sub>O decomposition

The catalytic decomposition of N<sub>2</sub>O into its elements can be carried out with varying degrees of efficiency by mixed oxides, noble metals and transition metal exchanged zeolites [69, 70]. Zeolites are unique matrices allowing the stabilization of small metal complexes, which can barely form over more open surfaces. Fe-zeolites of various framework types (MFI, BEA, FER, MOR, FAU) [85, 109, 117-120], compositions (silicates, titanosilicates, aluminosilicates, gallosilicates, borosilicates, germanosilicates) [121] and containing transition metals especially Fe, Co and Cu [69, 70, 100, 113, 122] and noble metals such as Pt, Rh, Ru [69, 70, 123] are studied.

A significant effect of the framework type of zeolites on the catalytic activity was observed. Pentasil-type frameworks (BEA, FER, MFI) loaded with iron are more efficient catalysts for direct N<sub>2</sub>O decomposition than other zeolites such as MOR, FAU, MAZ, and OFF [33, 124, 125].

Platinum [126-128], rhodium [126, 129, 130] and Pt-Rh alloys [129, 131] are studied in N<sub>2</sub>O decomposition. Noble metal catalysts have very high intrinsic activities for N<sub>2</sub>O decomposition [70]. But in the exhaust gas stream for adipic and nitric acid plants, N<sub>2</sub>O is present together with NO and other components, such as O<sub>2</sub>, H<sub>2</sub>O and SO<sub>2</sub>. Most noble metal catalysts are strongly deactivated by the presence of these other components, particularly NO [69, 132]. Iron zeolites show the opposite behavior a remarkable activity and stability for nitrous oxide decomposition in the presence of these poisons for other catalysts. This includes the insensitivity to O<sub>2</sub>, the positive effect of NO and SO<sub>2</sub> on the rate of N<sub>2</sub>O conversion and an acceptable resistance towards deactivation by H<sub>2</sub>O [22, 132-134].

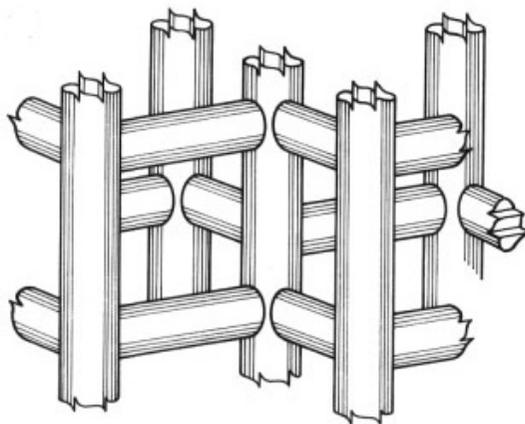

A synergism for N<sub>2</sub>O decomposition between Fe and Ru or Rh, loaded in high-silica zeolites was reported [135, 136]. Such bimetallic mordenite and ferrierite catalysts have also shown considerable N<sub>2</sub>O decomposition activity in the presence of NO [136]. However, the most studied catalyst for N<sub>2</sub>O decomposition into N<sub>2</sub> and O<sub>2</sub> is Fe-ZSM-5. The zeolite possesses excellent activity and selectivity in direct N<sub>2</sub>O decomposition and generates with N<sub>2</sub>O a very efficient oxidant at low temperatures [66].

### 2.3.1. ZSM-5 Zeolite

Zeolites, in a narrow definition, are porous crystalline aluminosilicates having a uniform pore structure and exhibiting ion-exchange behaviour. The framework of zeolites consists of SiO<sub>4</sub> and AlO<sub>4</sub> tetrahedron sharing oxygen ions located at their apices [137]. Since aluminium is trivalent, every AlO<sub>4</sub> unit carries a negative charge, which is compensated by a positive charge associated with a cation, usually protons or metal

cations from the I and II main group. The topology of the framework defines a structure type symbolized by group of three letters, e.g., MFI for the structure type of zeolite ZSM-5. A list of the ~130 currently accepted structure types, with their type materials, can be found in the Atlas of Zeolite Framework Types [138]. The description and classification of the topology of zeolites is based on the concept of larger units known as secondary building units (SBU) [138].

Pentasil zeolites with five-membered rings as secondary building unit are a class of industrially important molecular sieves. Synthetic materials with the MFI (Mobile Five) structure are the most prominent examples and have also been employed in the present work. The hollow tube model of the pore structure of the MFI structure is presented in Figure 2.8. The MFI-type topology shows a three-dimensional channel system. Due to its sorption and catalytic properties, ZSM-5 arouse great interest. It is a high-silica zeolite with Si/Al larger than ca. 7 first reported in 1972 by Argauer and Landolt in the Mobile Oil Corporation laboratories [139]. The all-silica end member is called silicalite-1 and was synthesized by Flanigen et al. in 1977 [140].

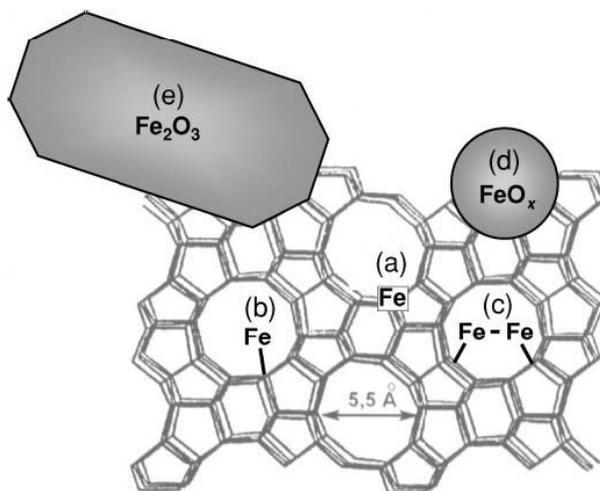

**Figure 2.8:** Channel system of MFI framework structure [141].

The pore system of ZSM-5 is of intermediate size and consists of channels formed by puckered 10-membered rings. Straight parallel channels with nearly circular cross section ( $d_p \approx 0.55$  nm) are linked together by zig-zag shaped continuous pores with elliptical shape ( $0.52 \times 0.58$  nm) and ten-ring apertures perpendicular to the channels, resulting in a three-dimensional cavity system. The framework density is  $1.8$  g/cm<sup>3</sup> and the specific micropore volume is  $0.19$  ml/g [142].

### 2.3.2. Preparation of Iron Containing ZSM-5

The preparation procedure of iron zeolites strongly influences the nature and distribution of iron species in the final material and the associated catalytic performance. Iron zeolites can be prepared by introducing the iron into the zeolite framework during the synthesis, so called hydrothermal synthesis, and into the zeolite matrix by post-synthesis modification. Depending on the preparation method iron species of different nature are produced and illustrated in Figure 2.9. These include isolated ions either (a) in framework positions (isomorphously substituted) or (b) in cationic positions in the zeolite channels, (c) binuclear and, in general, oligonuclear iron complexes in extra-framework positions, (d) iron oxide  $\text{FeO}_x$  nanoparticles of size  $\leq 2$  nm, and (e) larger iron oxide particles ( $\text{Fe}_2\text{O}_3$ ) in a wide distribution (up to 25 nm in size) located at the surface of the zeolite crystal [83, 82, 84].

**Figure 2.9:** Schematic representation of the different Fe species identified in Fe-ZSM-5 [84].

Isomorphously substituted ZSM-5 is prepared by hydrothermal synthesis. Iron is incorporated in the crystalline lattice located in tetrahedral position. An iron source such as  $\text{Fe}(\text{NO}_3)_3$ ,  $\text{FeCl}_3$  is either explicitly added to the synthesis solution [143, 144, 72] or a "natural" impurity level of Fe is incorporated into the zeolite framework. ZSM-5 contains about 200 ppm Fe from the synthesis with deionized water and 70 ppm Fe using bidistilled water, respectively [56]. The method guarantees a high dispersion of iron which results in selective and stable catalysts for  $\text{N}_2\text{O}$  decomposition.

By post-synthesis modification, iron is introduced into the zeolite matrix by gas-phase [145-147], aqueous [82] and solid-state [142, 82, 148, 144] ion exchange using different types of Fe-salts. Framework  $\text{AlO}_4$  units carry a negative charge which is compensated by a positive charge associated with a cation. This cation is replaced by iron with the ion-exchange method. The ion-exchange capacity of a zeolite depends on the chemical composition, i.e., a higher ion-exchange capacity is observed in zeolites of low  $\text{SiO}_2/\text{Al}_2\text{O}_3$  ratio. The specific ion-exchange capacity varies with the structure of the zeolite and the exchange cation. During preparation of Fe-ZSM-5 by wet ion exchange (WIE), only about the half of the full exchange capacity was achieved without the formation of small iron oxide particles [79, 91].

Very high iron loading can be attained by sublimation also called chemical vapour deposition (CVD) of  $\text{FeCl}_3$  onto the parent H-ZSM-5 zeolite [145, 146, 147]. Fe loadings as high as  $\text{Fe}/\text{Al}=1$  are reached, but it is generally observed that after washing and calcination iron is clustered to inactive  $\text{FeO}_x$  [149]. However, a small fraction of Fe yields excellent performance for  $\text{N}_2\text{O}$  decomposition (typically 0.5 wt%) [150-152].

Impregnation of zeolites is employed when the quantity of metal ion to be introduced is greater than would be obtainable by ion exchange, e.g. high-silica zeolites, but the distribution is more uniform in the ion-exchange sample [153]. The anion as well as the cation is introduced. The parent zeolite is soaked with a  $\text{FeCl}_3$  solution and thereafter calcined [72, 144, 154]. In industrial applications, wet ion exchange (WIE) and impregnation are the simplest methodologies, because they involve few steps and the process parameters are easily accessible.

### 2.3.3. Activation of Fe-ZSM-5 for $\text{N}_2\text{O}$ Decomposition

The pre-treatment conditions such as temperature and medium have a strong influence on the  $\text{N}_2\text{O}$  decomposition activity of the Fe-ZSM-5 catalyst. Nitrous oxide decomposition rates over Fe-ZSM-5 catalysts strongly increase after high-temperature calcination and high-temperature steaming [83, 89, 148, 152, 155, 156]. The catalytic activity is related to extra-framework iron species which are formed at this stage. Mechanistic details are still unclear, including such important aspects as the structure and nuclearity of the active iron sites.

High-temperature treatments can have various effects on the iron zeolite. However, in general, calcination in inert at high temperature leads to de-hydroxylation and auto-reduction of iron centers. Water vapour accelerates the hydrolysis of zeolite matrix bonds leading to Fe and Al extra-framework formation.

Iron ions of isomorphously synthesized zeolites migrate during calcination from the crystalline lattice into zeolite micropores or extra-framework iron ions are rearranged

to create active sites. EXAFS measurements performed on a isomorphously substituted Fe-ZSM-5 indicate that before activation at 1123 K in He, iron is located in tetrahedral positions in the MFI framework, but that after activation, the iron migrates to the charge-exchange positions associated with framework Al and is presented as isolated Fe(III) cation [80]. Active iron sites once formed upon calcination in He at 1323 K do not disappear due to re-hydroxylation [155]. An in situ Mössbauer spectroscopy study showed that the activation process (calcination in air, in vacuum, or in the presence of water vapour) causes an intensive reduction of iron, yielding binuclear Fe(II) complexes [72].

Steaming resulted in dealumination of the framework and growth and ordering of the iron oxide aggregates [83, 84]. Moreover, some of the occluded neutral iron oxide nanoparticles were transformed into charge-compensating iron complexes upon a protolysis reaction with the Brönsted protons [83]. The beneficial effect of severe activation treatments to sublimed Fe-ZSM-5, where iron is introduced at extra-framework positions, is taken as an indication that removal of lattice aluminium is important for the generation of active sites [152]. High-temperature treatment induces profound changes in the distribution of iron species, most notably a substantial fraction of oligonuclear and cationic Fe species are converted to Fe species stabilized by extra-framework Al (Fe-O-Al species) in zeolite pores [148]. Protons are known to accelerate the process of steam-induced aluminium migration [157] and steam-dealumination is likely to precede the clustering of iron in Fe-ZSM-5 [120].

## 2.4. Analysis Methods

Transient experiments were performed in this study to gain useful mechanistic information of the decomposition of  $\text{N}_2\text{O}$  over Fe-ZSM-5. Transient response techniques are a powerful tool for gaining insight into the mechanisms of complex catalytic reactions and to derive rate constants for the individual steps involved [158]. Under steady-state conditions, all elementary steps in series are progressing at the same rate and hence the measured rates hardly tell the precise kinetic structure, or mechanism, of catalytic reactions which usually consist of several elementary steps including adsorption of reactants, surface reaction, and desorption of products. When some perturbations are imposed on a reaction system under steady state, the transient response of the system as it approaches a new steady state exhibits a characteristic behaviour reflecting the nature of the sequence of steps which underlie observed kinetics but cannot be unveiled by the steady-state experiment. The transient response technique was applied with a Micromeritics AutoChem 2910 analyzer at atmospheric pressure and with the TAP setup in vacuum.

### 2.4.1. Transient Response Techniques at Atmospheric Pressure

The aim of the transient response method is to perturbate the reaction system to acquire useful information on the mechanism of the reactions from the resultant response. Any kind of variables that defines the chemical reaction system may be used for this purpose, i.e., concentration, temperature, pressure or flow rate. In imposing perturbation of any one of these variables, a well-defined forcing function must be used for the sake of simplicity of the analysis of the response. The possible functions will be rectangular step functions, rectangular pulses and ramp functions [158].

In the study of heterogeneous catalysis, it has been recognized that presence of impurities and the formation of intermediates on the catalyst surface plays an important role in surface catalysis. The pre-adsorption of a test molecule prior to a rectangular step function of the reactant provides information about the role of the test molecule on the chemical reaction. By measuring the transient response of the conversion or of side products, the probe molecule can be identified for example as inhibitor, promoter, co-catalyst, intermediate.

A powerful tool used to investigate the desorption, decomposition and reaction of species on the catalyst surface is the temperature-programmed desorption (TPD). A temperature programmer heats the catalyst at a constant rate. Decomposition and desorption of the surface species is followed with a mass spectrometer. The temperature at which a molecule desorbs also reflects how strongly it is bound to the surface [159]. Reaction intermediates, products and side products can be identified and the initial amount of the adsorbate before desorption quantified.

The transient response technique has been proved to be useful for the kinetic and mechanistic study of heterogeneous catalysis by furnishing information complementary to that obtained by steady-state experiments.

### 2.4.2. Temporal Analysis of Products

The TAP reactor system was originally created by John T. Gleaves in 1988 [160] to assist the catalyst development process. Improvements have been made from then on by optimizing the detection sensitivity as realized with the TAP-2 reactor setup [161], and by adding extra mass spectrometer analysis, as is the case with the Multitrack reactor setup [162, 163]. The TAP reactor system is an apparatus that is used to perform transient pulse experiments for micro kinetic analysis of complex heterogeneous catalytic reactions. It has been extensively applied in experimental studies on catalytic reaction mechanisms and other surface processes.

The critical difference between TAP and TAP-2 reactor systems is the positioning of the microreactor and the detector that measures the reactor effluent. In the TAP-2 system, the two devices are physically much closer, and as a result the detection efficiency of the TAP-2 system is much higher [164].

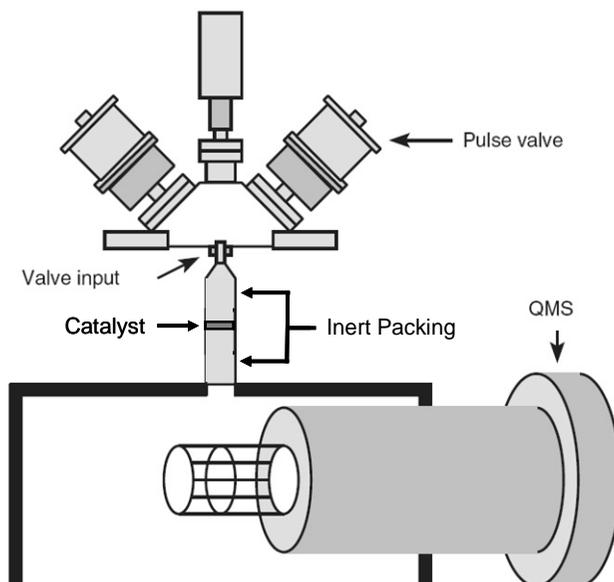

In heterogeneous catalysis, there are two known kinetic strategies, traditional experiments over industrial multicomponent catalyst under normal conditions (Continuous Stirred Tank Reactor and Plug Flow Reactor, working mostly in a steady-state regime) and surface science experiments under high vacuum conditions mostly over single crystals with well-defined surfaces which are very different from the industrial multicomponent catalyst. Consequently, traditional applied kinetics and surface science kinetics are separated by a "pressure" and "material" gap. The TAP approach can be defined as a "third kinetic strategy", which is bridging these "gaps". The TAP pulse response pressure domain ( $10^{-2}$ - $10^{-1}$  Pa) is located at the boundary between the traditional applied kinetics and surface science kinetics, and this domain can be extended [164]. Unlike surface science experiments, TAP pulse response experiments can be performed on practical catalytic materials at pressures higher than those used in surface science experiments.

The Temporal Analysis of Products (TAP) reactor system allows fast transient experiments in the millisecond time regime with submillisecond signal sampling [160]. In contrast, a nonsteady-state reactor setup operating at atmospheric pressure provides a time resolution of only about one second. Several advantages can be attributed to the operation in high vacuum. Since gas transport through the catalyst is governed by Knudsen diffusion, external mass and heat transfer limitations are completely absent and the diffusivities of the individual component of a gas mixture are independent of pressure, concentration, or the composition of the gas mixtures. This simplifies the equations needed to model the system significantly. Moreover, the collisions between gas-phase molecules are limited so that the transient response of product molecules in the TAP system is a measure of gas-solid interactions. The overall surface coverage is lower in vacuum minimizing hydroxylation and side reactions. The catalyst zone is isothermal even in the case of strongly exo- or endothermic reactions due to the small quantity of reactants introduced in the reactor.

### **TAP-2 Reactor Setup**

The TAP-2 reactor system can be used to perform transient as well as steady-state experiments at pressures ranging from  $10^{-7}$  to 250 kPa, and temperatures ranging from 300 to 1200 K. A simplified scheme of the key parts of a TAP-2 reactor system is presented in Figure 2.10. In a TAP experiment catalyst particles are sandwiched between inert particle beds in a small fixed bed microreactor. One end of the microreactor is attached to a manifold containing one or more high-speed pulse valves, and the other

end is attached to an ultra-high vacuum system that has a very high pumping speed. The gas exiting the reactor is monitored as a function of time with a quadrupole mass spectrometer detector. The intensity of the transient response is proportional to the exit flow rate of the corresponding gas. Introducing one or more very short pulses of reactant gas into the evacuated microreactor performs a standard TAP experiment. At sufficiently low pulse intensities the total gas pressure becomes negligible and the gas molecules move through the reactor via Knudsen diffusion.

**Figure 2.10:** The key parts of a TAP-2 reactor system with thin-zone packing [165].

The time-dependent gas flow [molecule/s] that escapes the microreactor is measured by a mass spectrometer, which makes it possible to measure very small signals with precise time resolution. A single pulse is typically very small ( $\sim 10^{13}$  to  $10^{17}$  molecules/pulse), and gas transport through the particle bed occurs by Knudsen diffusion. An important feature of this flow regime is that the diffusivities of the individual components of a gas mixture are independent of pressure, concentration, or the compositions of the gas mixture. The number of molecules per pulse is usually much smaller than the total number of active sites in the catalyst, and reaction of a single pulse typically changes the catalyst composition by less than 0.1% [166].

The simplest TAP reactor configuration is the one-zone reactor which is uniformly packed with particles. In practice, it is difficult to obtain temperature

uniformity at high temperatures in a one-zone reactor and was therefore advanced by sandwiching the catalyst zone between two inert zones, called the three-zone reactor [167].

The main advantage of the three-zone TAP reactor compared to the one-zone configuration is that the catalyst zone can be more easily maintained under isothermal conditions. However, it is difficult to maintain a uniform profile of the surface catalyst composition because of the gas concentration gradient, which is the driving force of diffusional transport.

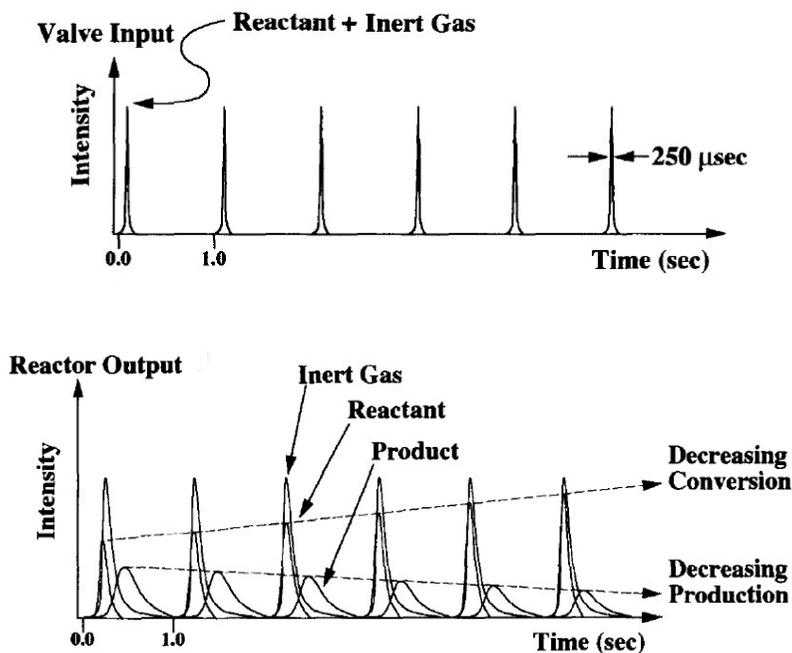

In 1999, Shekhtman et al. [168] proposed the thin-zone TAP reactor (TZTR) in which the thickness of the catalyst zone is made very small compared to the whole length of the reactor. Then, the change of gaseous concentration across the thin catalyst zone can be neglected, and the catalyst composition can be considered as uniform. Uniformity of catalyst composition and model simplicity make the thin-zone TAP reactor configuration very useful [164].

## **Types of Experiments**

Depending on the kind of information required different experimental modes are used. The reactant gas can be introduced into the microreactor in a variety of transient formats at both vacuum and atmospheric pressures as well as in form of pulses and as continuous gas feed.

### Single Pulse TAP Experiments

TAP pulse experiments in vacuum include the pulse input train from a single pulse valve and the reactor output that is measured by the mass spectrometer. Key features are illustrated in Figure 2.11. The output transient response spectrum indicated that different products are characterized by different transient responses and that the individual product responses can change with pulse number. Information on the catalytic performance is obtained by pulsing a mixture of a reactant and an inert reference gas. The integral size of the pulse responses allows calculation of conversions and yield, whereas the size and shape of the reference gas represents the dosed amount of reactant. Due to the high time resolution, information on the sequence of product formation can often be obtained by a comparison of the normalized pulse responses for different products [169-171]. The product formation on the surface requires a certain period of time for each step in the reaction sequence. Therefore, the pulse responses of secondary products are delayed in comparison to those of primary products while components formed during the same reaction step appear simultaneously. However, the former statement is only valid if the time for the diffusive mass transport is significantly smaller than the time required for reaction and if the desorption of products into the gas phase is a fast process and if the surface reactions are virtually irreversible [172].

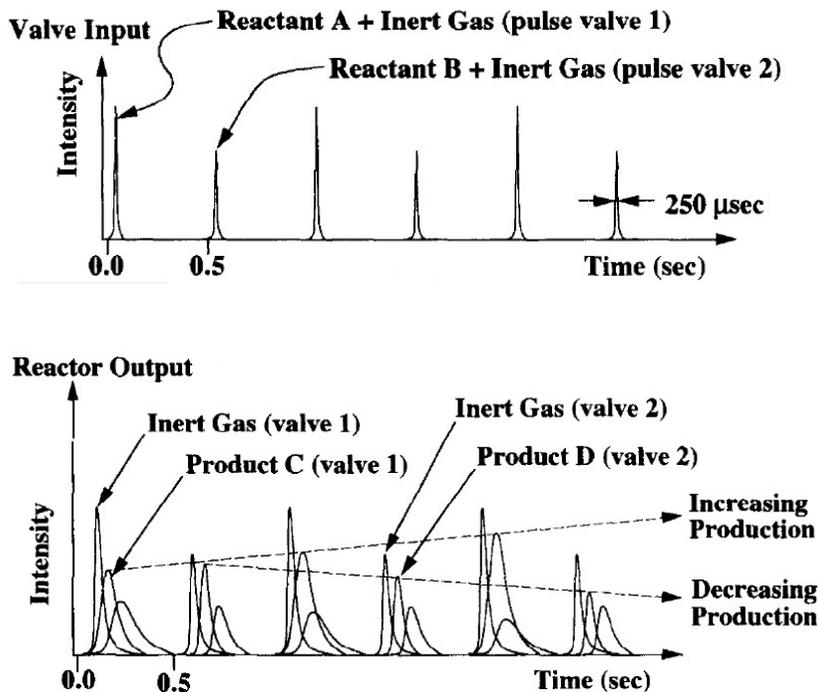

**Figure 2.11:** Key features of a single pulse TAP experiment showing a train of input pulses and the output transient responses [161].

Furthermore, the surface state of the catalyst can be changed in a distinct way by introducing a large number of pulses in a so-called multi-pulse experiment. This allows for example the surface reduction of an oxide catalyst when pulsing a reactive hydrocarbon or the titration of active sites with an irreversibly adsorbing reactant [173-176]. These experiments may also probe the performance of the catalyst under different working conditions [177-179].

#### Pump-probe TAP Experiments

In pump-probe experiments, different reactant-inert mixtures are introduced sequentially from separate pulse valves. Figure 2.12 illustrates the input pulses and transient response of such a sequential pulse experiment. The output transient response now contains products pulses coinciding with both valve inputs. For example, one valve may contain a reducing agent and the other valve an oxidizing agent. By varying the delay between the two single pulses and the frequency of repeating the cycle, information on the life-time and reactivity of the adsorbed species are obtained [173, 180-182]. These species are created during the first single pulse and probed during the second single pulse.

The pump-probe format is also useful for investigating catalyst activation. In this case, one pulse-valve is used to introduce the activating agent, and the other pulse-valve is used to introduce a reactive probe to monitor the state of the catalyst surface. By monitoring a number of reaction products, changes in activity and selectivity can be observed, and correlated with the incorporation of the activating species [161, 183].

**Figure 2.12:** Key features of a pump-probe TAP experiment using two pulse valves. The input pulse train which consists of alternating pulses of reactant A and B as well as the output transient responses are shown [161].

#### Elevated Pressure Experiments

In the elevated pressure configuration the microreactor can be operated as a conventional steady-flow or pulsed microreactor. Continuous gas feed allows the use of larger amounts of reactants which is often required for the pre-treatment of a catalyst. More pronounced changes in the state of the catalyst are applied at elevated pressures while the reactor effluent is continuously recorded and subsequently performing pulse experiments under evacuated conditions [184, 185].

### Temperature-Programmed Experiments

The reactor may be operated isothermally or may be temperature programmed. Applications such as temperature-programmed desorption (TPD), surface reaction (TPSR), oxidation (TPO) or reduction (TPR) can be performed. TPD experiments allow the characterization of adsorbates on the catalyst [186-188].

### Modeling of TAP Experiments

The composition of the flow provides information on the types of chemical transformations that have occurred in the microreactor, and the time dependence of the flow contains information on gas transport and kinetics. The determination of reaction rate constants for the elementary reaction steps requires setting up a model which describes the transient response of the system. The theoretical basis of TAP experiments is fully developed and well established [164, 165, 167, 168, 189-194]. TAP pulse response experiments are described by a set of partial differential equations that can be solved for certain cases analytically and for more complex systems numerically. Different calculation methods including regression analysis and moment analysis have been used for parameter estimation. The regression analysis involves comparing the experimental response to the model response based on the least square fit. The moment method can be performed when moment or moment-related expressions for the exit flow rate are known.

Quantitative information of the phenomena in the reactor can be extracted from the size and the shape of the responses by the use of mathematical models that describe the diffusion-reaction processes in the reactor. The required mathematical solution therefore describes the gas exit flow rate. The experimental gas exit flow rate can be determined only when the absolute calibration factor has been obtained. Matching of the experimental and the model exit flow rates provide the estimated parameters. When using the experimental response curve without converting into the exit flow rate curve, only the shape of the response is concerned.

Knudsen diffusion is the dominant mass transport mechanism in pulse TAP experiments apart from some viscous influence at the time of the introduction of the reactant pulse, in case the microreactor filling is non-porous. Knudsen diffusion occurs at sufficient low pressure (small gas density) or in small pores when the mean free path of the molecule is much greater than the distance to the surrounding walls. This implies that the collisions between molecules and the solid particles dominate and that intermolecular collisions are negligible. The simple hydrodynamics (mostly Knudsen flow) allows one to focus on the intrinsic kinetic equations.

In case of microporous solids (zeolites, active carbons) the situation is more complicated. The mass transport may be conducted by configurational diffusion where

the molecular diameter is comparable to the channel diameter. Studies have shown that the direct access of molecules to the micropores is highly improbable [195, 196]. Thus, a sequential mechanism can be postulated consisting of the collision and sorption of the molecules with the outer particle surface, random mobility at the outer surface similar to a two-dimensional gas, the entering into the micropores, and diffusion to sorption sites inside the pores [197]. A number of studies deal with the determination of diffusivities in microporous zeolites [163, 198-200] and other porous materials [201, 202] by using the TAP reactor. The modeling was extended to biporous materials (meso- and micropores) including first order reaction within the micropores [203, 204]. The existence of internal diffusion limitations on porous particles needs to be verified carefully as concentration profiles inside the pores for transient experiments might arise even in the absence of chemical reaction [201, 205-208]. In the case of microporous solids internal mass transport has to be accounted for explicitly [205].

# Chapter 3

## EXPERIMENTAL PART

### 3.1. Studied Catalysts

Three different ZSM-5 zeolites were used in the present study. Extrudates, Fe-ZSM-5<sub>5500</sub>, were kindly provided by Zeochem AG (Uetikon, Switzerland). They were found to contain 5500 ppm of iron as an impurity originating from a binder used for pelletizing. The zeolite was calcined in a flow of He (60 ml (STP)/min) for 1 h at 1323 K for activation.

The isomorphously substituted ZSM-5 containing 350 ppm Fe (Fe-ZSM-5<sub>350</sub>) was synthesized via hydrothermal route [1]. The hydrothermal synthesis for the Fe-ZSM-5<sub>200</sub> containing 200 ppm Fe and its characterization is described elsewhere [2,3]. It is important to note that an iron source was not added intentionally to the synthesis solution in order to obtain zeolite samples containing a "natural" impurity level of Fe. Therefore, the Fe-ZSM-5<sub>200</sub> was prepared with deionized water. The catalysts were activated by heating at 1323 K in He (50 ml (STP)/min) for 1 h and 8 h, respectively. The main characteristics of the parent zeolites are summarized in Table 3.1.

**Table 3.1:** Main characteristics of the studied Fe-ZSM-5 catalysts.

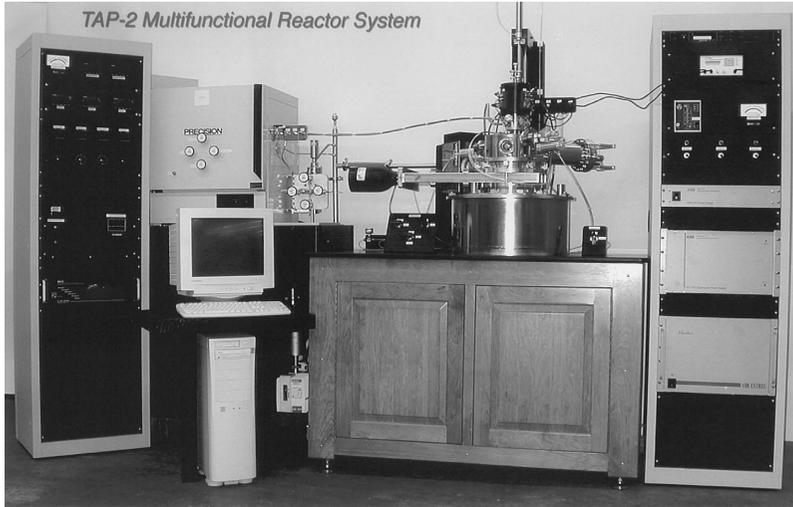

<i>Catalyst</i>	$F_e$ loading, wt%	<i>Si/Al</i> ratio	<i>Method of catalyst</i> activation	Fe(II) sites, $10^{18}$ sites/g		
				$C_{Fe}^{N_2O}$	$C_{Fe}^{TPD}$	$C_{Fe}^{CO}$
Fe-ZSM-5 <sub>200</sub>	0.020	42	1323 K, 8h in He	2.0	1.2	1.4
Fe-ZSM-5 <sub>350</sub>	0.035	42	1323 K, 1h in He	2.8	1.9	2.06
Fe-ZSM-5 <sub>5500</sub>	0.550	25	1323 K, 1h in He	3.4	2.6	2.6

The active Fe(II) sites concentrations listed in Table 3.1 were determined by D. Bulushev in transient response experiments with the Micromeritics AutoChem 2910 analyzer. The fraction of iron sites involved in the formation of surface oxygen,  $(O)_{Fe}$ , from  $N_2O$  was measured via transient response methods during  $N_2O$  decomposition over the catalyst at 523 K. The determination of the active sites concentration, abbreviated as  $C_{Fe}^{N_2O}$ , is discussed in detail in section 5.2. The deposited oxygen, which is able to recombine forming  $O_2$ , and the concentration of the corresponding Fe(II) sites,  $C_{Fe}^{TPD}$ , were estimated from the amount of molecular oxygen evolved during temperature-programmed desorption (523-873 K). The deposited oxygen, which is active in low-temperature CO oxidation,  $C_{Fe}^{CO}$ , was measured via the transient response of  $CO_2$  during CO oxidation at 523 K. These methods were described in detail elsewhere [4]. Studies of the  $N_2O$  decomposition [4-9] and the hydroxylation of benzene to phenol with  $N_2O$  [1, 3] were already published with the catalysts summarized in Table 3.1.

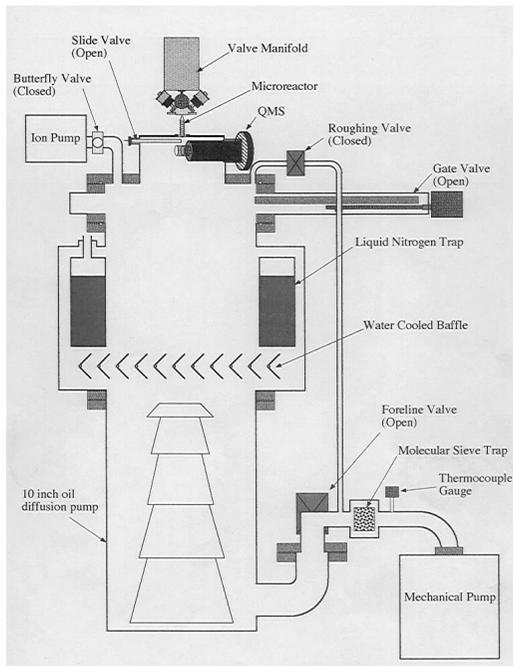

## 3.2. Temporal Analysis of Products

### 3.2.1. Setup

The interaction of  $N_2O$ , CO, NO,  $NO_2$ ,  $H_2O$  and  $O_2$  with iron containing ZSM-5 and its surface species were investigated by multi-pulse, pump-probe and temperature-programmed desorption experiments in a TAP-2 setup [10] pictured in Figure 3.1. It consists of the four main parts: a gas mixing station, a microreactor with four high-speed pulse valves, a vacuum system, and a mass spectrometer. A scheme of the main parts of the TAP setup is presented in Figure 3.2.

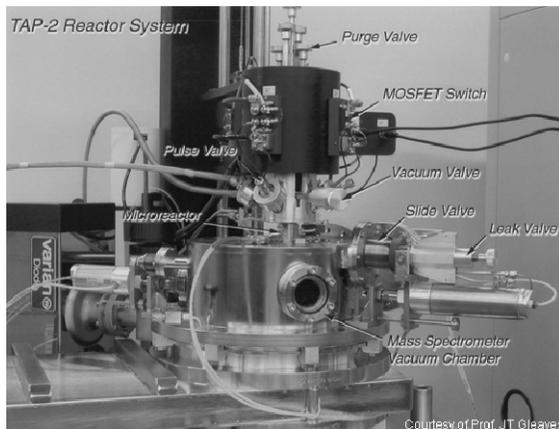

**Figure 3.1:** Photo of TAP-2 system. Courtesy of Prof. J.T. Gleaves.

**Figure 3.2:** Scheme of TAP-2 system [10].

An enlarged image of the pulse valves, microreactor and the analyzer is presented in Figure 3.3.

**Figure 3.3:** Photo of the TAP pulse valves, reactor and analyzer. Courtesy of Prof. J.T. Gleaves.

The tubular microreactor is constructed of stainless steel with an inner diameter of 6.4 mm and 31.8 mm in length. The entrance of this reactor seals via a small volume against the valve-manifold assembly through an O-ring. The reactor outlet is continuously evacuated by an oil diffusion pump that is pumped by a mechanical pump. The pulse valves allow a rapid injection of very small amounts of reactant with a typical pulse width between 80 and 200  $\mu\text{s}$  into the microreactor. The responses of a reactant and products are recorded as a function of time with the quadrupole mass spectrometer (ABB Extrel) located directly underneath the reactor exit. Three gas blending stations serve to prepare certain gas mixtures and to determine the size of the gas pulse by means of a pressure transducer. Typical pulse intensities in vacuum experiments range from  $10^{13}$  to  $10^{17}$  molecules/pulse [10]. The purchased TAP system contained two gas blending stations and a third one was home-made with the same functionality as the original stations in order to be able to pulse three different reaction mixtures over the catalyst in a short period of time.

### 3.2.2. Description of the Experiments

A Fe-ZSM-5 layer of 50 mg was placed between two beds of quartz particles (200-250  $\mu\text{m}$  particle size) and exposed to vacuum ( $< 10^{-5}$  Pa). The temperature of the reactor was measured by a thermocouple positioned in the centre of the catalyst bed. TAP experiments were carried out at 523 K, 593 K, 661 K, 703 K, 803 K and 946 K with different gas mixtures, which were introduced by pulses in the microreactor. Prior

to the measurements, the catalyst was evacuated in the TAP reactor at 946 K for 30 min, and then cooled to the studied temperature. This pre-treatment will be referred to from now on as "standard" in TAP experiments.

The utilized gases were provided by Carbagas (Lausanne, Switzerland) and are summarized in Table 3.2 with their purities and the typical inlet pulse size. Ar served as an inert tracer. The gas blends were produced on the basis of pure gases in the gas blend stations besides the CO and NO mixtures which were purchased already diluted with Ar. The inlet pulse size was calculated from the number of pulses necessary to reduce the pressure of a closed volume. The typical inlet pulse size of the utilized blends was small enough to allow the transport in the reactor to occur through Knudsen diffusion.

Water was dozed gaseous without Ar as tracer. About 50 ml of deionized water were filled into the gas blend reservoir, then the blend station and the feed line were evacuated and the whole gas blend station as well as all parts which lead to the reactor heated to 323 K. Water evaporates and saturates the void. The vapour pressure of 12,3 kPa is adjusted for water at 323 K [11].

**Table 3.2:** Gas blends for TAP studies, their purities and typical pulse size.

<i>Gas mixture</i>	<i>Purity of reactant gas</i>	<i>Pulse size, 10<sup>14</sup> molecules/pulse</i>
Ar	> 99.998%	-
10 vol% CO in Ar	> 99.997%	5
80 vol% N <sub>2</sub> in Ar	> 99.995%	5
80 vol% N <sub>2</sub> O in Ar	> 99.0%	5
10 vol% NO in Ar	> 99.9%	6.5
60 vol% NO <sub>2</sub> in Ar	> 99.0%	5.5
25 vol% O <sub>2</sub> in Ar	> 99.95%	1.5

System control and data acquisition are performed with a computer. A pulse is injected within 200  $\mu$ s, depending on gas and reactor temperature, it takes from 100 ms to a few seconds to pass the reactor. The time period, called cycle time, between the pulse injection until the next pulse is kept constant and usually larger than the time the reactant needs to pass the reactor. To accurately capture these transients it is necessary to sample the reactor output at a submillisecond data acquisition rate. Since the ABB Extrel mass spectrometer requires at least one second for a typical spectral scan, it is not possible to collect high-speed transients. Consequently, vacuum pulse response data are obtained by fixing the mass to charge number at a specific value during a pulse and monitoring the change of the detector response as a function of time. During the following cycle another mass to charge ratio is registered. Reactant, reaction products and inert tracer are analyzed sequential in real-time using the MS. Thus, each collected transient response originates from another pulse. Since the amount of reactants in a

single pulse is much smaller than the amount of active sites a single pulse causes only a very small perturbation of the catalytic system. Several pulses are representative for one defined catalyst state. However, during a train of pulses the catalyst state can be gradually changed and the individual reactant or products response can change with pulse number.

Depending on the type of experiment the following mass to charge ratios ( $m/e$ ) were registered simultaneously by the mass spectrometer: 18 ( $\text{H}_2\text{O}$ ), 28 ( $\text{N}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{CO}$ ), 30 ( $\text{NO}$ ,  $\text{N}_2\text{O}$ ,  $\text{NO}_2$ ), 32 ( $\text{O}_2$ ), 40 ( $\text{Ar}$ ), 44 ( $\text{N}_2\text{O}$ ,  $\text{CO}_2$ ), 46 ( $\text{NO}_2$ ). The mass spectrometer was only calibrated for the titration of active sites discussed in section 5.2. Since there is no possibility to by-pass the reactor in the TAP system, the reactor content needs to be changed from the catalyst to an inert material for calibration. This takes too much time regarding the instability of mass spectrometer. Calibration factors with  $\pm 30\%$  error could be reached which is not satisfactory for quantification regarding the time and effort which was invested to obtain the calibration factors. Furthermore, the pulse size can only be determined by an indirect measurement via pressure drop in a closed volume correlated to a high number of pulses. This brings in an additional source of error. Therefore, the main part of this study was done without quantification of the transient responses.

In principle, three transient methods were applied:

1) A series of pulses from a single valve served for treating the catalyst with different reactants ( $\text{N}_2\text{O}$ ,  $\text{CO}$ ,  $\text{NO}$ ,  $\text{NO}_2$ ,  $\text{H}_2\text{O}$ ). The reactant was introduced by repetitive pulsing. The cycle time was fixed in the range of 3 s to 15 s depending on the time the involved compounds needed to desorb. The Fe-ZSM-5<sub>500</sub> was studied with large numbers of pulses so-called multi-pulses. The pulse responses of  $\text{N}_2\text{O}/\text{Ar}$  were investigated at a temperature range from 523 K to 946 K.  $\text{N}_2\text{O}$  and  $\text{NO}$  interactions at 523 K and 593 K with the catalyst were carried out in general with 600 pulses.  $\text{NO}_2$  treatments at 523 K were performed with 300 pulses.  $\text{H}_2\text{O}$  was pulsed at 593 K and 703 K until the saturation of the catalyst was detected with the mass spectrometer.  $\text{CO}$  served as reducing agent for surface oxygen at 523 K and 593 K and was fed into the reactor as long as  $\text{CO}_2$  was formed.  $\text{O}_2/\text{Ar}$  was only pulsed at 803 K.

2) In pump-probe experiments different reactant mixtures were introduced sequentially from separate pulse valves. One valve contained for example  $\text{N}_2\text{O}/\text{Ar}$  and the other valve either  $\text{CO}/\text{Ar}$ ,  $\text{H}_2\text{O}/\text{Ar}$  or  $\text{NO}/\text{Ar}$ . The first reactant (usually  $\text{N}_2\text{O}$ , pump) formed intermediates on the catalyst during the first pulse. When the second reactant (e. g.  $\text{CO}$ , probe) was fed into the reactor, chemical reactions occurred and product formation is observed. The time delay between the first and second pulse was variable from 0.01 s to 9.5 s. The sequence was repeated and the total cycle time was fixed to 10 s or 20 s. The Fe-ZSM-5<sub>500</sub> was investigated by dual-pulse experiments at 523 K with  $\text{N}_2\text{O}/\text{CO}$  and at 803 K with  $\text{N}_2\text{O}/\text{H}_2\text{O}$ . The Fe-ZSM-5<sub>500</sub> and Fe-ZSM-5<sub>200</sub>

were studied in  $\text{N}_2\text{O}/\text{NO}$  and  $\text{NO}/\text{N}_2\text{O}$  pump-probe experiments at 661 K, 803 K and 946 K.

3) Complementary, TPD (temperature-programmed desorption) experiments were carried out to gain information about surface species. Hence, after a defined sequence of pulses the catalyst temperature was increased linearly by 45 K/min from the studied temperature to 916 K in vacuum. Almost all multi-pulse experiments with the Fe-ZSM-5<sub>5500</sub> at 523 K and 593 K were completed by a TPD run.

### 3.2.3. Preliminary Tests

Experimental pulse responses of the inert gas Ar were compared with criterions of the Knudsen regime in order to verify that the TAP-2 system was well adjusted. The beginning of the Knudsen regime was determined by lowering the pulse intensity and observing when the pulse shape becomes independent of the pulse intensity. Additionally, the Knudsen regime was evidenced by comparing the experimental response transformed to dimensionless form to the standard diffusion curve. If the curves match then the gas flow is in the Knudsen regime and the supposed boundary conditions are fulfilled.

For any TAP pulse response experiment that involves only gas transport (no reaction or adsorption) the plot of the dimensionless exit flow versus dimensionless time will give one curve regardless of the gas, bed length, particle size, or reactor temperature. The curve is called the standard diffusion curve (SDC) [10]. The dimensionless exit flow  $\overline{F_{Ar}}$  as a function of dimensionless time  $\tau$  is expressed in the following equation:

$$\overline{F_{Ar}} = \pi \sum_{m=0}^{\infty} (-1)^m (2m+1) \exp\left(- (m+0.5)^2 \pi^2 \tau\right) \quad (3.1)$$

The standard diffusion curve was generated with MATLAB® based on Equation (3.1) and is compared in Figure 3.4 to the dimensionless form of an experimental Ar response. Pure Ar was pulsed within 125  $\mu\text{s}$  into the reactor filled with quartz particles (200-250  $\mu\text{m}$  particle size) at 373 K. The peak height  $H_p$  of the area-normalized Ar flow was determined to 7.3  $\text{s}^{-1}$ . The parameter  $k'$  was derived from the following equation:

$$H_p = 1.85 \frac{D_{eAr}}{\varepsilon_b L^2} \Rightarrow k' = \frac{D_{eAr}}{\varepsilon_b L^2} = \frac{H_p}{1.85} \quad (3.2)$$

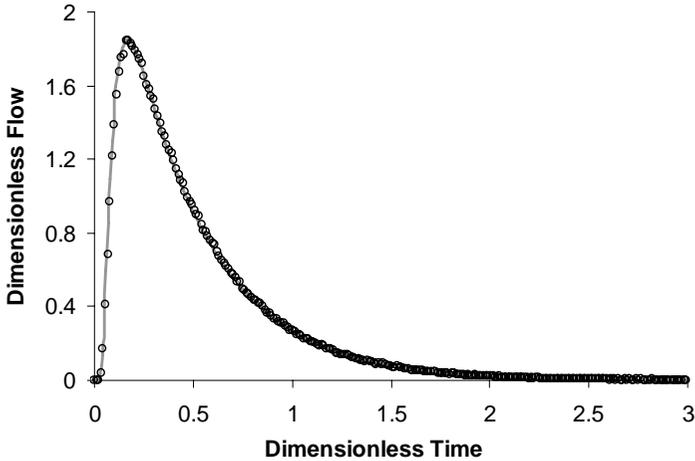

The dimensionless form of the experimental Ar response was generated from the area-normalized Ar flow  $\frac{F_{Ar}(t)}{N_{Ar}}$  by using the constant  $k$  and the following correlations:

$$\overline{F_{Ar}}(\tau) = \frac{\varepsilon_b L^2}{D_{eAr}} \cdot \frac{F_{Ar}(t)}{N_{Ar}} \quad \text{and} \quad \tau = t \cdot \frac{D_{eAr}}{\varepsilon_b L^2} \quad (3.3)$$

The dimensionless flow was derived by the product of the area-normalized flow and  $1/k'$ . The dimensionless time was calculated by multiplying the time with  $k'$ . The theoretical standard diffusion curve and the dimensionless curve generated from an experimental Ar response in Figure 3.4 overlap perfectly. Therefore, it can be concluded that the gas flow was in the Knudsen regime.

Another way of distinguishing the Knudsen diffusion regime without having to determine the effective diffusivity of the gas, the length of the reactor, or the fractional voidage of the bed is the characteristics of the curve maximum. Provided the gas transport is in Knudsen diffusion regime, the product of peak height  $\overline{F_{Ar,p}}$  and peak time  $\tau_p$  is equal to 0.31 which is correct for the dimensionless curve generated from the experimental Ar response:

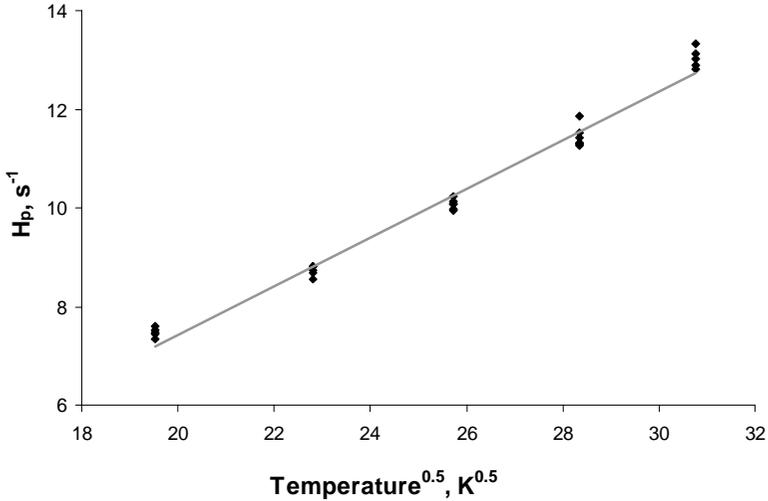

$$\overline{F_{Ar,p}} \cdot \tau_p = 0.31 \quad (3.4)$$

**Figure 3.4:** Standard diffusion curve (solid line) compared to dimensionless form of experimental Ar response (open symbols).

Further, experiments with different pulse valves and at different temperatures showed also the accordance between TAP theory and experimental response data. Figure 3.5 presents the results from an experiment in which Ar was pulsed over inert quartz pellets while the temperature was varied. The peak height  $H_p$  is plotted as a function of the square root of the temperature. In a diffusion controlled process the peak height  $H_p$  is directly proportional to the effective diffusion coefficient  $D_{eAr}$  which is a function of the square root of the temperature as shown in Equation (3.5). Thus, the data in Figure 3.5 should be a straight line. The results confirmed the Knudsen diffusion regime.

$$H_p = 1.85 \frac{D_{eAr}}{\varepsilon_b L^2} \quad \text{and} \quad D_{eAr} = \frac{\varepsilon_b d_i}{\tau_b 3} \sqrt{\frac{8RT}{\pi M_{Ar}}} \Rightarrow H_p \sim \sqrt{T} \quad (3.5)$$

**Figure 3.5:** Peak height of area-normalized Ar response as function of the square root of the reactor temperature.

The results in this section demonstrate the validity of the Knudsen flow assumptions for the experiments with an inert gas performed with the TAP-2 system. In particular, the functionality of the setup was proven therewith. However, the gas movement through the catalyst governed by Knudsen diffusion was not of first priority in this study since extensive micro kinetic modeling was not performed.

### 3.3. Micromeritics AutoChem 2910 Analyzer

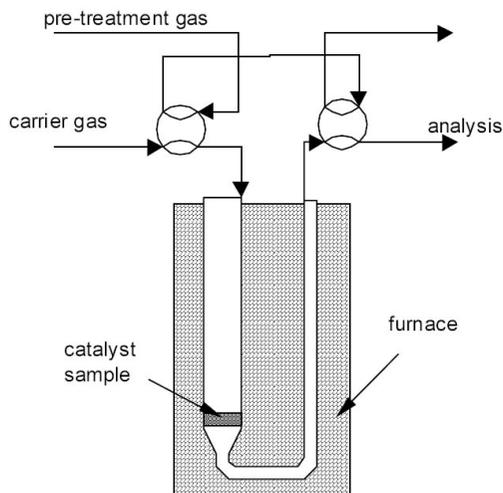

All transient response experiments at atmospheric pressure were performed in a AutoChem 2910 analyzer (Micromeritics) illustrated in Figure 3.6.

**Figure 3.6:** Image of the Micromeritics AutoChem 2910 analyzer.

A simplified scheme of the analyzer is shown in Figure 3.7. It is provided with a ThermoStar 200 (Pfeiffer Vacuum) quadrupole mass spectrometer to analyze the composition of the gas phase. The setup as well as a fused silica capillary connected to the mass spectrometer were heated up to 383 K.

The following mass to charge ratios were monitored simultaneously by the mass spectrometer: 4 (He), 18 ( $\text{H}_2\text{O}$ ), 28 ( $\text{N}_2$ ,  $\text{N}_2\text{O}$ , CO), 30 (NO,  $\text{N}_2\text{O}$ ,  $\text{NO}_2$ ), 32 ( $\text{O}_2$ ), 40 (Ar), 44 ( $\text{N}_2\text{O}$ ,  $\text{CO}_2$ ), 46 ( $\text{NO}_2$ ). It was calibrated using gaseous mixtures of known compositions. Therefore, crawled data, gas concentrations, without the contribution of fragments of other gases are presented throughout the work from measurements with the Micromeritics analyzer. The utilised gas mixtures were provided by Carbagas (Lausanne, Switzerland), used without further purification and summarized in Table 3.3 with their purities. Ar served as an inert tracer and He as inert carrier gas. Other mixtures were created by mixing different gas blends or by diluting with He in the Micromeritics analyzer. The total flow rate of the different gas mixtures was kept always constant at 20 ml (STP)/min. Deionized water was pulsed on the catalyst using a 5  $\mu\text{l}$  syringe via an injector into a 20 ml (STP)/min He flow. Adsorption of water was controlled by the mass spectrometer.

**Figure 3.7:** Scheme of the Micromeritics AutoChem 2910 analyzer.

0.40 g of Fe-ZSM-5 was placed in a quartz plug-flow reactor. Before every run the catalyst was pre-treated in He (50 ml (STP)/min) at 1323 K for 1 h, then cooled to the studied temperature. To this pre-treatment is hereafter referred as "standard" pre-treatment at atmospheric pressure. The reactor was purged by He (50 ml (STP)/min) for 10 min after each treatment in order to clean the feed lines and to desorb weakly adsorbed species from the catalyst.

**Table 3.3:** Utilized gas mixtures and their purities.

<i>Gas mixture</i>	<i>Purity of reactant gas</i>
Ar	> 99.998%
He	> 99.999%
3 vol% CO, 2 vol% Ar in He	> 99.997%
2 vol% CO <sub>2</sub> in He	> 99.998%
2 vol% N <sub>2</sub> in He	> 99.999%
2 vol% N <sub>2</sub> O, 2 vol% Ar in He	> 99.998%
0.5 vol% NO, 0.5 vol% Ar in He	> 99.9%
0.5 vol% NO <sub>2</sub> , 0.5 vol% Ar in He	> 99.0%
2 vol% O <sub>2</sub> in He	> 99.998%

Temperature-programmed desorption (TPD) measurements were performed in a He flow of 20 ml (STP)/min in the range of 523-1323 K with a 30 K/min ramp. During temperature-programmed reaction (TPR) studies the catalyst was heated in a He flow of 20 ml (STP)/min with 10 K/min.

The amounts of evolved gases in the transient flow, TPR and TPD runs were determined by integration of the measured curves. Transient response experiments at atmospheric pressure with the Micromeritics setup were performed mainly with NO<sub>2</sub> (chapter 7) and H<sub>2</sub>O (chapter 8) as reactants investigating the Fe-ZSM-5<sub>3500</sub> and Fe-ZSM-5<sub>350</sub> at temperatures in the range of 523 K to 673 K. The amount of sites active in N<sub>2</sub>O decomposition at 523 K of the Fe-ZSM-5<sub>3500</sub> and of the Fe-ZSM-5<sub>350</sub> are determined in section 5.2 and section 7.2, respectively. NO and O<sub>2</sub> flow experiments at 523 K with the Fe-ZSM-5<sub>350</sub> are discussed in section 6.3.

### 3.4. Diffuse Reflectance Infrared Fourier Transform Spectroscopy

A Perkin-Elmer FTIR spectrometer with a MCT detector was used for the DRIFTS experiments. The Fe-ZSM-5<sub>350</sub> (~0.015 g) ground in an agate mortar was placed into a cup of a SpectraTech 003-102 DRIFTS cell with CaF<sub>2</sub> windows. The cell was attached to a setup described earlier [12]. Pure Ar and a mixture of 0.5 vol% NO<sub>2</sub>, 0.5 vol% Ar in He (purities in Table 3.3) were used with a flow rate of 20 ml (STP)/min to investigate the surface species formed on the catalyst from NO<sub>2</sub> at room temperature and 523 K. Before every run the activated catalyst was pre-treated in the cell in Ar at 823 K for 1 h. DRIFT spectra taken every 0.5 min were obtained by averaging 32 scans with a resolution of 4 cm<sup>-1</sup>. A single beam spectrum of the catalyst before introduction of the NO<sub>2</sub> containing mixture into the cell at the studied temperature was taken as a background.

# Chapter 4

## CO OXIDATION AS MEASURE FOR REACTIVITY OF SURFACE OXYGEN

N<sub>2</sub>O decomposition over iron containing ZSM-5 has been suggested to proceed via Fe(II) transition to Fe (III) generating active oxygen species called by Panov and co-workers atomic " $\alpha$ -oxygen" [1, 2]. This oxygen is capable of selectively oxidizing benzene to phenol, CH<sub>4</sub> to methoxy species and H<sub>2</sub> to H<sub>2</sub>O at low temperatures [3-5].  $\alpha$ -Oxygen possesses also high reactivity in converting CO to CO<sub>2</sub> at low temperatures (< 523 K) [6-9]. The ability of surface oxygen to oxidize CO is used in this manuscript as measure for its reactivity. If the deposited oxygen is able to oxidize CO it is considered as  $\alpha$ -oxygen and will be symbolized by "(O)<sub>Fe</sub>" with the suffix "Fe" standing for active iron site. Oxygen in brackets with another suffix signifies surface oxygen inactive in CO oxidation.

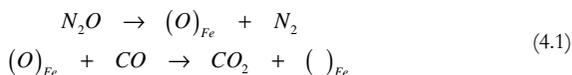

### 4.1. Reactivity of Oxygen Deposited by N<sub>2</sub>O on Fe-ZSM-5

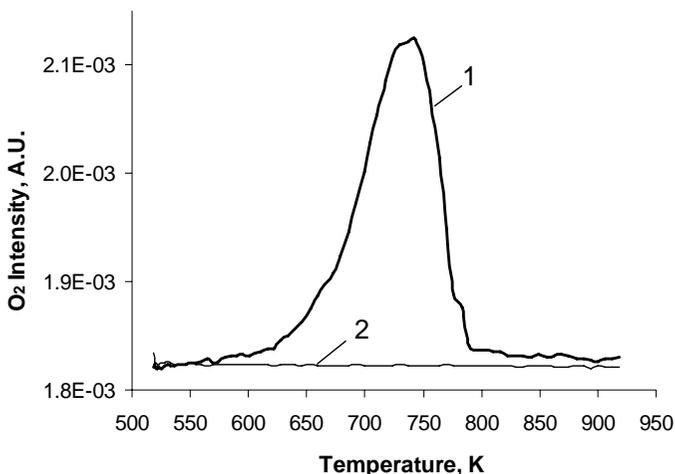

The reactivity of surface oxygen was characterized by its capacity to oxidize CO to CO<sub>2</sub>. Surface atomic oxygen was loaded on the Fe-ZSM-5<sub>5500</sub> at 523 K by introducing 600 pulses of N<sub>2</sub>O using the TAP-2 setup. Upon this pre-treatment the interaction of CO with the catalyst was studied at the same temperature. The unreacted part of the CO pulses is shown in Figure 4.1a while the formed CO<sub>2</sub> is pictured in Figure 4.1b. The generation of CO<sub>2</sub> during the first 180 pulses was clearly observed accompanied by the partial consumption of CO. CO<sub>2</sub> was formed as long as surface oxygen was available to oxidize CO. After the consumption of the reactive surface oxygen pool, CO didn't undergo further reactions since the area below the last 120 pulses stayed equal. CO<sub>2</sub> is known to adsorb reversibly on the catalyst [6] which is observed by its broad pulse response. Thus, the oxygen loaded by N<sub>2</sub>O on the Fe-ZSM-5 was reactive, oxidizing CO to CO<sub>2</sub> and therefore considered as reactive  $\alpha$ -oxygen symbolized with (O)<sub>Fe</sub> in this manuscript.

**Figure 4.1:** Transient CO (a) and CO<sub>2</sub> (b) pulse responses obtained during the interaction of CO with the Fe-ZSM-5<sub>5500</sub> loaded with atomic surface oxygen from 600 N<sub>2</sub>O pulses at 523 K.

The surface oxygen before and after CO interaction was studied also by TPD experiments. The typical oxygen TPD profile after oxygen loading from N<sub>2</sub>O on the Fe-ZSM-5<sub>5500</sub> at 523 K is shown in Figure 4.2, curve 1. The TPD profile of oxygen after N<sub>2</sub>O pre-treatment followed by CO interaction presented in Figure 4.2, curve 2 indicates that no surface oxygen remained after the CO treatment which would desorb between 523 and 916 K. For the TAP measurements it can be concluded that the oxygen loaded from N<sub>2</sub>O on the Fe-ZSM-5<sub>5500</sub> at 523 and as well at 593 K (not shown), which was desorbed during TPD experiments, was found to be completely reactive regarding CO oxidation:

**Figure 4.2:** TPD profiles of oxygen after its loading from  $N_2O$  (1) and after  $N_2O$  interaction followed by CO treatment (2) at 523 K of the Fe-ZSM-5<sub>5500</sub>.

These results are in line with the observations reported by Kiwi-Minsker et al. with a very similar catalyst using the Micromeritics AutoChem 2910 setup at atmospheric pressure [9].  $N_2O$  generated surface oxygen which oxidized CO to  $CO_2$  and the subsequent TPD showed no oxygen desorption between of 550 and 1250 K. Furthermore, the authors reported also that the total amount of consumed surface oxygen only corresponded to about 65% of the total amount of oxygen chemisorbed from  $N_2O$ . Sachtler and co-workers found during the study of the isotopic exchange of oxygen on Fe/MFI as well that the number of exchangeable oxygen atoms was smaller than the number of O atoms adsorbed from  $N_2O$ , and assigned this difference to the partial consumption of oxygen from the re-oxidation of pre-reduced iron species [10]. Therefore, it can not be concluded straightforward that every loaded oxygen is active in CO oxidation. Even though, CO oxidation with  $\alpha$ -oxygen in a static vacuum setup showed that the amount of formed  $CO_2$  was equal to [6] or only 10% below [7] the amount of pre-loaded oxygen from  $N_2O$ .

## 4.2. Summary of CO Interaction with the Fe-ZSM-5 after different Pre-treatments

CO interaction with the Fe-ZSM-5<sub>5500</sub> was performed using the TAP setup after several pre-treatments in order to probe for reactive surface species. Table 4.1 summarizes these experiments whereas the evolution of CO<sub>2</sub> indicates reactive (O)<sub>Fe</sub>. The listed experiments and the obtained results are discussed in detail in the following chapters.

**Table 4.1:** Summary of CO interaction with the Fe-ZSM-5<sub>5500</sub> after different pre-treatments at 523 and 593 K performed with the TAP setup.

<i>Temperature,</i> K	<i>Pre-treatment</i>	<i>CO<sub>2</sub> evolution during</i> <i>CO interaction</i>	<i>Discussed in</i> <i>section</i>
523	N <sub>2</sub> O	+	4.1
593	N <sub>2</sub> O	+	4.1
523	NO	-	6.4
	N <sub>2</sub> O→NO	very small	6.4
	N <sub>2</sub> O→NO→N <sub>2</sub> O	+	6.4
	NO→N <sub>2</sub> O	+	6.4, 6.5
523	NO <sub>2</sub>	-	7.1
	NO <sub>2</sub> →N <sub>2</sub> O	-	7.2
	N <sub>2</sub> O→NO <sub>2</sub>	-	7.2
593	N <sub>2</sub> O→H <sub>2</sub> O	-	8.2

In general, it can be stated that only N<sub>2</sub>O neither NO<sub>2</sub> nor NO is capable of generating reactive surface oxygen on the Fe-ZSM-5<sub>5500</sub>. H<sub>2</sub>O, NO or NO<sub>2</sub> treatments after oxygen loading from N<sub>2</sub>O resulted in the transformation or removal of (O)<sub>Fe</sub> so that CO<sub>2</sub> wasn't formed anymore during CO treatment.

# Chapter 5

## CATALYTIC N<sub>2</sub>O DECOMPOSITION

The N<sub>2</sub>O decomposition to N<sub>2</sub> and O<sub>2</sub> over Fe-ZSM-5 is known to involve iron containing sites and proceeds via atomic surface oxygen loading and gaseous N<sub>2</sub> formation from N<sub>2</sub>O as a first step

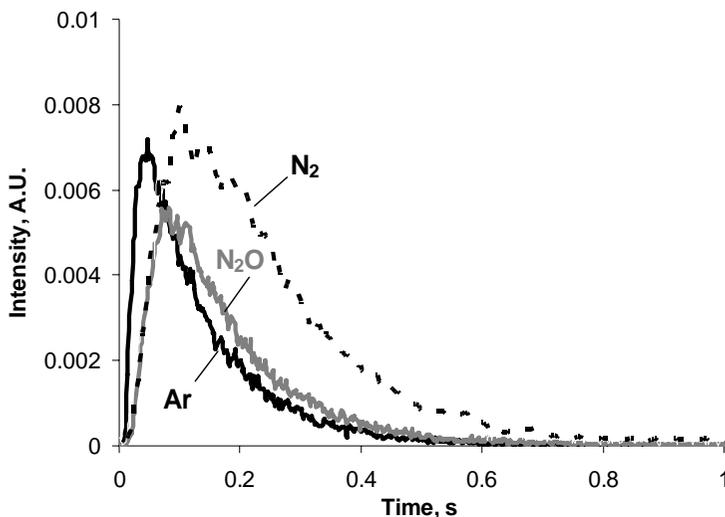

and

the recombination/formation of gaseous oxygen as a second step. Based on these two steps, the dynamics of N<sub>2</sub>O decomposition is discussed in this chapter. Different temperatures are used to distinguish these reaction steps in N<sub>2</sub>O decomposition.

## 5.1. Oxygen Loading from N<sub>2</sub>O

Fe-ZSM-5, which is an active catalyst for N<sub>2</sub>O decomposition at atmospheric pressure, decomposes N<sub>2</sub>O under vacuum conditions too. N<sub>2</sub>O was repeatedly pulsed with the TAP setup at 593 K over the iron containing zeolite and the responses of reactant, product and inert tracer are illustrated in Figure 5.1. Nitrogen appeared in the reactor outlet almost simultaneously with nitrous oxide, while no molecular oxygen could be observed by the mass spectrometer during these experiments. Thus, the formation of surface atomic oxygen (O)<sub>Fe</sub> was evidenced by the release of gaseous N<sub>2</sub> through partial decomposition of N<sub>2</sub>O. The TAP experiments at low temperatures (593 K and 523 K) are in line with Equation (5.1).

**Figure 5.1.:** Transient response curves of N<sub>2</sub>O, Ar and N<sub>2</sub> obtained after introduction of single N<sub>2</sub>O/Ar pulses over the Fe-ZSM-5<sub>5500</sub> catalyst at 593 K.

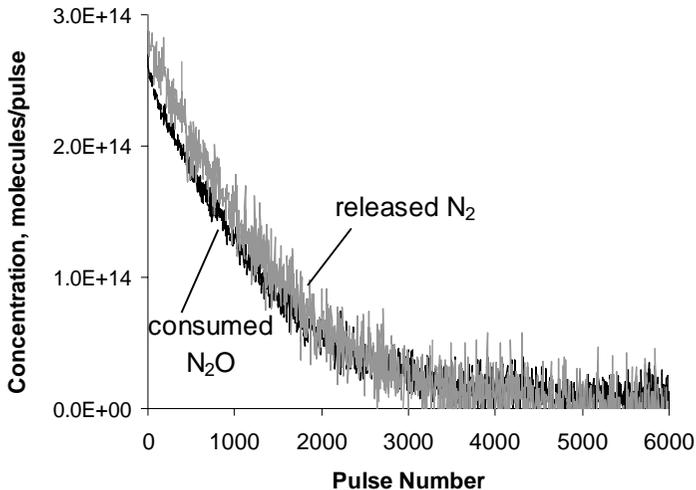

During a train of N<sub>2</sub>O/Ar pulses over the standard pre-treated catalyst, the N<sub>2</sub>O conversion as well as the N<sub>2</sub> production were progressively decreasing until no N<sub>2</sub>O decomposition was observed anymore meaning that all the active sites were saturated with oxygen. This characteristic is the basis of the following section where the titration of the sites active in N<sub>2</sub>O decomposition in the Fe-ZSM-5 sample is described.

## 5.2. Titration of Active Sites

N<sub>2</sub>O reacted at low temperatures (< 600 K) with the catalyst resulting in the formation of gaseous nitrogen and oxygen bound by the catalyst as in Equation (5.1). A complete saturation of the active sites can be reached by N<sub>2</sub>O exposure at low temperatures where oxygen was stored and did not desorb. The concentration of active sites of the Fe-ZSM-5,  $C_{Fe}^{N_2O}$ , was defined as the number of deposited surface atomic oxygen (O)<sub>Fe</sub> per mass of catalyst. It was indirectly calculated by the amount of decomposed N<sub>2</sub>O molecules or released N<sub>2</sub> molecules until saturation. The standard pre-treated catalyst was considered as surface atomic oxygen free.

### 5.2.1. Pulse Technique under Vacuum

A titration of the active sites of the Fe-ZSM-5<sub>5500</sub> was achieved with the TAP-system. N<sub>2</sub>O/Ar (80/20) pulses were introduced in the TAP reactor at 593 K. The pulse size was about  $4.8 \cdot 10^{14}$  molecules/pulse. The N<sub>2</sub>O and N<sub>2</sub> responses were measured at the outlet of the reactor and the area below the pulse responses determined. A typical curve resulting from the multi-pulse experiments with N<sub>2</sub>O at 593 K is shown in Figure 5.2.

**Figure 5.2:** Multi-pulse titration experiment. Released amount of N<sub>2</sub> and consumed N<sub>2</sub>O during N<sub>2</sub>O pulsing at 593 K versus pulse number over 0.0994 g standard pre-treated Fe-ZSM-5<sub>5500</sub>. Pulse size:  $4.8 \cdot 10^{14}$  molecules/pulse.

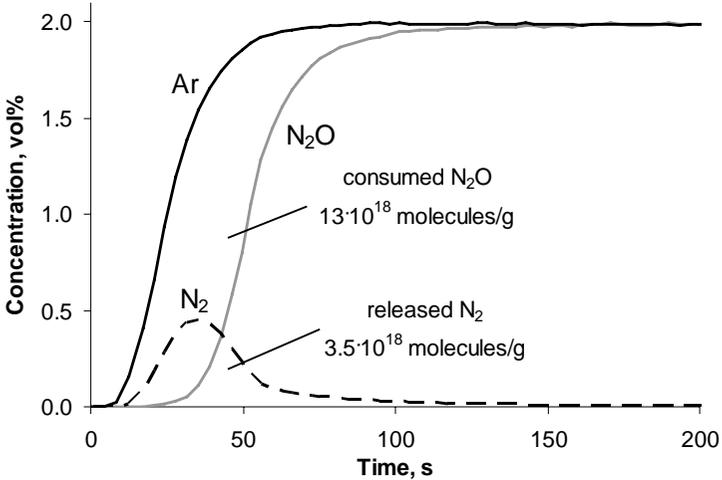

The amount of produced N<sub>2</sub> and consumed N<sub>2</sub>O per pulse is plotted versus pulse number. The N<sub>2</sub>O conversion in the first pulse (ca. 60%) decreased with the pulse number as a consequence of the gradual saturation of the active sites in the catalyst. The decrease was sharper during the first 3000 pulses and gradually approached the value of zero conversion after 6000 pulses. The injections continued until the catalyst was saturated which was indicated when all subsequent N<sub>2</sub>O peaks remained the same size.

The concentration of active sites ( $C_{Fe}^{N_2O}$ ) was estimated from the amount of N<sub>2</sub> released assuming that a single oxygen atom was chemisorbed on each active site. A summarization of the released amount of N<sub>2</sub> per pulse over 6000 N<sub>2</sub>O pulses gave  $C_{Fe}^{N_2O}$ . An integration of the consumed amount of N<sub>2</sub>O over the pulse number represented the amount of decomposed N<sub>2</sub>O plus reversibly adsorbed N<sub>2</sub>O and can, therefore, deviate from the amount of released N<sub>2</sub>. The found concentrations were  $(3.0 \pm 0.6) \cdot 10^{18}$  molecules/g released N<sub>2</sub> and  $(2.8 \pm 0.6) \cdot 10^{18}$  molecules/g consumed N<sub>2</sub>O for various catalyst loadings between 0.02 and 0.1g. Assuming the validity of Equation (5.1), the amount of released N<sub>2</sub> molecules/g corresponds to the amount of active sites/g.

The equality of the values for the released N<sub>2</sub> and consumed N<sub>2</sub>O is in line with the results of Panov [1]. They measured the concentration of active sites in a static vacuum setup from the amount of the N<sub>2</sub> released or the N<sub>2</sub>O consumed, since these two amounts were found to be equal. This shows that the reversible adsorption of N<sub>2</sub>O isn't very pronounced in vacuum and the amount of released N<sub>2</sub> or consumed N<sub>2</sub>O is equal to the amount of active sites. Thus, the concentration of active sites found with the TAP setup was about  $3.0 \cdot 10^{18}$  sites/g.

### 5.2.2. Transient Flow Method at Atmospheric Pressure

The amount of active sites in the Fe-ZSM-5<sub>500</sub> was also measured via transient response method at atmospheric pressure during N<sub>2</sub>O decomposition over the catalyst at 523 K. The reaction gas phase was monitored in the reactor outlet after switching in the inlet from He to a mixture of 2 vol% N<sub>2</sub>O, 2 vol% Ar in He. The gas-phase composition as a function of time for the Fe-ZSM-5<sub>500</sub> catalyst is presented in Figure 5.3.

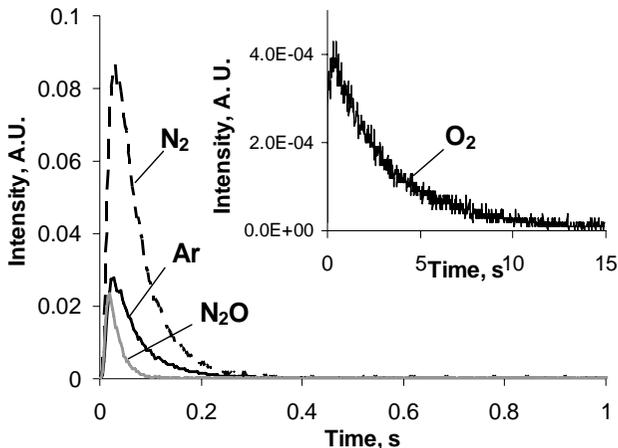

**Figure 5.3:** Transient responses at 523 K obtained after the switch from He to the 2 vol% N<sub>2</sub>O + 2 vol% Ar + 96 vol% He mixture over Fe-ZSM-5<sub>500</sub> catalyst.

The reaction was assumed to proceed as in Equation (5.1) through evolution of a stoichiometric amount of N<sub>2</sub> into the gas phase and deposition of one oxygen atom per each Fe(II). The concentration of active sites was determined by integration of the peak of the released nitrogen to  $3.5 \cdot 10^{18}$  sites/g. The integration of the area between the Ar and N<sub>2</sub>O response allowed the estimation of the amount of consumed N<sub>2</sub>O which was found to be  $13 \cdot 10^{18}$  molecules/g. The amount of reversibly adsorbed N<sub>2</sub>O ( $13 \cdot 10^{18}$  molecules/g –  $3.5 \cdot 10^{18}$  molecules/g =  $9.5 \cdot 10^{18}$  molecules/g) was about three times higher than  $C_{Fe}^{N_2O}$ . This is different to experiments in vacuum by Panov [1] at 523 K where the amount of consumed N<sub>2</sub>O and released N<sub>2</sub> were found to be equal. The difference is attributed to the higher partial pressure of N<sub>2</sub>O (2 kPa instead of 0.027-0.053 kPa) in the transient response method.

It could be shown that the pulse experiment in vacuum as well as the transient response method at atmospheric pressure resulted in about the same concentration of active sites ( $\sim 3 \cdot 3.5 \cdot 10^{18}$  sites/g) which was determined from the N<sub>2</sub> release. Taking into consideration that the catalyst sample contained 5500 ppm Fe, only 5% of the total amount of Fe atoms in the zeolite were active in oxygen loading from N<sub>2</sub>O. This indicates that a very large fraction of the iron in the zeolite is unable to activate the N<sub>2</sub>O molecule under TAP and atmospheric conditions at temperatures below 600 K.

### 5.3. Molecular Oxygen Formation

Above 600 K the formation of molecular oxygen accompanied by the evolution of N<sub>2</sub> was observed during N<sub>2</sub>O decomposition over Fe-ZSM-5. In contrast to lower temperatures (<600 K) surface oxygen recombined and desorbed as in Equation (5.2). The transient responses upon pulsing N<sub>2</sub>O at 803 K are presented in Figure 5.4. The inset with a 15 times larger time scale shows O<sub>2</sub> that was desorbed in a broad peak.

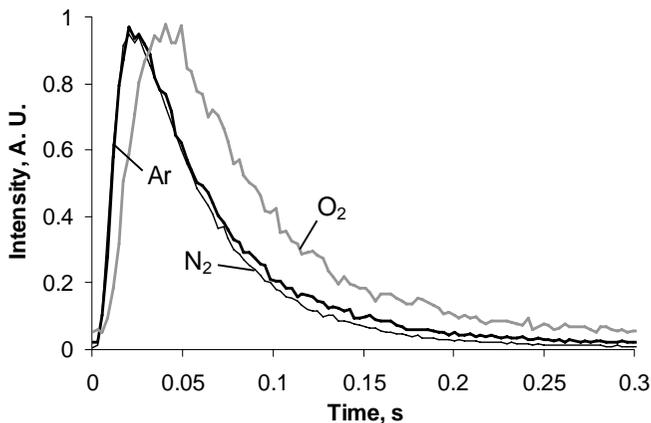

**Figure 5.4:** Transient response curves of N<sub>2</sub>O, Ar and N<sub>2</sub> obtained after introduction of single N<sub>2</sub>O/Ar pulses over the Fe-ZSM-5<sub>5500</sub> catalyst at 803 K. O<sub>2</sub> formation during N<sub>2</sub>O decomposition at 803 K (inset).

The N<sub>2</sub>O curve didn't intersect the Ar curve which is the diffusion-only case. Gleaves and coworkers [2] have demonstrated that such behavior was indicative of irreversible adsorption and reaction. The conversion of N<sub>2</sub>O was about 80%. A large amount of N<sub>2</sub> was produced as well as O<sub>2</sub>. These responses provide valuable qualitative information on the reaction mechanism and will be further studied in the next section.

The single-pulse experiment of N<sub>2</sub>O was repeated with the Fe-ZSM-5 at even higher temperature 946 K. The height-normalized transient responses of Ar, O<sub>2</sub> and N<sub>2</sub> are illustrated in Figure 5.5. The N<sub>2</sub>O conversion at 946 K was about 95%.

Higher temperatures accelerate the diffusion process. The molecules passed the reactor very fast leading to sharp response curves. The normalized Ar and N<sub>2</sub> curves were very similar indicating that the formation of N<sub>2</sub> by N<sub>2</sub>O decomposition was very fast and not retarded. The response of O<sub>2</sub> (peak maximum at 0.05 s) was only delayed by

0.03 s with respect to N<sub>2</sub> instead of 0.5 s at 803 K. The sharpening of the O<sub>2</sub> response at 946 K indicated that the oxygen recombination/desorption was faster and significantly accelerated compared to 803 K. However, the delayed O<sub>2</sub> response showed that the recombination/desorption of oxygen was still the slowest step.

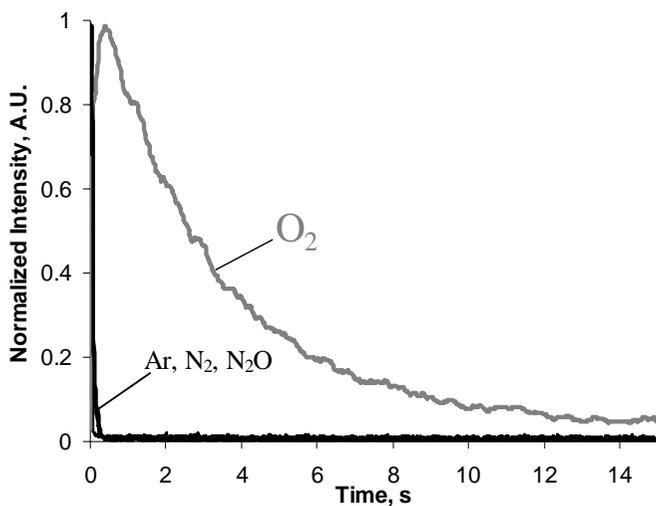

**Figure 5.5:** Height-normalized transient response curves of Ar, O<sub>2</sub> and N<sub>2</sub> obtained after introduction of single N<sub>2</sub>O/Ar pulses over the Fe-ZSM-5<sub>5500</sub> catalyst at 946 K.

## 5.4. The Mechanism of Oxygen Formation

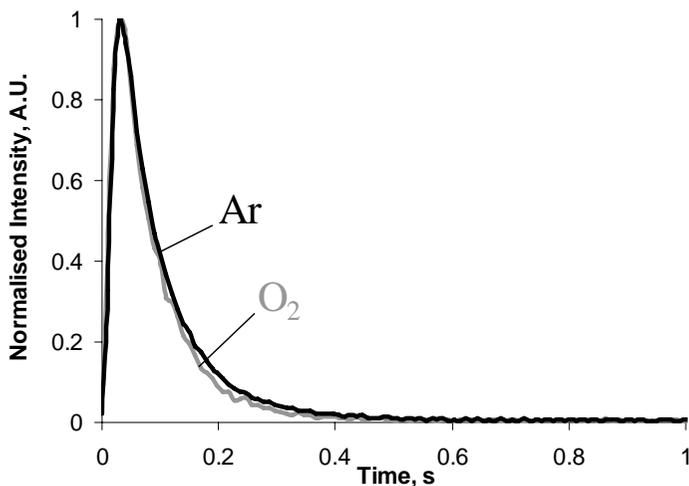

### 5.4.1. Qualitative Assumptions from Pulse Shapes

In order to extract qualitative data from the previous responses the height-normalized responses observed during a N<sub>2</sub>O single-pulse experiment at 803 K over Fe-ZSM-5 are shown in Figure 5.6. The pulse shapes were easier to compare in this way. The N<sub>2</sub>O, Ar and N<sub>2</sub> were similar in shape compared to the O<sub>2</sub> response signal being much broader and deviating from the other curves. Possible reasons for the shape of O<sub>2</sub> can be mechanistic features of N<sub>2</sub>O decomposition or simply the non-reactive adsorption-desorption phenomena of O<sub>2</sub> along the catalyst bed [3]. Therefore, a mixture of O<sub>2</sub> and Ar was pulsed at the same temperature (803 K) over the Fe-ZSM-5<sub>5500</sub>. The height-normalized response curves are shown in Figure 5.7. The pulse responses of Ar and O<sub>2</sub> were very similar in shape. Ar as inert tracer hardly undergoes adsorption-desorption processes with the zeolite and represents the diffusion-only case [2], so did oxygen. Therefore, the broader and delayed oxygen response from a N<sub>2</sub>O pulse

compared to the Ar response in Figure 5.6 is due to mechanistic features of the  $\text{N}_2\text{O}$  decomposition.

**Figure 5.6:** Height-normalized transient response curves obtained after introduction of single  $\text{N}_2\text{O}/\text{Ar}$  pulses over the Fe-ZSM-5<sub>5500</sub> catalyst at 803 K.

**Figure 5.7:** Height-normalized transient response curves obtained after introduction of single  $\text{O}_2/\text{Ar}$  pulses over the Fe-ZSM-5<sub>5500</sub> catalyst at 803 K.

From Figure 5.6 it can be seen that O<sub>2</sub> still desorbed during 15 s from the catalyst even though all N<sub>2</sub>O molecules left the reactor within 0.5 s. Additionally, while oxygen still desorbed, no N<sub>2</sub> was produced anymore since N<sub>2</sub> evolved within 0.5 s. Thus, the deposition of active surface oxygen by N<sub>2</sub>O was finished within 0.5 s, while the recombination and desorption of oxygen took up to 15 s. Therefore, it can be concluded that the rate-determining step of the N<sub>2</sub>O decomposition at 803 K was the recombination/desorption of oxygen.

In the literature two possible rate-determining steps for the N<sub>2</sub>O decomposition are discussed. Mechanistic studies have substantiated that O<sub>2</sub> formation is the rate-determining step in N<sub>2</sub>O decomposition over iron containing zeolites [3-8]. Basically, two pathways leading to O<sub>2</sub> have been put forward. At one side, the reaction of adsorbed oxygen species, (O)<sub>Fe</sub>, with gas-phase N<sub>2</sub>O was proposed to result in O<sub>2</sub> formation over Fe-ZSM-5 [9, 10].

On the other side, the recombination of two surface oxygen atoms into molecular oxygen was suggested as a source of O<sub>2</sub> in N<sub>2</sub>O decomposition over Fe-ZSM-5 (Equation (5.2)) [3-6, 11].

Heyden et al. have developed a comprehensive mechanistic model for the direct decomposition of N<sub>2</sub>O on Fe-ZSM-5 on the basis of DFT calculations [12, 13]. They state that the rate-determining step in the reaction path is N<sub>2</sub>O dissociation, releasing a N<sub>2</sub> molecule and leaving an O atom on the site (Equation (5.1)).

In case of Equation (5.3) being the rate-determining step, the TAP experiments should show O<sub>2</sub> production while N<sub>2</sub>O is present and N<sub>2</sub> is produced. This could be the case in the first 0.5 s after N<sub>2</sub>O introduction while N<sub>2</sub>O, N<sub>2</sub> and O<sub>2</sub> evolved simultaneously as seen in Figure 5.6. However, the main part of O<sub>2</sub> was produced when N<sub>2</sub>O left the reactor and the formation of N<sub>2</sub> was finished. Therefore, the most reasonable explanation for the observed TAP results is given in Equation (5.2), that oxygen recombination/desorption is the rate-determining step. O<sub>2</sub> was produced in absence of N<sub>2</sub>O and without formation of N<sub>2</sub> in parallel.

If the dissociation of N<sub>2</sub>O as proposed by Heyden et al. [12, 13] is the rate-determining step while the recombination/desorption of oxygen is fast, then O<sub>2</sub> and N<sub>2</sub> would be produced as long as N<sub>2</sub>O is present on the catalyst. When N<sub>2</sub>O passed the catalyst bed, oxygen should desorb very fast since this step is not considered to be slow. The desorption of O<sub>2</sub> in TAP experiments took up to 15 s compared to 0.5 s for the N<sub>2</sub>O passage and N<sub>2</sub> formation. Thus, TAP experiments are not in line with the third mechanistic proposal. TAP results confirm recombination/desorption of surface oxygen as the rate-determining step.

### 5.4.2. Kinetic Fit on Oxygen Decay

The kinetics of the oxygen formation was analyzed to derive insights into plausible reaction pathways leading to O<sub>2</sub>. At 803 K oxygen was loaded on the catalyst during a N<sub>2</sub>O pulse. The N<sub>2</sub>O decomposition and N<sub>2</sub> evolution was finished within 0.5 s since N<sub>2</sub>O passed the reactor within this time and no gaseous N<sub>2</sub> was produced anymore after this time delay. Only gaseous O<sub>2</sub> was formed up to 15 s. Therefore, it can be assumed that from 0.5 s on after the injection of N<sub>2</sub>O only the final step of the catalytic cycle took place: the formation and desorption of oxygen, yielding gas-phase O<sub>2</sub> and free iron sites (Equation (5.2)).

Since re-adsorption of O<sub>2</sub> was negligible in TAP experiments as shown in section 5.4.1, the relative rate of desorption, defined as the change in adsorbate coverage per unit of time, is given by

$$-\frac{d\theta_o}{dt} = k \cdot \theta_o^n \quad (5.4)$$

in which  $\theta_o$  is the coverage of active sites with oxygen,  $t$  the time,  $n$  the order of recombination/desorption and  $k$  the rate constant. The desorption rate is proportional to the registered O<sub>2</sub> flow at the reactor exit  $I_{O_2}$  in units of mass per time:

$$-\frac{d\theta_o}{dt} \sim I_{O_2} \quad (5.5)$$

The amount of oxygen on the catalyst at a certain time  $t'$  can be calculated by an integration of the area below the oxygen response curve from time  $t'$  until all oxygen is desorbed at  $t \rightarrow \infty$ :

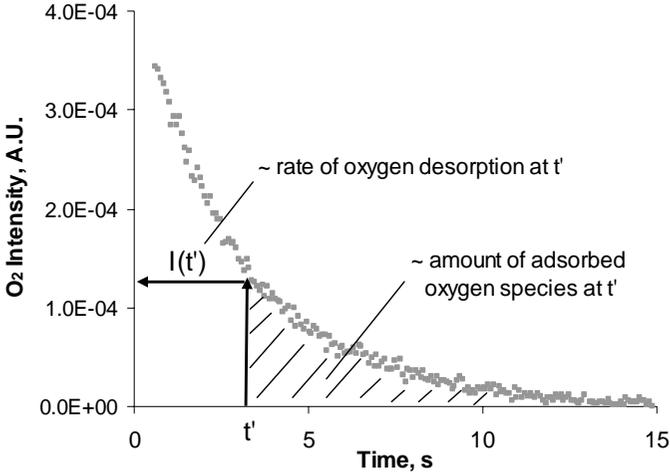

$$\theta_o(t=t') \sim \int_{t=t'}^{t \rightarrow \infty} I_{O_2} \cdot dt \quad (5.6)$$

By implementing Equation (5.5) and (5.6) in Equation (5.4), the following expression is reached which contains two kinetic constants and two measurable terms:

$$I_{O_2} \Big|_{t=t'} = k_1 \cdot \left( \int_{t=t'}^{t \rightarrow \infty} I_{O_2} \cdot dt \right)^n \quad (5.7)$$

The desorption of surface oxygen loaded from one N<sub>2</sub>O pulse at 803 K is presented in Figure 5.8. As indicated, the oxygen desorption rate was proportional to the gas flow  $I_{O_2}$  at  $t'$  and the amount of adsorbed oxygen species at  $t'$  was determined by the

integration of  $I_{O_2}$  from  $t'$  until oxygen desorption was completed in this case at 15 s. The first 0.5 s upon the N<sub>2</sub>O injection were not considered since the reaction system is much more complex due to the decomposition of N<sub>2</sub>O and the formation of N<sub>2</sub>.

**Figure 5.8:** Height-normalized transient response O<sub>2</sub> curve obtained after introduction of single N<sub>2</sub>O/Ar pulse over the Fe-ZSM-55500 catalyst at 803 K.

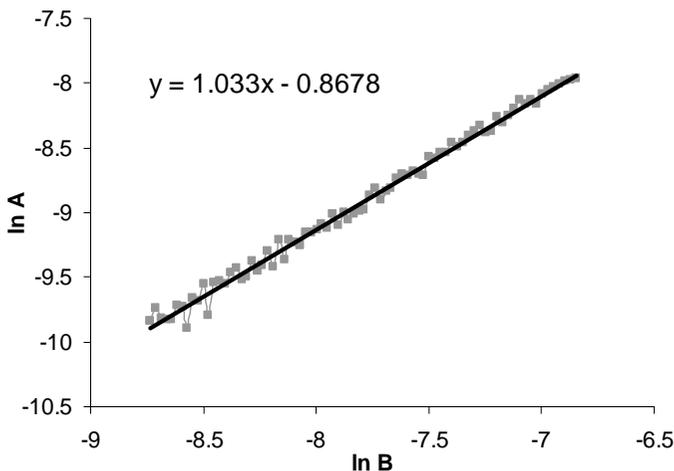

Equation (5.8) is the linearised form of Equation (5.7) by taking the logarithm. The slope represents the order of the desorption of oxygen.

$$\ln \left[ \underbrace{I_{O_2} \Big|_{t=t'}}_A \right] = \ln k_1 + n \cdot \ln \left[ \underbrace{\int_{t=t'}^{t \rightarrow \infty} I_{O_2} \cdot dt}_B \right] \quad (5.8)$$

Figure 5.9 exemplifies  $\ln A$  versus  $\ln B$  for the oxygen desorption seen in Figure 5.8. The straight line demonstrates the agreement between experiment and theory while the slope corresponds to the order of oxygen desorption. Several transient responses of O<sub>2</sub> derived from pulse experiments with the TAP reactor were fitted with Equation (5.8) to determine the order of oxygen desorption which was found to be  $0.95 \pm 0.1$ .

A desorption order of about one corresponds to a monomolecular desorption. An associative desorption as the recombination of two monoatomic surface oxygen species, (O)<sub>Fes</sub> proposed in Equation (5.2) would result in an order of two. Therefore, intermediate reactions steps may be added to Equation (5.2) to be in line with the kinetic analysis of the transient TAP experiments. The involvement of adsorbed NO<sub>x</sub> species catalyzing the desorption of oxygen can be excluded since the NO<sub>x,ads</sub> species were

already desorbed at temperatures around 800 K as shown in the TPD experiments in chapter 6.

**Figure 5.9:** Linearization of oxygen desorption curve of Figure 5.8 by Equation (5.8).

The first order dependence of the oxygen desorption can be explained for example by the slow desorption of bimolecular oxygen. Other authors already suggested the formation of oxygen via desorption of a bimolecular oxygen species. Kondratenko et al. [14] concluded from the simultaneous fitting of N<sub>2</sub>O, N<sub>2</sub> and O<sub>2</sub> TAP responses upon N<sub>2</sub>O decomposition over Fe-ZSM-5 that a biatomic oxygen precursor was formed upon N<sub>2</sub>O decomposition over a Fe site with monoatomic adsorbed oxygen species. This biatomic precursor was transformed to another biatomic oxygen species, which decomposed yielding gas-phase O<sub>2</sub> and free iron site. Heyden et al. [13] assumed biatomic oxygen species of different structure and triatomic oxygen species as surface precursors for gaseous O<sub>2</sub> evolution in DFT modeling. Bell and coworkers [8, 15, 16] proposed N<sub>2</sub>O decomposition proceeded via dissociative adsorption of N<sub>2</sub>O on a vacant iron site, releasing a N<sub>2</sub> molecule and leaving an O atom on the site. A second N<sub>2</sub>O molecule decomposed on the same site, so that two O atoms were attached to the same site. These atoms recombined to form an O<sub>2</sub> molecule, which then desorbed from the iron site. The linear dependence of the oxygen desorption rate on the surface coverage of oxygen derived from TAP experiments is in accordance with the suggestions made in literature.

# Chapter 6

## EFFECT OF NO ON N<sub>2</sub>O DECOMPOSITION

At 523 K only the formation of surface atomic oxygen (O)<sub>fc</sub> on Fe containing sites and gaseous N<sub>2</sub> from N<sub>2</sub>O takes place. Oxygen recombines only at higher temperatures indicating that, in general, the accepted rate-determining step in N<sub>2</sub>O decomposition is the desorption of oxygen from the catalyst surface [1-3] whereupon is also concluded in chapter 4 based on TAP experiments. The addition of gaseous NO enhances the activity of Fe containing zeolites [1, 3-5]. Slow NO formation on the catalyst surface from N<sub>2</sub>O interaction is observed over Fe- and Cu-zeolites [6-10]. NO/NO<sub>2</sub> [3, 5, 11] as well as nitrite/nitrate [12] redox cycles are proposed for active sites regeneration in N<sub>2</sub>O decomposition.

Perez-Ramirez et al. [3] studied the N<sub>2</sub>O decomposition over homemade isomorphously substituted extra-framework Fe-ZSM-5 with the Multitrack, a TAP like system. It was supposed that adsorbed NO may accommodate oxygen loaded by N<sub>2</sub>O on an adjacent site, allowing the deposition of a second oxygen and supporting the recombination of both. Adsorbed NO may even facilitate the migration of atomic oxygen to enhance their recombination. They observed NO-induced NO<sub>2</sub> desorption while they didn't report NO<sub>x,ads</sub> formation from N<sub>2</sub>O in the absence of adsorbed NO.

## 6.1. NO<sub>x,ads</sub> Formation from N<sub>2</sub>O on Fe-ZSM-5 at Low Temperatures

Adsorbed surface species on the Fe-ZSM-5<sub>500</sub> catalyst were investigated by temperature-programmed desorption experiments after different numbers of N<sub>2</sub>O pulses at 593 K as well as at 523 K using the TAP setup. At these temperatures N<sub>2</sub>O formed gaseous N<sub>2</sub> and atomic surface oxygen, (O)<sub>Fe</sub>, involving Fe containing sites. The formation of gaseous oxygen by N<sub>2</sub>O decomposition took place at temperatures higher than 661 K. No gaseous NO/NO<sub>2</sub> was detected while pulsing N<sub>2</sub>O in the range of 523 K to 946 K.

After N<sub>2</sub>O pulsing over the zeolite at 593 K, only O<sub>2</sub> and NO were detected during the TPD runs which are illustrated in Figure 6.1. Oxygen loaded during the N<sub>2</sub>O interaction of 300, 600 and 1800 pulses was released with peaks at 713 K, 701 K and 678 K, respectively (Figure 6.1a). With increasing amount of performed N<sub>2</sub>O pulses, the amount of accumulated surface oxygen increased and the maximum temperature of the oxygen desorption shifted to lower temperature (by ~35 K) indicating an easier oxygen desorption. According to Figure 6.1b, which shows the corresponding NO TPD profiles, it increased the amount of NO formed and accumulated on the surface with increasing the number of performed N<sub>2</sub>O pulses. It is interesting to note that NO desorbed during these TPD experiments always at the very end of the oxygen desorption with the maxima at 707-757 K. The parallel evolution of O<sub>2</sub> and NO in the TPD experiments suggests a common surface species which decomposes to O<sub>2</sub> and NO. Therefore, the surface NO detected in the TPD runs was assigned to surface NO<sub>x,ads</sub> species.

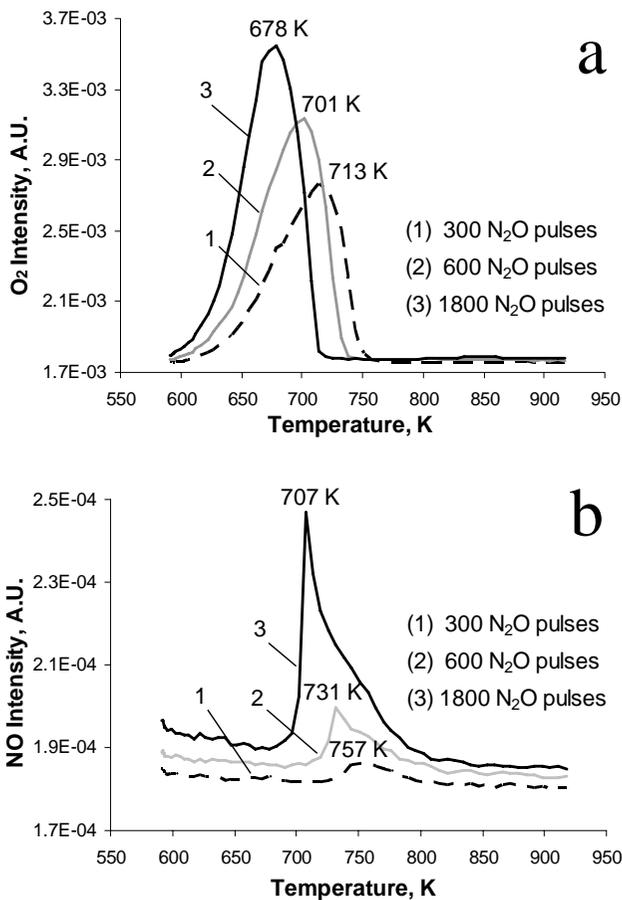

At 523 K the loading of oxygen on iron sites from N<sub>2</sub>O as well as the formation of NO<sub>x,ads</sub> was much slower. TPD runs after N<sub>2</sub>O multi-pulse experiments showed desorption of gaseous O<sub>2</sub>, but the NO concentration was below the detection limit, see Figure 6.3b, curve 1. The absence of detected NO<sub>x,ads</sub> species at 523 K proved that they did not correspond to an impurity in the dosed N<sub>2</sub>O blend at 593 K since adsorption phenomena should be strengthened at lower temperature. Nevertheless, the desorption maxima of oxygen decreased as well (744 K to 730 K) with increasing number of N<sub>2</sub>O pulses (600 to 1200, not shown) indicating the existence of surface NO<sub>x,ads</sub> on the catalyst.

These results evidenced the creation of adsorbed NO<sub>x</sub> on the zeolite during N<sub>2</sub>O decomposition:

As the amount of accumulated NO<sub>x</sub> increased, the oxygen desorption temperature shifted to lower temperatures suggesting the ease of oxygen desorption. The

data lead to the conclusion that the formed NO<sub>x</sub> surface species ease the desorption of (O)<sub>Fe</sub>. To confirm this, special experiments with NO pre-adsorption are performed and discussed in the following section.

**Figure 6.1:** O<sub>2</sub> (a) and NO (b) TPD profiles obtained after 300 (1), 600(2) and 1800 (3) pulses of N<sub>2</sub>O over the Fe-ZSM-5<sub>5500</sub> catalyst at 593 K.

## 6.2. N<sub>2</sub>O Interaction with NO Adsorbed on Fe-ZSM-5

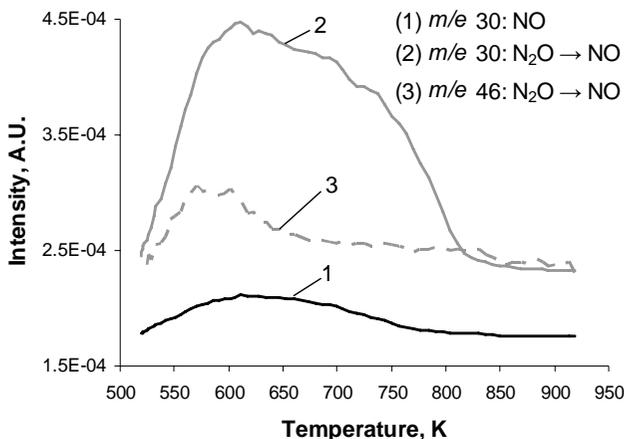

The effect of pre-adsorbed NO on the desorption of oxygen loaded from N<sub>2</sub>O is studied at 523 K using the TAP setup. NO is adsorbed on the catalyst by NO and

N<sub>2</sub>O→NO treatments. First only the adsorption of NO on the Fe-ZSM-5<sub>5500</sub> is discussed in this chapter and then the interaction of N<sub>2</sub>O with the NO<sub>ads</sub> containing zeolite is investigated.

### 6.2.1. NO Adsorption on Fe-ZSM-5

Only a small amount of irreversible adsorbed NO remained on the catalyst after 600 NO pulses over the Fe-ZSM-5<sub>5500</sub> at 523 K. In Figure 6.2, curve 1, it can be seen that NO desorbed in a broad peak during the TPD experiment. No oxygen desorbed and, therefore, it was not formed during the interaction of NO with the catalyst.

About 10 times more NO was adsorbed on the catalyst which was pre-treated with 600 N<sub>2</sub>O pulses compared to the standard pre-treatment. NO/NO<sub>2</sub> TPD profiles of the catalyst after N<sub>2</sub>O→NO treatment at 523 K are presented in Figure 6.2, curve 2 and 3. Surface oxygen was loaded from N<sub>2</sub>O pulses (600) which was mainly desorbed by the subsequent NO pulses (600) as discussed in detail in section 6.3. Only a small amount of oxygen remained on the catalyst to form NO<sub>x,ads</sub> species (not shown).

**Figure 6.2:** NO TPD profiles obtained after pulsing NO (1) and N<sub>2</sub>O→NO (2), NO<sub>2</sub> TPD profile obtained after pulsing N<sub>2</sub>O→NO (3) over the Fe-ZSM-5<sub>5500</sub> catalyst at 523 K.

The concentration of irreversibly adsorbed NO on the Fe-ZSM-5<sub>5500</sub> was surprisingly around ten times larger on oxygen containing surface as compared to the standard pre-treated catalyst (Figure 6.2). As already mentioned, the initial iron oxidation state is probably +II after the pre-treatment for 30 min at 946 K in vacuum. The interaction of the oxidant N<sub>2</sub>O with the Fe-ZSM-5 oxidizes a fraction of the active iron

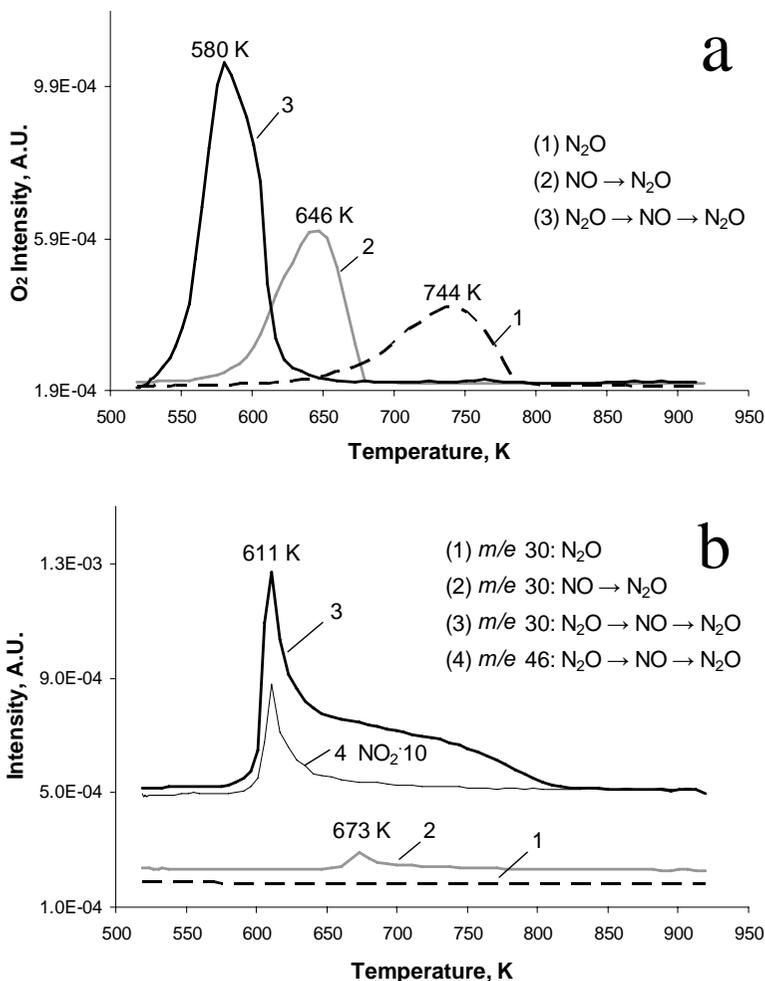

sites to Fe(III) through the deposition of atomic oxygen. According to infrared studies NO adsorbs strongly on Fe(II) and not to any significant extent on Fe(III) [13, 14]. However, the TAP studies showed much higher affinity of NO with the Fe-ZSM-5 containing (O)<sub>Fe</sub> species. The same tendency was observed during transient response experiments in [11] where the amount of irreversibly adsorbed NO doubled after N<sub>2</sub>O pre-treatment compared to the calcined catalyst. NO adsorption was somehow provided by the (O)<sub>Fe</sub> sites while forming NO<sub>x,ads</sub> and initiating the oxygen recombination and desorption even at low temperature as 523 K (discussed in section 6.3).

### 6.2.2. Interaction of N<sub>2</sub>O with Fe-ZSM-5 Containing NO<sub>ads</sub>

The interaction of N<sub>2</sub>O with adsorbed NO on the Fe-ZSM-5<sub>5500</sub> was studied at 523 K. Therefore, TPD profiles were compared after the interaction of N<sub>2</sub>O with the differently pre-treated catalyst: (1) only standard pre-treated ("clean" catalyst), (2) NO, (3) N<sub>2</sub>O→NO. After pre-treatment (1) no surface species were detected. In the other pre-treatments NO was adsorbed. The catalyst contained after pre-treatment (3) about 10 times more NO<sub>ads</sub> than after pre-treatment (2) which is discussed in the previous section. The amount of performed N<sub>2</sub>O pulses (600 pulses) was constant but didn't lead to saturation with atomic oxygen of the catalyst. N<sub>2</sub>O pulses over the catalyst with adsorbed NO resulted neither in NO desorption, nor in gaseous NO<sub>2</sub> formation while surface oxygen from N<sub>2</sub>O was loaded. The consequent O<sub>2</sub> TPD profiles are presented in Figure 6.3a. The maximum of the oxygen desorption shifted strongly to lower temperatures from 744 K to 646 K and 580 K, respectively. The amount of deposited (O)<sub>Fe</sub> was 1.3 times larger in the presence of adsorbed NO (Figure 6.3a, curve 2) and was 3.4 times larger after N<sub>2</sub>O→NO pre-treatment (Figure 6.3a, curve 3) compared to the NO<sub>ads</sub> free catalyst (Figure 6.3a, curve 1).

Figure 6.3b illustrates the corresponding NO TPD profiles. No NO (curve 1) was detected after the N<sub>2</sub>O only pulsing contrary to the NO (curve 2) and N<sub>2</sub>O→NO (curve 3) pre-treated cases. NO desorbed each time at the very end of the oxygen desorption. Partially NO and O<sub>2</sub> evolved simultaneously which was assigned to a common NO<sub>x,ads</sub> species. They appeared as sharp peak similar to the NO<sub>x</sub> surface species generated during N<sub>2</sub>O interaction at 593 K as discussed in section 6.1.

Curve 3 and curve 4 of Figure 6.3b show the responses for the mass to charge ratio ( $m/e$ ) 30 (NO) and  $m/e$  46 (NO<sub>2</sub>) during the TPD after the N<sub>2</sub>O→NO→N<sub>2</sub>O multi-pulse sequence. They had the same maxima at 611 K indicating that a common surface species contributed to  $m/e$  30 (NO), 46 (NO<sub>2</sub>) and to 32 (O<sub>2</sub>). Hence, adsorbed NO<sub>2</sub> or even higher oxidized nitrogen oxide species were formed on the catalyst and their assignment was ambiguous.

**Figure 6.3:** O<sub>2</sub> (a) and NO/NO<sub>2</sub> (b) TPD profiles obtained after pulsing N<sub>2</sub>O (1), NO → N<sub>2</sub>O (2), N<sub>2</sub>O → NO → N<sub>2</sub>O (3) and NO<sub>2</sub> TPD profile obtained after pulsing N<sub>2</sub>O → NO → N<sub>2</sub>O (b, 4) over the Fe-ZSM-5<sub>5500</sub> catalyst at 523 K.

Pure NO<sub>ads</sub> (Figure 6.2, curve 1) desorbed in a broad peak during the TPD runs while the NO<sub>x,ads</sub> species (Figure 6.1b and Figure 6.3b) appeared in a sharp peak. The NO TPD profile (Figure 6.3b, curve 3) after the N<sub>2</sub>O → NO → N<sub>2</sub>O multi-pulse sequence showed a sharp peak, to which in parallel NO<sub>2</sub> and O<sub>2</sub> was evolved, and a broad desorption peak of NO only at higher temperatures, which was not accompanied by O<sub>2</sub>

or NO<sub>2</sub> desorption. Therefore, it can be concluded that the catalyst after the N<sub>2</sub>O→NO→N<sub>2</sub>O multi-pulse sequence contained NO<sub>x,ads</sub> as well as NO<sub>ads</sub>.

The amount of loaded (O)<sub>Fe</sub> was elevated with increasing NO concentration on the catalyst (Figure 6.3) while NO<sub>ads</sub> is not known to significantly enhanced oxygen loading from N<sub>2</sub>O [11]. An explanation on the basis of the reaction mechanism is not evident. However, a transport phenomenon could be the reason for this observation. In TAP studies the transport mechanism into the micro pores was assumed as sorption at the exterior of the zeolite particles and only the adsorbed molecules diffuse into the pores [15-17]. An enhanced surface oxygen migration due to NO<sub>ads</sub> was proposed in [3]. This would in TAP experiments raise the degree of pore efficiency and explain the increased (O)<sub>Fe</sub> formation during the N<sub>2</sub>O interaction with the catalyst containing more adsorbed NO.

The more NO (Figure 6.2) was preadsorbed on the catalyst prior to the N<sub>2</sub>O interaction, the more NO<sub>x,ads</sub> species were formed during the final N<sub>2</sub>O interaction (Figure 6.3b). The increase of the NO<sub>x,ads</sub> concentration were accompanied by a decrease of the desorption temperatures of oxygen (~160 K, Figure 6.3a) in TPD runs. Thus, NO<sub>x,ads</sub> species (Figure 6.3b) formed from NO<sub>ads</sub> and N<sub>2</sub>O facilitated the rate-determining step the oxygen recombination/desorption.

In summary, the rate-determining step which is the recombination and desorption of surface atomic oxygen [1-3] is promoted by preadsorbed NO<sub>x</sub> species. NO<sub>ads</sub> did not inhibit oxygen loading from N<sub>2</sub>O, however, considerably lowered the desorption temperature of (O)<sub>Fe</sub>. Therefore, different but adjacent sites for NO adsorption and surface atomic oxygen formation from N<sub>2</sub>O are proposed. Other studies [3, 4, 11] excluded as well the competitive adsorption of atomic oxygen and NO on the same active sites of Fe-ZSM-5. Adsorbed NO is further oxidized by N<sub>2</sub>O to NO<sub>x</sub> species acting as a "co-catalyst" in N<sub>2</sub>O decomposition.

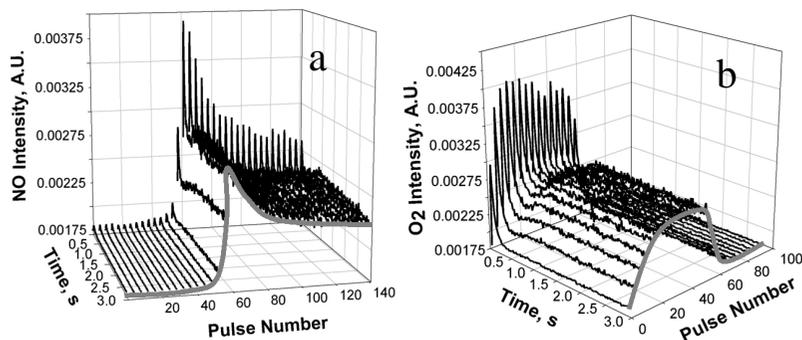

The nature of the NO<sub>x,ads</sub> species is not definite. Different mechanisms are proposed to explain the promoting effect of them in N<sub>2</sub>O decomposition. NO/NO<sub>2</sub> [3, 5, 11] and NO<sub>2</sub>/NO<sub>3</sub> [12] redox cycles are discussed.

### 6.3. NO Interaction with Fe-ZSM-5 Containing (O)<sub>Fe</sub>

In the previous sections, it is shown that adsorbed NO is formed from N<sub>2</sub>O on the Fe-ZSM-5<sub>500</sub>. NO<sub>x,ads</sub> species facilitate the desorption of oxygen during TPD

experiments. It is also interesting to investigate the interaction of NO with the catalyst loaded with oxygen from N<sub>2</sub>O.

NO pulses over the Fe-ZSM-5<sub>5500</sub> pre-loaded with (O)<sub>Fe</sub> from 600 N<sub>2</sub>O pulses at 593 K resulted in a strong irreversible adsorption of NO during the first pulses as illustrated in Figure 6.4a. In parallel the desorption of gaseous O<sub>2</sub> was provoked (Figure 6.4b). NO pulses over N<sub>2</sub>O pre-treated catalyst at even lower temperature (523 K) caused also oxygen to desorb. The following TPD run is discussed in section 6.2.1 and presented a major NO peak (Figure 6.2, curve 2) and some NO<sub>2</sub> (Figure 6.2, curve 3). NO adsorbed in large quantities while only a small amount of NO<sub>x,ads</sub> species were formed during NO and (O)<sub>Fe</sub> interaction. The main part of surface oxygen was desorbed due to NO pulsing:

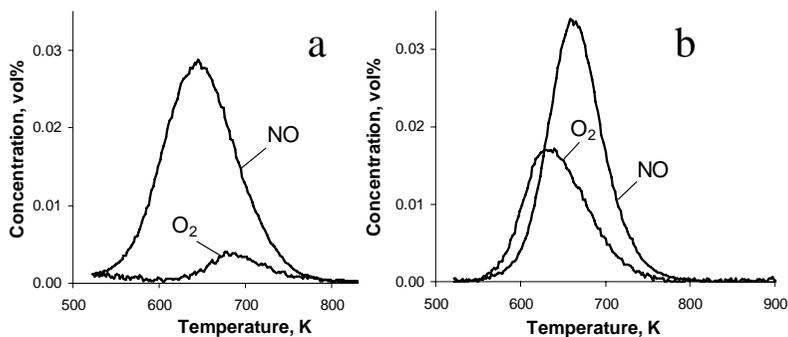

**Figure 6.4:** NO pulses (a) over the Fe-ZSM-5<sub>5500</sub> at 593 K after (O)<sub>Fe</sub> deposition from N<sub>2</sub>O provoked the desorption of oxygen (b). Grey line: guide for eyes.

The competition of NO and loaded oxygen for the same sites was excluded since oxygen loading from N<sub>2</sub>O (section 6.2) on the catalyst after NO pre-treatments was easy and initiate neither NO, nor NO<sub>2</sub> desorption. The investigation of the interaction of N<sub>2</sub>O with preadsorbed NO using the Micromeritics AutoChem 2910 setup at atmospheric pressure showed as well that atomic oxygen was easily loaded [11]. However, the desorption of surface oxygen upon NO interaction was not observed during transient response experiments at atmospheric pressure. The consumption of loaded oxygen by NO was proposed with the formation of adsorbed NO<sub>x</sub> species, which could be located not directly on the iron sites [11]:

The difference is that in TAP experiments the surface oxygen was released by NO interaction and in Micromeritics experiments oxygen was consumed by NO and NO<sub>x,ads</sub> species were formed. This discrepancy was clarified by flow experiments with the Micromeritics setup. It was assumed that the larger part of the freed oxygen in TAP experiments left the reactor directly since it had hardly any possibility to interact with the next catalyst layer (only thin zeolite layer of 1 mm) where O<sub>2</sub> would oxidise NO<sub>ads</sub> to NO<sub>x,ads</sub> species. If this assumption is correct, then it must be possible for molecular oxygen to oxidize NO<sub>ads</sub>.

The generated surface species from the interaction of NO, NO → O<sub>2</sub> and O<sub>2</sub> with the Fe-ZSM-5<sub>350</sub> were compared. The TPD profiles after NO treatment for 5 min at 523 K are shown in Figure 6.5a. The evolution of the adsorbed NO as well a small amount of O<sub>2</sub> was observed. The simultaneous desorption of NO and O<sub>2</sub> was always an indication of common NO<sub>x,ads</sub> species. Thus, NO<sub>x,ads</sub> species were formed on the catalyst from NO only at atmospheric pressure. The TPD profiles after the interaction of O<sub>2</sub> for 5 min at 523 K with the NO pre-treated (5 min at 523 K) Fe-ZSM-5<sub>350</sub> are illustrated in Figure 6.5b.

**Figure 6.5:** TPD profiles obtained after interaction of NO (0.5 vol%, 5 min) (a) and consecutive interaction of NO (0.5 vol%, 5 min) and O<sub>2</sub> (1.5 vol%, 5 min) (b) with the Fe-ZSM-5<sub>350</sub> at 523 K.

The subsequent interaction of NO<sub>ads</sub> and O<sub>2</sub> led to the formation of more NO<sub>x,ads</sub> species than after NO interaction only as seen by the increased amount of desorbed oxygen. It is important to note that O<sub>2</sub> was not found in TPD experiments (not shown) after the interaction of O<sub>2</sub> for 5 min with the standard pre-treated catalyst. In summary, O<sub>2</sub> didn't adsorb on the "clean" catalyst but it interacted with the NO pre-treated catalyst forming NO<sub>x,ads</sub> species.

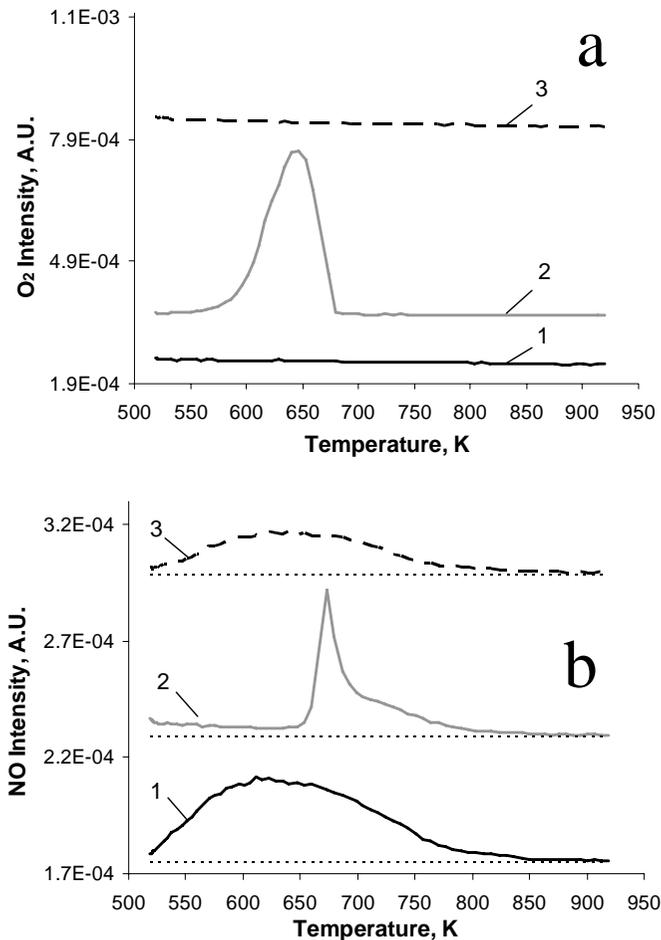

TAP experiments showed that NO pulses led to the desorption of surface atomic oxygen, (O)<sub>FeS</sub>, at low temperatures (523 K and 593 K) where the desorption of O<sub>2</sub> was not observed during N<sub>2</sub>O interaction with the Fe-ZSM-5. NO adsorbed in large amounts on the catalyst and formed a minor part of NO<sub>x,ads</sub> species. In contrast to TAP results,

the desorption of oxygen upon NO interaction with (O)<sub>Fe</sub> at 523 K was not observed in transient experiments at atmospheric pressure [11]. The thin catalyst bed in the TAP reactor was left quickly by O<sub>2</sub> whereas during experiments at atmospheric pressure the freed O<sub>2</sub> had the possibility to react further with NO<sub>ads</sub> or with gas phase NO forming finally NO<sub>x,ads</sub> species. That is a possible explanation for the difference to flow experiments where the desorption of oxygen during the interaction of NO with (O)<sub>Fe</sub> was not observed.

#### 6.4. NO<sub>x,ads</sub> Species Reactivity in CO Oxidation

In the previous sections it was shown that NO<sub>x,ads</sub> species are formed by the interaction of N<sub>2</sub>O with the standard pre-treated Fe-ZSM-5<sub>5500</sub> and even more with the NO pre-treated catalyst. These NO<sub>x,ads</sub> species facilitate the oxygen desorption in TPD experiments and are proposed as "co-catalyst" in the N<sub>2</sub>O decomposition. Their reactivity concerning CO oxidation is discussed in this section as well as their influence on the reactivity of atomic surface oxygen loaded from N<sub>2</sub>O.

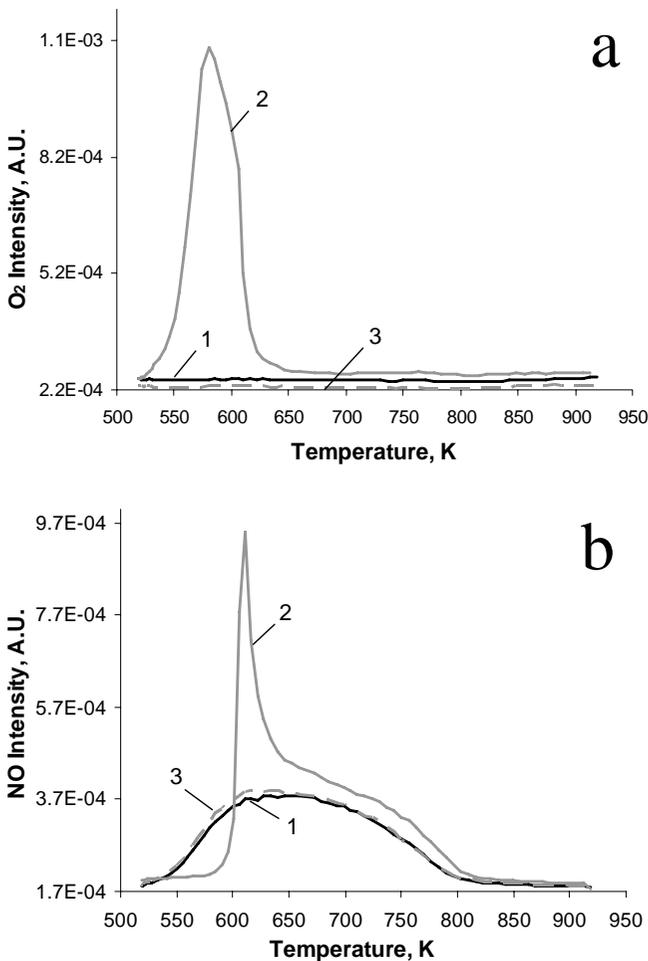

Only a small amount of irreversibly adsorbed NO remained on the catalyst after 600 NO pulses over the Fe-ZSM-5<sub>5500</sub> at 523 K. In Figure 6.6b, curve 1 it can be seen that NO desorbed in a broad peak during the TPD experiment. No oxygen (Figure 6.6a, curve 1) desorbed and was, therefore, not formed during NO treatment. 600 N<sub>2</sub>O pulses subsequent to the NO pre-treatment loaded surface oxygen which desorbed in a TPD run with a maximum at 640 K (Figure 6.6a, curve 2). NO evolved (Figure 6.6b, curve 2) in a sharp peak at the end of the oxygen desorption indicating NO<sub>x,ads</sub> species. The interaction of CO with the surface species formed after NO→N<sub>2</sub>O treatment led to the formation of CO<sub>2</sub>. CO oxidation took place. In the following TPD run it could be observed that all surface oxygen was removed by CO (Figure 6.6a, curve 3) and NO desorbed in a broad peak as irreversibly adsorbed NO (Figure 6.6b, curve 3). Thus, CO was oxidized by surface oxygen and the NO<sub>x,ads</sub> species were reduced to adsorbed NO.

**Figure 6.6:** O<sub>2</sub> (a) and NO (b) TPD profiles obtained after pulsing NO (1), NO→N<sub>2</sub>O (2) and NO→N<sub>2</sub>O→CO (3) over the Fe-ZSM-5<sub>5500</sub> catalyst at 523 K.

About 10 times more NO was adsorbed at 523 K on the catalyst which was pre-treated with 600 N<sub>2</sub>O pulses loading surface oxygen as compared to the standard pre-treatment. In section 6.3 it is shown that NO provoked the desorption of the main part of the surface oxygen, only a small amount remained on the catalyst to form NO<sub>x,ads</sub> species. Several CO pulses reduced these NO<sub>x,ads</sub> species to NO<sub>ads</sub> only. Hence, after a N<sub>2</sub>O→NO→CO treatment of the Fe-ZSM-5<sub>5500</sub> at 523 K the TPD experiment indicated only NO (Figure 6.7a and b, curve 1) which desorbed in a broad peak as already observed in Figure 6.6b, curve 1. 600 N<sub>2</sub>O pulses over the N<sub>2</sub>O→NO pre-treated catalyst resulted in the generation of surface oxygen and NO<sub>x,ads</sub> species which is

discussed in section 6.2 but for easier comparison once more presented in Figure 6.7a and b, curve 2.

**Figure 6.7:** O<sub>2</sub> (a) and NO (b) TPD profiles obtained after pulsing N<sub>2</sub>O→NO→CO (1), N<sub>2</sub>O→NO→N<sub>2</sub>O (2) and N<sub>2</sub>O→NO→N<sub>2</sub>O→CO (3) over the Fe-ZSM-5<sub>5500</sub> catalyst at 523 K.

The interaction of CO with the surface species formed during the N<sub>2</sub>O→NO→N<sub>2</sub>O treatment generated CO<sub>2</sub> at 523 K. The residual surface species are illustrated in Figure 6.7a and b, curve 3. Oxygen was completely removed and the NO<sub>x,ads</sub> species were reduced to NO<sub>ads</sub>. NO desorbed again as broad peak such as after the N<sub>2</sub>O→NO→CO treatment (Figure 6.7a and b, curve 1) very similar to the desorption of

only NO in Figure 6.6b, curve 1 and 3. The only difference was that the N<sub>2</sub>O→NO pre-treatment (Figure 6.7) led to a 10 times larger amount of adsorbed NO as compared to the NO pre-treatment (Figure 6.6). Thus, even in the presence of much higher NO concentrations, the whole surface oxygen was removed by CO and the NO<sub>x,ads</sub> species were reduced to NO<sub>ads</sub>.

The same NO and O<sub>2</sub> TPD profiles were generated upon the treatment of the (O)<sub>Fe</sub> and NO<sub>x,ads</sub> containing catalyst with CO as after the adsorption of gaseous NO as seen in Figure 6.6 and Figure 6.7. Only NO<sub>ads</sub> was detected and no oxygen could be found upon increasing the temperature to 916 K in vacuum. The interaction of CO with the catalyst produced CO<sub>2</sub> in the presence of adsorbed NO<sub>x</sub> species, reduced them to NO<sub>ads</sub> and efficiently scavenged off all atomic oxygen. Thus, the reactivity of (O)<sub>Fe</sub> in CO oxidation was not diminished by the presence of NO<sub>x,ads</sub> species on the catalyst in TAP experiments. These observations are summarized in the following equation:

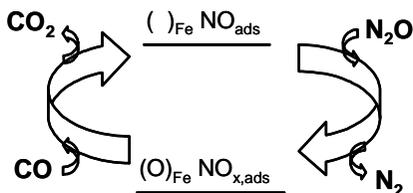

In line with these conclusions are results from El-Malki et al. [7]. Nitro and nitrate groups were detected in FTIR spectra obtained by N<sub>2</sub>O exposure to Fe/MFI at 473 K. Additionally, the same bands were observed over Fe/MFI samples upon simple exposure to a flow of NO and O<sub>2</sub> in He at the same temperature. It is interesting that a treatment with CO at 473 K of samples containing nitro and nitrate bands led to the disappearance of them, indicating their high reactivity towards CO. The bands of the NO<sub>x</sub> groups disappeared also upon contacting the sample with benzene vapor at 473 K but remained intact at room temperature.

Studies at atmospheric pressure reported an inhibiting effect of adsorbed NO/NO<sub>x</sub> species on the oxygen reactivity in CO oxidation [11]. By using the transient response method it was observed that the presence of NO<sub>x,ads</sub> did not inhibit the surface oxygen loading from N<sub>2</sub>O at 523 K. However, the reactivity of (O)<sub>Fe</sub> towards CO oxidation at low temperatures (< 523 K) was drastically diminished for a catalyst with pre-adsorbed NO/NO<sub>x</sub> species. Surface NO<sub>x</sub> species probably blocked the sites necessary for CO activation, which were in vicinity of the loaded atomic oxygen as was concluded. The concentration of NO<sub>ads</sub> on the catalyst in the vacuum system was certainly lower than at atmospheric pressure and, therefore, a diminished reactivity of the surface oxygen in CO oxidation was not observed in TAP experiments.

In summary, NO has a catalytic effect in direct N<sub>2</sub>O decomposition by accelerating the O<sub>2</sub> desorption whereas CO as reducing agent regenerates active iron sites. Apparently the catalytic surface species, NO<sub>x,ads</sub> were formed during N<sub>2</sub>O interaction with the assistance of NO<sub>ads</sub> and were easily reduced by CO to irreversibly

adsorbed NO<sub>ads</sub>. Adsorbed NO underwent a redox cycle where N<sub>2</sub>O oxidizes NO<sub>ads</sub> to NO<sub>x,ads</sub> which was reduced by CO to NO<sub>ads</sub> as schematically pictured below:

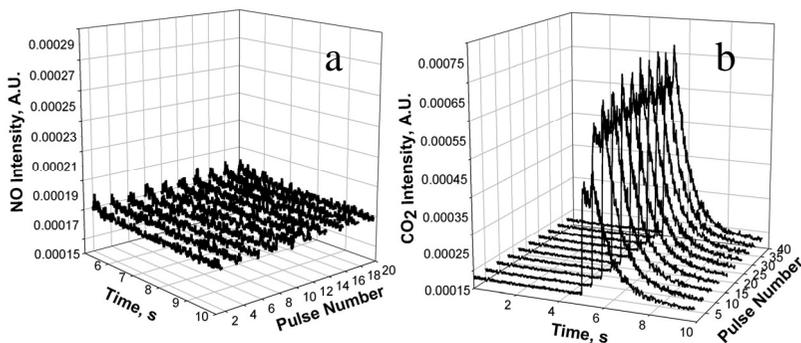

## 6.5. Deposited Oxygen Reactivity in Presence of Reversibly Adsorbed NO

NO pulses at 523 K over the Fe-ZSM-5<sub>500</sub> using the TAP setup resulted in a very broad NO response, indicating the strong adsorption of NO on the catalyst. It took about 5 min to desorb the reversibly adsorbed NO from the catalyst after the NO introduction was stopped. Irreversibly adsorbed NO stayed on the catalyst and desorbed only by increasing the reactor temperature. The role of irreversibly adsorbed NO is elucidated in section 6.1 to 6.4. It was either formed during N<sub>2</sub>O interaction or adsorbed during NO treatments. The influence of reversibly adsorbed NO on the activity of oxygen loaded from N<sub>2</sub>O was studied in N<sub>2</sub>O/CO pump-probe experiments at 523 K. Oxygen was loaded from N<sub>2</sub>O which formed with CO the product CO<sub>2</sub> in case that the loaded oxygen was active in CO oxidation. N<sub>2</sub>O was pulsed at 0 s and CO at 5 s. The cycle time was 10 s.

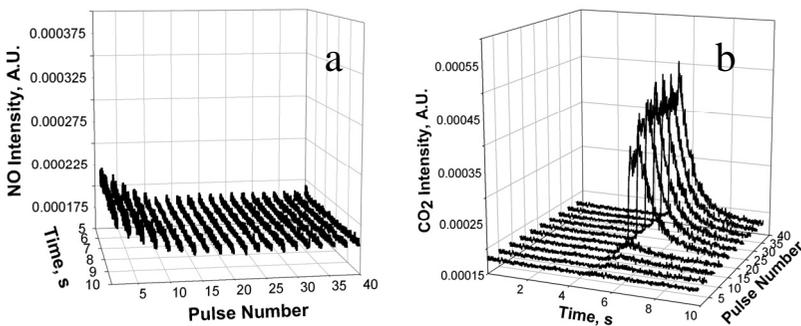

At first, the catalyst was pre-treated with 600 NO pulses. Thereafter, the reversibly adsorbed NO desorbed during a period of 10 min without pulses. In a subsequent N<sub>2</sub>O/CO pump-probe experiment was observed that reversibly adsorbed NO was completely desorbed (Figure 6.8a). CO<sub>2</sub> was formed from the oxygen loaded from N<sub>2</sub>O and CO as from the very first cycle (Figure 6.8b).

In a second experiment, the catalyst was again pre-treated with 600 NO pulses and the N<sub>2</sub>O/CO pump-probe experiment was performed right after the NO treatment so that reversibly adsorbed NO was still on the catalyst. The desorption of reversibly adsorbed NO is shown in Figure 6.9a. During the first 15 cycles NO was detected and desorbed. At the same time CO<sub>2</sub> was not formed as presented in Figure 6.9b. Only after the 15<sup>th</sup> cycle, CO<sub>2</sub> was created from the surface oxygen loaded from N<sub>2</sub>O and CO.

The reversibly adsorbed NO inhibited the formation of CO<sub>2</sub> by blocking sites necessary for the activation of the reactants CO or surface oxygen. Another possibility is that oxygen was not loaded from N<sub>2</sub>O in the presence of reversibly adsorbed NO which could not be found out in TAP experiments. A TPR experiment (section 7.3) with a mixture of NO and N<sub>2</sub>O at atmospheric pressure with the Micromeritics AutoChem 2910 setup showed that oxygen loading from N<sub>2</sub>O at 523 K or the N<sub>2</sub>O decomposition at higher temperatures was never suppressed by the presence of gaseous NO. Thus, oxygen loaded from N<sub>2</sub>O on the catalyst was not active in CO oxidation in the presence of reversibly adsorbed NO in vacuum conditions.

**Figure 6.8:** NO (a) and CO<sub>2</sub> (b) responses obtained during the oxidation of CO, pulsed at 5 s, with (O)<sub>Fe</sub> loaded from a N<sub>2</sub>O pulse at 0 s over the Fe-ZSM-5<sub>500</sub> at 523 K in the absence of reversibly adsorbed NO.

**Figure 6.9:** NO (a) and CO<sub>2</sub> (b) responses obtained during the oxidation of CO, pulsed at 5 s, with (O)<sub>Fe</sub> loaded from a N<sub>2</sub>O pulse at 0 s over the Fe-ZSM-5<sub>500</sub> at 523 K in the presence of reversibly adsorbed NO during the first 15 pulses.

Irreversibly adsorbed NO promoted the N<sub>2</sub>O decomposition by accelerating the desorption of surface oxygen and reversibly adsorbed NO inhibited the oxidation of CO

with surface oxygen. The dual role of NO, acting as a promoter in N<sub>2</sub>O decomposition and as an inhibitor in N<sub>2</sub>O reduction with CO was also discussed for experiments at atmospheric pressure and the findings were attributed to the presence of different iron species [18]. NO was found to selectively inhibit the reduction of N<sub>2</sub>O of isolated iron sites at low temperature, disabling CO and N<sub>2</sub>O activation.

Pirngruber et al. [19] proposed that de-hydroxylation at 873 K created vacancies in the coordination sphere of iron that allowed the adsorption of two or even three molecules of NO on one site. Bulushev et al. [6] assigned in DRIFTS studies thermally stable NO species during NO interaction to mononitrosyl Fe<sup>2+</sup>(NO) species involved in surface bi- and oligonuclear iron species, probably with aluminum in vicinity. Dinitrosyl Fe<sup>2+</sup>(NO)<sub>2</sub> or trinitrosyl Fe<sup>2+</sup>(NO)<sub>3</sub> species also existed while the iron Fe-ZSM-5 was exposed to gaseous NO. However, they were found to be unstable in inert gas flow. Therefore, the promoting effect of irreversibly adsorbed NO was assigned to mononitrosyl species while dinitrosyl and trinitrosyl sites were related to reversibly adsorbed NO.

In general, iron species accepting two or three NO molecules should possess high coordinative unsaturation and are probably isolated. The amount of produced CO<sub>2</sub> in the presence of reversibly adsorbed NO was almost negligible. This would mean that the majority of active sites were highly coordinative unsaturated.

In summary, NO possesses a dual role acting as promoter in N<sub>2</sub>O decomposition and as an inhibitor in N<sub>2</sub>O reduction with CO. The inhibiting effect was shown by reversibly adsorbed NO with TAP experiments in vacuum. Oxygen loaded from N<sub>2</sub>O on the catalyst was not active in CO oxidation in the presence of reversibly adsorbed NO.

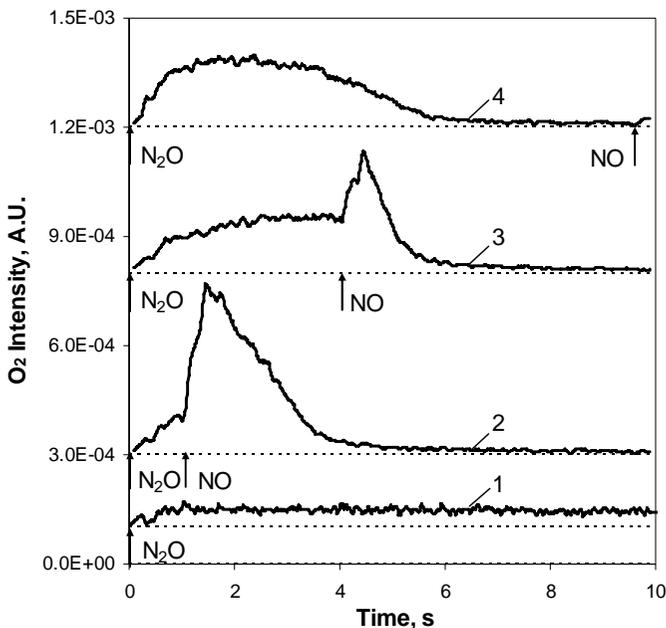

## 6.6. Effect of NO on N<sub>2</sub>O Decomposition Studied in Pump-Probe Experiments

NO promotes the N<sub>2</sub>O decomposition over Fe-ZSM-5. Mechanistic studies at different temperatures (593-946 K) were performed using so-called pump-probe experiments. The Fe-ZSM-5<sub>3500</sub> and the Fe-ZSM-5<sub>200</sub> catalyst were tested and compared to check for the importance of the inactive part of Fe. The Fe-ZSM-5<sub>200</sub> contained only 7% inactive Fe and the Fe-ZSM-5<sub>3500</sub> around 95%. Generally, the results were quite similar to the results obtained with the Multitrack system [3].

### 6.6.1. N<sub>2</sub>O/NO Pump-Probe Experiments

The effect of NO on the N<sub>2</sub>O interaction was studied using pump-probe experiments, in which pulses of N<sub>2</sub>O and NO were consecutively fed to the reactor. A pulse of N<sub>2</sub>O was followed by a pulse of NO. Before each alternating pulse experiment the catalyst was heated at 946 K for 30 min followed by approximately 1000 pulses of N<sub>2</sub>O ( $3.8 \cdot 10^{14}$  molecules/pulse) at the studied temperature.

N<sub>2</sub>O and NO were sequentially introduced over the Fe-ZSM-5<sub>5500</sub> at 661 K. The time interval between the two pulses was varied from 1 to 9.5 s and the alternate pulsing was repeated in cycles of 10 s. Some oxygen responses are exemplified in Figure 6.10 for N<sub>2</sub>O at 0 s (curve 1) and for a delay time of 1 s (curve 2), 4 s (curve 3) and 9.5 s (curve 4) between the N<sub>2</sub>O pulse at 0 s and the NO pulse. Only nitrous oxide interaction with the Fe-ZSM-5<sub>5500</sub> at 661 K (curve 1) resulted in very slow oxygen desorption which can be observed through a very broad response. In the case of 1 s (curve 2) and 4 s (curve 3) delay time, NO was introduced, when the oxygen from the previous N<sub>2</sub>O pulse was still in adsorbed state. The amount of evolved oxygen per cycle was independent of the time interval between the N<sub>2</sub>O and the NO pulse. The NO pulse provided the appearance of an additional very sharp O<sub>2</sub> response. This sharp peak was not observed when Ar was pulsed instead of NO. It was not accompanied by nitrogen or NO<sub>2</sub> evolution. The NO response itself was very broad (not shown). Initial sharpening of the oxygen response at the time of the N<sub>2</sub>O pulse was observed especially when the NO pulse was short-time before the N<sub>2</sub>O pulse as in Figure 6.10, curve 4 with 0.5 s between the NO and N<sub>2</sub>O pulses (9.5s between the N<sub>2</sub>O and NO pulses). This indicates that NO or NO<sub>x</sub> species were in adsorbed state before the N<sub>2</sub>O pulse. Switching off NO pulsing resulted in NO desorption and transition of the catalyst behavior to the original one, with a very broad O<sub>2</sub> response (not shown) like that shown in Figure 6.10, curve 1 in accordance with the data reported in [3].

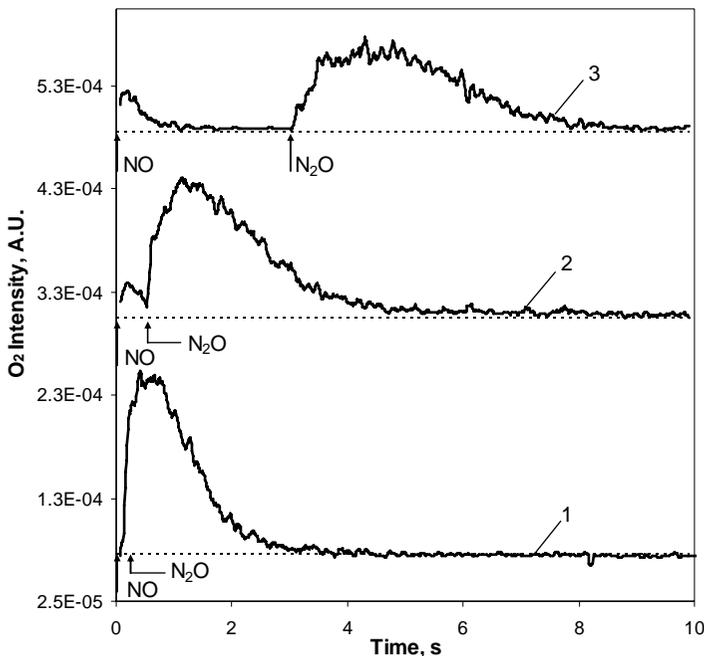

**Figure 6.10:** Oxygen response profiles obtained during catalytic decomposition of N<sub>2</sub>O over Fe-ZSM-5<sub>500</sub> at 661 K pulsing only N<sub>2</sub>O at 0 s (1) and pulsing N<sub>2</sub>O at 0 s and NO at 1 s (2), 4 s (3), 9.5 s (4), respectively.

During the NO addition the O<sub>2</sub> profile (curve 2 to 4) sharpened at the time of the N<sub>2</sub>O pulse, indicating a significantly faster O<sub>2</sub> desorption in N<sub>2</sub>O/NO alternating cycles, than in the experiment with N<sub>2</sub>O only. Additionally, the NO pulse led to a sharp O<sub>2</sub> response. It is shown in chapter 5 that surface oxygen from N<sub>2</sub>O was loaded very quickly and there was no O<sub>2</sub> re-adsorption on the Fe-ZSM-5 catalyst. Hence, the shape of the O<sub>2</sub> response was provided by its desorption as a rate-determining step for N<sub>2</sub>O decomposition. Consequently the NO pulse accelerated the desorption of the loaded oxygen.

NO/N<sub>2</sub>O pump-probe experiments were also performed with the Fe-ZSM-5<sub>500</sub> at 661 K and shown in Figure 6.11. NO was pulsed 0.1 s, 0.5 s and 3 s before the N<sub>2</sub>O pulse and repeated in a 10 s cycle. It is seen that the oxygen peak sharpened with decreasing time between the NO and N<sub>2</sub>O pulse from 3 to 0.1 s. The decrease of the time interval resulted in higher concentration of adsorbed NO/NO<sub>x</sub> species during the N<sub>2</sub>O pulse. The oxygen desorbed during the N<sub>2</sub>O pulse much faster in case when NO was adsorbed before the N<sub>2</sub>O pulse, which is in line with the data [3]. The amount of desorbed oxygen per cycle was constant and independent of the time interval. Thus, adsorbed NO species facilitated oxygen desorption in accordance with TPD data (section

6.1 and 6.2) without the conversion of NO<sub>ads</sub> to gaseous products as NO<sub>2</sub> in the gas phase was observed.

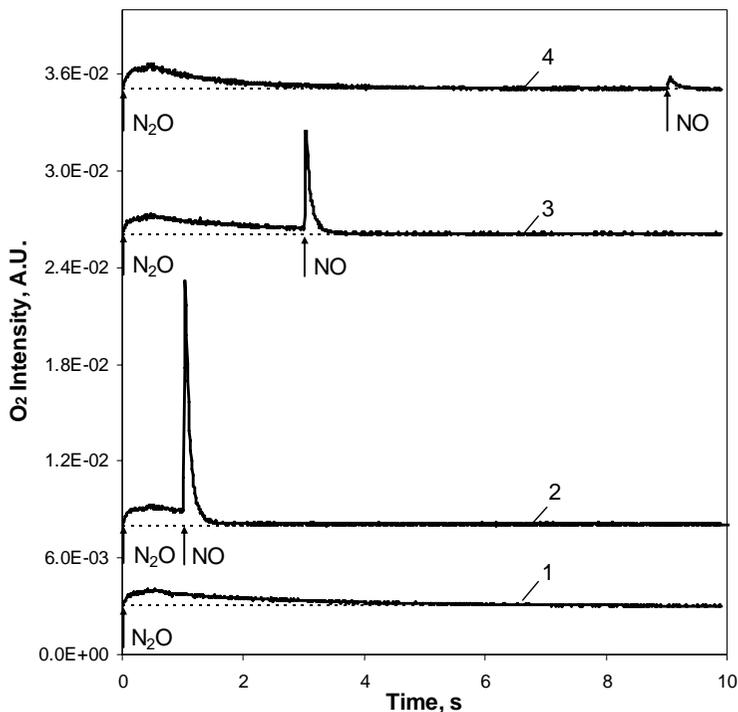

**Figure 6.11:** Oxygen response profiles obtained during pulsing NO at 0 and N<sub>2</sub>O at 0.1 s (1), 0.5 s (2) and 3 s (3), respectively over Fe-ZSM-5<sub>500</sub> at 661 K.

Similar initial sharpening of the oxygen response was observed at 661 K during N<sub>2</sub>O/NO experiments (Figure 6.10), which showed that NO or NO<sub>x</sub> species were in adsorbed state before the N<sub>2</sub>O pulse. The difference of N<sub>2</sub>O/NO to NO/N<sub>2</sub>O pump-probe experiments was that NO was introduced, when the oxygen from the previous N<sub>2</sub>O pulse was still in adsorbed state (Figure 6.10) contrary to the pulse consequence, when the NO pulse was introduced 0.1-3 s before the N<sub>2</sub>O pulse (Figure 6.11). In the latter case oxygen already desorbed before the NO pulse. No gaseous NO<sub>2</sub> was detected during the reaction under any reported conditions contrary to the results of Perez-Ramírez et al. [3] at 773 K. Decomposition of NO to N<sub>2</sub> and O<sub>2</sub> was never observed during those mechanistic studies of the NO-assisted N<sub>2</sub>O decomposition.

At 803 K N<sub>2</sub>O decomposed into N<sub>2</sub> and O<sub>2</sub> while O<sub>2</sub> desorbed from the catalyst within 10 s. In N<sub>2</sub>O/NO pump-probe experiments the time interval between the N<sub>2</sub>O, always pulsed at 0 s, and NO pulses was varied from 1 to 9 s and repeated in cycles of 10 s. Some oxygen responses are exemplified in Figure 6.12. The oxygen response didn't get significantly sharpened at the N<sub>2</sub>O pulse but oxygen desorbed very fast while NO

was introduced. The integration of the oxygen response showed that the amount of released O<sub>2</sub> per cycle was constant and absolutely independent of the time interval at 803 K as well as at 661 K.

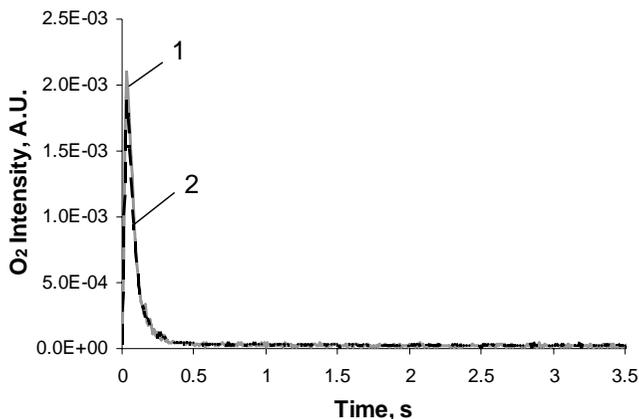

In contrast with the studies at 661 K where a few alternating pulse experiments cycles had to be performed in order to obtain a constant oxygen desorption profile, the promoting effect on the reaction at 803 K was already with the first NO pulse completely developed. This suggests a slow accumulation of NO on the catalyst at 661 K while at higher temperatures NO is only very weakly bonded to the catalyst and, therefore, almost instantaneously desorbed.

**Figure 6.12:** Oxygen response at 803 K during catalytic decomposition of N<sub>2</sub>O over Fe-ZSM-5<sub>500</sub>: pulsing only N<sub>2</sub>O at 0 s (1) and NO-assisted by pulsing N<sub>2</sub>O at 0 s and NO after different time intervals: 1 s (2), 3 s (3) and 9 s (4).

A N<sub>2</sub>O/NO pump-probe experiment at high temperature (946 K) with a time interval of 3 s between the N<sub>2</sub>O and NO pulse is illustrated in Figure 6.13. The cycle time was 10 s. The O<sub>2</sub> profiles received by introducing N<sub>2</sub>O only or sequentially pulsing N<sub>2</sub>O and NO strongly resembled each other, indicating that the promotion of NO was negligible. Obviously, oxygen was completely desorbed before the NO pulse was introduced and NO was desorbed before N<sub>2</sub>O was pulsed. Additionally, the oxygen

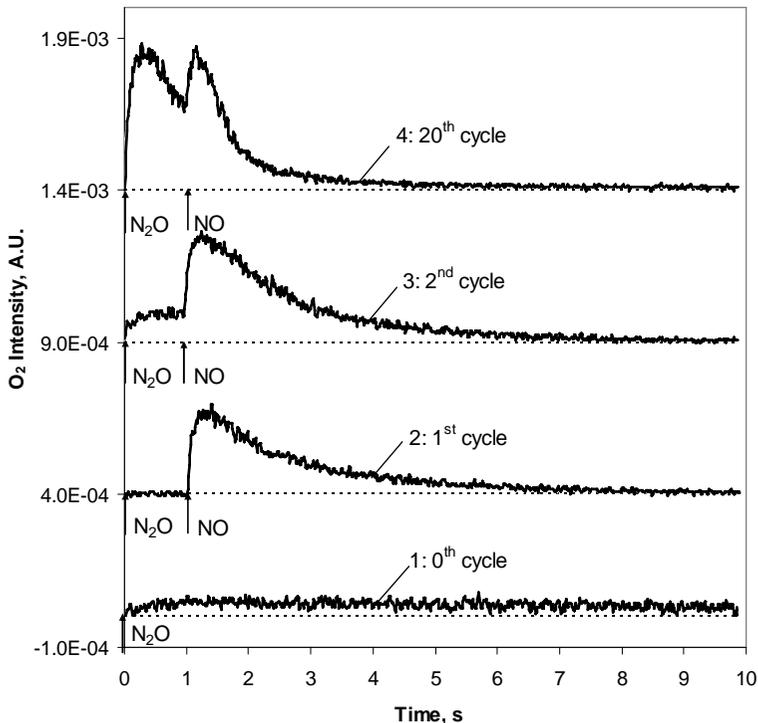

recombination/desorption at 946 K was already much faster compared to lower temperatures as discussed in chapter 5 and more difficult to accelerate further.

**Figure 6.13:** Oxygen profiles obtained during catalytic decomposition of N<sub>2</sub>O over Fe-ZSM-5<sub>500</sub> at 946 K: pulsing N<sub>2</sub>O at 0 s (1) and pulsing N<sub>2</sub>O and NO at 0 s and 3 s (2), respectively.

All the experiments presented in this section were repeated with another Fe-ZSM-5 sample. The zeolite contains only 200 ppm Fe and different to the catalyst applied so far as no binder was used during fabrication. Therefore, the Fe-ZSM-5<sub>500</sub> contains iron compounds and provides more than 95% inactive Fe atoms. The homemade Fe-ZSM-5<sub>200</sub> catalyst contains almost exclusively active iron sites (93%).

In general, the same results were obtained for the 200 ppm and the 5500 ppm Fe sample in N<sub>2</sub>O/NO pump-probe experiments in the range of 593 to 946 K which proved that the observed effects were related to iron sites active in N<sub>2</sub>O decomposition and not to inactive Fe atoms from the binder. The oxygen response after the interaction from N<sub>2</sub>O and NO with the Fe-ZSM-5<sub>200</sub> at 661 K is exemplified in Figure 6.14. Curve 1 shows the nitrous oxide interaction with the zeolite which resulted in very slow oxygen desorption observed through a very broad response. Curves 2, 3, and 4 illustrate the oxygen profile during catalytic decomposition of nitrous oxide pulsing N<sub>2</sub>O at 0 s and NO at 1 s during the 1<sup>st</sup>, 2<sup>nd</sup> and 20<sup>th</sup> cycle, respectively in pump-probe experiments. The O<sub>2</sub> profile sharpened during the NO addition at the time of the N<sub>2</sub>O pulse and the NO pulse with increasing cycle number. NO slowly accumulated on the catalyst and augmented its promoting effect on the oxygen desorption with increasing cycle number resulting in a constant response after 20 cycles.

**Figure 6.14:** Oxygen profiles obtained during catalytic decomposition of N<sub>2</sub>O over Fe-ZSM-5(20) at 661 K pulsing only N<sub>2</sub>O at 0 s (1) and pulsing N<sub>2</sub>O and NO at 0 and 1 s (curve 2-4), respectively. The 1<sup>st</sup>, 2<sup>nd</sup> and 20<sup>th</sup> cycle of the N<sub>2</sub>O/NO pump-probe experiment are shown in curve 2 to 4.

### 6.6.2. Discussion

The effect of NO on surface atomic oxygen deposited on Fe-ZSM-5 from N<sub>2</sub>O was investigated in N<sub>2</sub>O/NO pump-probe experiments at different temperatures. In TAP experiments the promoting effect of NO on the oxygen recombination/desorption was observed at 661 K where oxygen desorption usually took place but only very slowly (Figure 6.10, curve 1). The presence of adsorbed NO facilitated the oxygen recombination/desorption significantly during the N<sub>2</sub>O pulse (Figure 6.10, curve 2 to 4). Additionally, the NO pulse led to a spontaneous oxygen release of the residual surface oxygen (Figure 6.10, curve 2 and 3). The sharp oxygen evolution during the NO pulse as observed in Figure 6.10 was not reported earlier. The explanation of this peak is connected to the interaction of gaseous NO with loaded oxygen species forming gaseous

oxygen. In similar studies Perez-Ramirez et al. [3] did not observe O<sub>2</sub> desorption at the time of the NO pulse which was probably connected to a delayed NO pulse respectively to the time period of O<sub>2</sub> desorption. If all oxygen species were already desorbed, the addition of NO had no instant effect.

Both adsorbed NO from previous cycles and introduced NO accelerated the desorption of surface oxygen. A constant amount of oxygen desorbed per cycle independently of the time interval between the two pulses. Probably NO<sub>2,ads</sub> was formed during the interaction of added NO with adsorbed oxygen on the catalyst:

This NO<sub>2,ads</sub> transferred oxygen to adsorbed oxygen quickly and decomposed back to NO<sub>ads</sub> and molecular oxygen in the next step:

NO<sub>2</sub> was not detected in the gas phase. Perez-Ramirez et al. [3] observed a decoupled formation of O<sub>2</sub> and NO<sub>2</sub>. NO<sub>2</sub> was considered to be mainly released due to displacement by NO and probably by thermal desorption, while O<sub>2</sub> was formed during the N<sub>2</sub>O pulses. Adsorbed NO is suggested to facilitate the oxygen transfer through NO<sub>2</sub> intermediates, enhancing the change of recombination to O<sub>2</sub>.

TAP studies showed that NO had an enduring effect at least until the next N<sub>2</sub>O pulse where it accelerated the O<sub>2</sub> recombination/desorption as compared to the N<sub>2</sub>O only case seen by the initial sharpening in Figure 6.10. In line with this observation are the data of Figure 6.11 where smaller time delays between the NO and N<sub>2</sub>O pulse led to faster oxygen desorption by the time of the N<sub>2</sub>O pulse. The sharpening of the oxygen response during the N<sub>2</sub>O pulse could be expressed by the following equation in which adsorbed NO facilitates the desorption of oxygen without the conversion of NO<sub>ads</sub> to gaseous products:

Temperature-programmed desorption in vacuum (section 6.1 and 6.2) and transient response experiments at atmospheric pressure [1, 11] confirmed as well that NO<sub>x,ads</sub> species facilitate the rate-determining step - the oxygen desorption.

At 803 K oxygen desorbs relatively fast within 10 s upon a N<sub>2</sub>O pulse. N<sub>2</sub>O/NO pump-probe studies presented also a spontaneous oxygen release of the residual surface oxygen during the NO pulse (Figure 6.12). Oxygen is permanently released whereas the NO pulse increased the desorption rate of the residual surface oxygen rapidly,

exemplified in Figure 6.12. The initial sharpening during the N<sub>2</sub>O pulse was much less pronounced at 803 K than at 661 K since NO is quickly desorbed from the catalyst surface at this elevated temperature. A constant amount of oxygen was desorbed during a cycle independently of the time delay between the N<sub>2</sub>O and NO pulse.

At higher temperatures as 946 K no obvious effect of NO on the oxygen desorption could be detected (Figure 6.13). The addition of NO had no measurable influence on the oxygen release and consequently on the N<sub>2</sub>O decomposition since the oxygen desorption was already very fast at this temperature which is discussed in chapter 5.

All the results found in section 6.6.1 could be reproduced with a home-made catalyst Fe-ZSM-5<sub>200</sub> (exemplified in Figure 6.14) containing almost only active Fe sites compared to the discussed commercial Fe-ZSM-5<sub>5500</sub> with the majority of inactive iron from a binder. This evidences that the presented results originate from iron sites active in N<sub>2</sub>O decomposition and they were not influenced by inactive iron which was also present in the Fe-ZSM-5<sub>5500</sub>.

## 6.7. Summary

The interaction of N<sub>2</sub>O and NO with the Fe-ZSM-5<sub>5500</sub> at 523 K and 593 K were investigated by the TAP reactor for further mechanistic insight into the N<sub>2</sub>O decomposition. Surface species were studied in temperature-programmed desorption experiments and the reactivity of surface oxygen was characterized by its capacity to oxidize CO. Table 6.1 summarizes these experiments. In addition, N<sub>2</sub>O/CO pump-probe experiments served for the elucidation of the effect of reversibly adsorbed NO. The NO-assisted N<sub>2</sub>O decomposition was studied with N<sub>2</sub>O/NO pump-probe experiments at higher temperatures (661 K to 946 K).

During the interaction of N<sub>2</sub>O with the zeolite at 593 K atomic surface oxygen was loaded and NO<sub>x,ads</sub> species were formed accompanied by N<sub>2</sub> evolution (section 6.1). The concentration of surface oxygen and NO<sub>x,ads</sub> species increased with increasing number of performed N<sub>2</sub>O pulses. At the same time the temperature of maximum oxygen desorption decreased by ~35 K. Adsorbed NO<sub>x</sub> acts as "co-catalyst" and facilitate the desorption of oxygen which is, in general, accepted as the rate-determining step of the N<sub>2</sub>O decomposition. At 523 K all reactions of N<sub>2</sub>O with the Fe-ZSM-5<sub>5500</sub> were slower. Therefore, less surface oxygen was loaded and the NO<sub>x,ads</sub> species were below the detection limit.

**Table 6.1:** Summary of formed surface species and their capacity to oxidize CO upon different treatments of the Fe-ZSM-5<sub>5500</sub> with N<sub>2</sub>O and NO at 523 and 593 K using the TAP setup.

Temperature, K	Treatment	TPD responses			CO <sub>2</sub> evolution during CO interaction
		O <sub>2</sub>	NO	NO <sub>x</sub>	
523	N <sub>2</sub> O	+	-	-	+
	NO	-	+	-	-
	N <sub>2</sub> O→NO	-	+	+	very little
	N <sub>2</sub> O→NO→N <sub>2</sub> O	+	+	+	+
	NO→N <sub>2</sub> O	+	+	+	+
593	N <sub>2</sub> O	+	+	+	+
	N <sub>2</sub> O→NO	-	+	+	very little

The interaction of N<sub>2</sub>O with the Fe-ZSM-5<sub>5500</sub> containing adsorbed NO showed the formation of NO<sub>x,ads</sub> species (section 6.2). An increasing NO<sub>x,ads</sub> species concentration was accompanied by a shift of the oxygen desorption to significantly lower temperatures (by ~160 K) in TPD runs. Hence, NO<sub>x,ads</sub> species formed from pre-adsorbed NO and N<sub>2</sub>O facilitated the desorption of oxygen.

NO pulses over the (O)<sub>Fe</sub> containing catalyst led to the recombination and desorption of surface atomic oxygen at low temperatures (523 K and 593 K) where the desorption of O<sub>2</sub> was not observed during N<sub>2</sub>O interaction with the Fe-ZSM-5<sub>5500</sub> (section 6.3). NO adsorbed in large amounts at the same time on the catalyst and formed a minor part of NO<sub>x,ads</sub> species. NO/NO<sub>x</sub> adsorbed finally on adjacent sites to the N<sub>2</sub>O decomposing sites since the reloading of oxygen from N<sub>2</sub>O took place without any difficulty (section 6.2).

The NO<sub>x,ads</sub> species which were formed during N<sub>2</sub>O interaction with the assistance of NO<sub>ads</sub> were easily reduced to irreversibly adsorbed NO<sub>ads</sub> (section 6.4). Hence, adsorbed NO underwent a redox cycle where N<sub>2</sub>O oxidizes NO<sub>ads</sub> to NO<sub>x,ads</sub> which was reduced by CO to NO<sub>ads</sub>. In addition, the atomic surface oxygen loaded from N<sub>2</sub>O was fully reactive in CO oxidation. The reactivity of (O)<sub>Fe</sub> was not diminished by the presence of NO<sub>ads</sub>/NO<sub>x,ads</sub> species on the catalyst in TAP experiments.

N<sub>2</sub>O/CO pump-probe experiments showed that oxygen loaded from N<sub>2</sub>O on the catalyst was not active in CO oxidation in the presence of reversibly adsorbed NO in vacuum conditions (section 6.5). The reversibly adsorbed NO probably blocked sites necessary for the activation of the reactants CO or surface oxygen. Irreversibly adsorbed NO promoted the N<sub>2</sub>O decomposition and reversibly adsorbed NO inhibited the oxidation of CO with surface oxygen.

N<sub>2</sub>O/NO pump-probe experiments at 661 K demonstrated an accelerated oxygen desorption at the time of the N<sub>2</sub>O pulse due to adsorbed NO/NO<sub>x</sub> species. The subsequent NO pulse accelerated the desorption of the residual surface oxygen at 661 K and 803 K. At both temperatures a constant amount of oxygen was desorbed during a cycle independent of the time delay between the N<sub>2</sub>O and NO pulse. NO promoted the desorption of oxygen. Adsorbed NO accommodated oxygen from N<sub>2</sub>O forming higher oxidized nitrogen oxide species which decomposed back to NO<sub>ads</sub> and molecular oxygen. Thus, the recombination of surface oxygen loaded from N<sub>2</sub>O was accelerated by a NO/NO<sub>x</sub> redox cycle.

At higher temperature such as 946 K the desorption of oxygen was already fast that no effect of NO was observed on the recombination and desorption of surface oxygen.

The findings from the N<sub>2</sub>O/NO pump-probe experiments were reproduced with a home-made catalyst Fe-ZSM-5<sub>200</sub> containing almost only active Fe sites compared to the discussed commercial Fe-ZSM-5<sub>5500</sub> with 95% inactive iron. This evidences that the presented results originated from iron sites active in N<sub>2</sub>O decomposition.

# Chapter 7

## NO<sub>2</sub> INTERACTION WITH Fe-ZSM-5

Nitrogen dioxide (NO<sub>2</sub>) is a reddish brown, highly reactive and more toxic than NO and N<sub>2</sub>O. NO<sub>2</sub> is in equilibrium with NO and O<sub>2</sub>:

The decomposition of NO<sub>2</sub> is endothermic with a standard reaction enthalpy of 57.09 kJ/mol which is about constant from 298 to 1200 K [1]. Therefore, the equilibrium is shifted to the right with increasing temperature. With a standard reaction Gibbs energy of 35.27 kJ/mol, the equilibrium constant is unity at 780 K. The equilibrium between NO+O<sub>2</sub> and NO<sub>2</sub> is swiftly established over Fe-ZSM-5 [2].

A simple two-step mechanism involving cation redox cycles on extra-framework Fe sites is often considered for the N<sub>2</sub>O decomposition such as described in chapter 5. Additional pathways involving NO/NO<sub>2</sub> [3-5] and NO<sub>2</sub>/NO<sub>3</sub> [6] species are discussed when NO<sub>x</sub> species are produced as surface or gas phase species. Adsorbed NO<sub>2</sub> is an intermediate of the catalytic N<sub>2</sub>O decomposition cycle and is formed when adsorbed NO accommodates oxygen from N<sub>2</sub>O leading to the facilitation of oxygen recombination/desorption [3, 4, 7-9]

It was hypothesized that NO<sub>2</sub> is also able to produce adsorbed (atomic) oxygen which could be used as selective oxidant [4]. The interaction of gaseous NO<sub>2</sub> with Fe-ZSM-5 is rarely studied especially at low temperatures where the NO/NO<sub>2</sub> equilibrium is shifted to NO<sub>2</sub>. It is interesting to know whether NO<sub>2</sub> can similarly to N<sub>2</sub>O provide atomic surface oxygen which can also oxidize CO already at 523 K. Furthermore, to what extent does NO<sub>2</sub> resemble the autocatalytic effect of NO<sub>x,ads</sub> species or the assisting role of NO in the N<sub>2</sub>O decomposition? TAP experiments in vacuum and transient response experiments at atmospheric pressure were performed to elucidate the function of NO<sub>2</sub> in the N<sub>2</sub>O decomposition network over Fe-ZSM-5 at 523 K.

The transient experiments which were performed at 523 K with NO<sub>2</sub> using the TAP setup in vacuum with the Fe-ZSM-5<sub>5500</sub> and the Micromeritics Analyzer at atmospheric pressure with the Fe-ZSM-5<sub>350</sub> are summarized in Table 7.1. Temperature-programmed reaction (TPR) flow experiments at atmospheric pressure with N<sub>2</sub>O, NO<sub>2</sub>, N<sub>2</sub>O+NO and N<sub>2</sub>O+NO<sub>2</sub> mixtures are discussed in section 7.3. The surface species formed from NO<sub>2</sub> on the catalyst were investigated with in situ DRIFTS and the findings are presented in section 7.4.

**Table 7.1:** Summary of NO<sub>2</sub> interactions with Fe-ZSM-5 at 523 K performed with the TAP setup and the Micromeritics Analyzer.

<i>Catalyst Treatment</i>	<i>TAP setup</i>	<i>Micromeritics Analyzer</i>	<i>Section</i>
NO <sub>2</sub>	+	+	7.1
NO <sub>2</sub> →CO	+	+	7.1
NO <sub>2</sub> →N <sub>2</sub> O	+	+	7.2
NO <sub>2</sub> →N <sub>2</sub> O→CO	+	-	7.2
N <sub>2</sub> O→NO <sub>2</sub>	+	+	7.2
N <sub>2</sub> O→NO <sub>2</sub> →CO	+	+	7.2

## 7.1. Formation of Surface Species from NO<sub>2</sub>

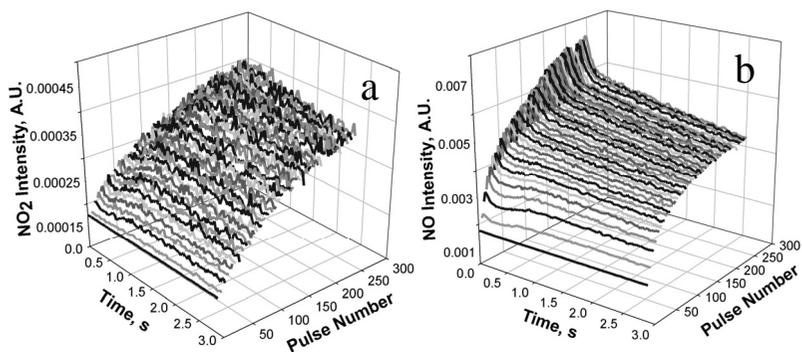

### 7.1.1. Pulse Experiments with TAP Setup under Vacuum

NO<sub>2</sub> is described as reactive intermediate in the N<sub>2</sub>O decomposition over Fe-ZSM-5. Furthermore, it was proposed that NO<sub>2</sub> could provide reactive oxygen as N<sub>2</sub>O does. In order to elucidate this hypothesis NO<sub>2</sub> was dosed over Fe-ZSM-5<sub>5500</sub> and the formed surface species were studied in TPD and CO oxidation experiments. 300 pulses

of NO<sub>2</sub> were introduced at 523 K over the Fe-ZSM-5<sub>5500</sub>. The NO<sub>2</sub> and NO pulse responses are seen in Figure 7.1. The NO<sub>2</sub> pulse response was very broad, probably due to strong reversible adsorption:

NO desorbed very slowly. The similar shape of NO<sub>2</sub> and NO was certainly due to NO<sub>2</sub> fragmentation to NO and oxygen inside the ionization chamber of the mass spectrometer [10].

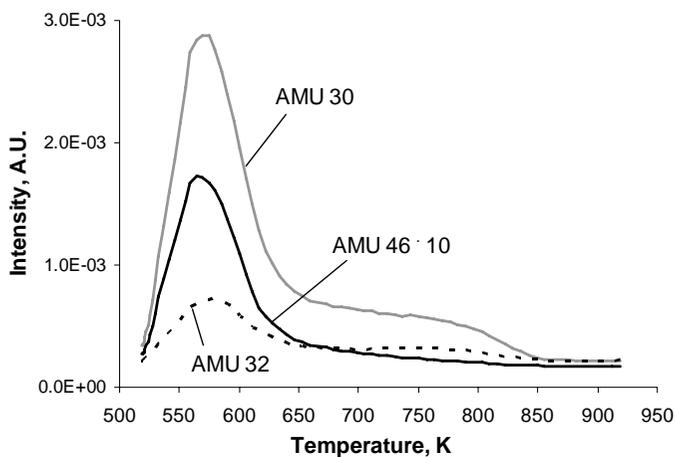

**Figure 7.1:** NO<sub>2</sub> (a) and NO (b) responses during the introduction of NO<sub>2</sub> pulses over the Fe-ZSM-5<sub>5500</sub> at 523 K.

However, the peak at the beginning of the NO response was clearly not present in the NO<sub>2</sub> response and indicated the production of NO from NO<sub>2</sub>. The oxygen response didn't contain this initial peak. It can be assumed that the oxygen formed during NO<sub>2</sub> decomposition was adsorbed on the catalyst surface:

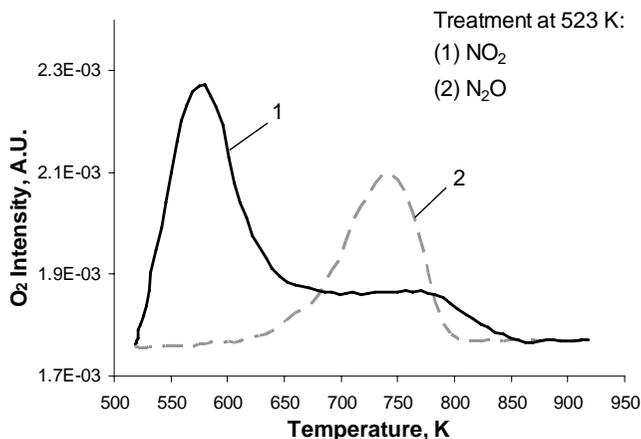

The surface species formed during NO<sub>2</sub> interaction with the catalyst were studied in a subsequent TPD experiment. Figure 7.2 shows the TPD profiles of AMU 46, 32 and 30. A desorption maxima was observed around 573 K in the profiles of AMU 46, 32 and 30 indicating the decomposition of a NO<sub>x,ads</sub> species. A shoulder around 793 K was only observed in the AMU 32 and 30 profiles indicating the desorption of an additional, different surface species. The desorption profiles with a maxima around 573 K and a shoulder around 773 K indicated two different species on the catalyst or two different sites which interacted with NO<sub>2</sub>.

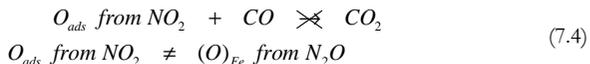

**Figure 7.2:** TPD profiles of AMU 46, 32, 30 after 300 pulses of NO<sub>2</sub> in Ar over Fe-ZSM-5<sub>5500</sub> at 523 K.

The existence of active atomic surface oxygen can be clarified by a comparison of the AMU 32 profile with typical (O)<sub>Fe</sub>-TPD profiles. Figure 7.3 summarizes the AMU 32 TPD profiles recorded after different treatments of the Fe-ZSM-5<sub>5500</sub> at 523 K: (1) 300 pulses NO<sub>2</sub> and (2) 600 pulses N<sub>2</sub>O. Profile (2) presents reactive atomic oxygen loaded from N<sub>2</sub>O. Neither the desorption maxima, nor the shape of the (O)<sub>Fe</sub>-TPD profiles were similar to the AMU 32 profile after NO<sub>2</sub> interaction with the catalyst. The formation of reactive atomic surface oxygen from NO<sub>2</sub> seemed to be unlikely.

**Figure 7.3:** Comparison of AMU 32 TPD profiles after: 300 pulses NO<sub>2</sub> (1) and 600 pulses N<sub>2</sub>O (2) over Fe-ZSM-5<sub>5500</sub> at 523 K.

In order to verify the reactivity of the surface species, formed from NO<sub>2</sub>, CO pulses were introduced after exposing the catalyst to NO<sub>2</sub>. No formation of CO<sub>2</sub> was observed which would be the case in the presence of reactive atomic oxygen on the catalyst. This is summarized in the following equations:

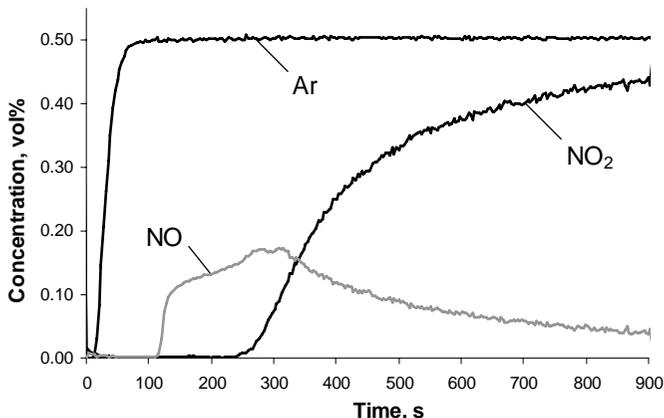

Thus, it can be concluded that NO<sub>2</sub> adsorbed on the catalyst, accompanied by NO release, forming two different NO<sub>x,ads</sub> species which were inactive in CO oxidation. The TPD profiles (not shown) obtained upon NO<sub>2</sub>→CO treatment were identical to that shown in Figure 7.2 after NO<sub>2</sub> only treatment. This is in line with the inactivity of the surface species from NO<sub>2</sub> with respect to CO oxidation to CO<sub>2</sub>.

In order to get quantitative information, the interaction of NO<sub>2</sub> with Fe-ZSM-5<sub>350</sub> was investigated in transient response experiments at atmospheric pressure.

### 7.1.2. Quantitative Flow Experiments at Atmospheric Pressure

The interaction of gaseous NO<sub>2</sub> and the Fe-ZSM-5<sub>350</sub> was investigated during transient response experiments at atmospheric pressure and 523 K. The possibility of NO<sub>2</sub> to provide active surface oxygen was of special interest. The gas composition at the outlet as a function of time after a step change in the reactor inlet from He to a mixture of 0.5 vol% NO<sub>2</sub>, 0.5 vol% Ar in He for the Fe-ZSM-5<sub>350</sub> sample is presented in Figure 7.4.

**Figure 7.4:** Response curves of Ar, NO<sub>2</sub> and NO obtained at 523 K during introduction of the 0.5 vol% NO<sub>2</sub>, 0.5 vol% Ar mixture in He on the Fe-ZSM-5<sub>350</sub> catalyst.

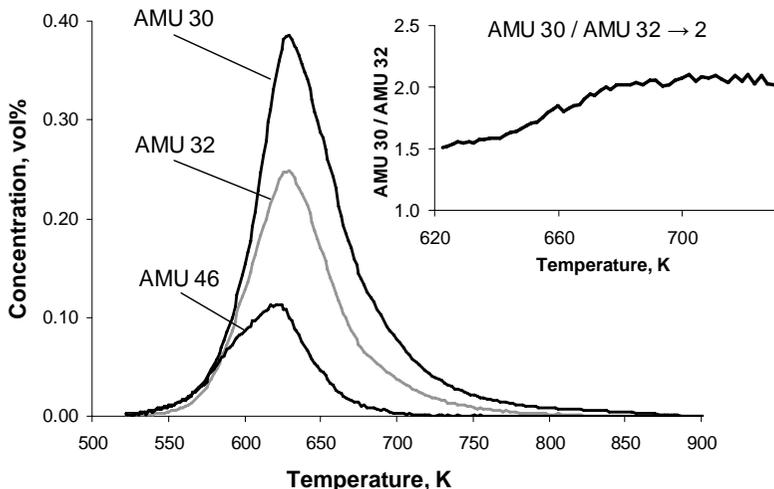

The non-ideal reactor behavior, as compared to the plug flow, was represented by the concentration-time profile of the inert tracer Ar. NO<sub>2</sub> evolution was delayed with respect to Ar due to decomposition and adsorption on the catalyst surface:

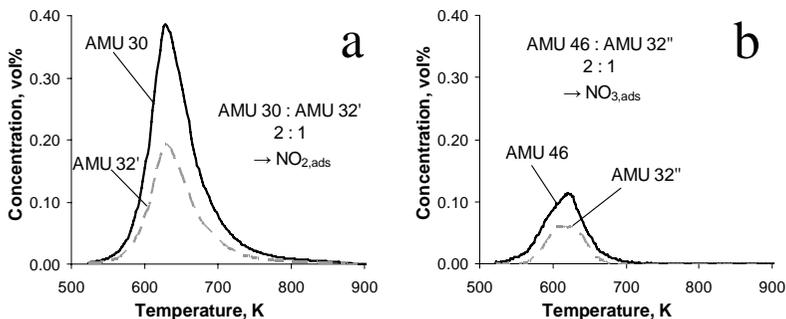

The formation of NO was observed during the NO<sub>2</sub> interaction for 15 min with the catalyst but no N<sub>2</sub> and O<sub>2</sub> evolution took place. 50·10<sup>18</sup> molecules/g NO<sub>2</sub> were adsorbed/decomposed and 16·10<sup>18</sup> molecules/g NO were produced. The transient production of NO was assigned to the decomposition of NO<sub>2</sub> on the catalyst to gaseous NO and adsorbed oxygen (Equation (7.3)). The evolution of gaseous NO was delayed by 100 s to the introduction of NO<sub>2</sub>. Probably, initially formed NO was adsorbed on the zeolite. A blank experiment with quartz pellets in the reactor did not show NO formation during a NO<sub>2</sub> step response experiment at 523 K (not shown). Therefore, the Fe-ZSM-5<sub>350</sub> was necessary for the decomposition of NO<sub>2</sub> at low temperature.

The surface species formed on the Fe-ZSM-5<sub>350</sub> during the NO<sub>2</sub> interaction were investigated by a TPD experiment. The catalyst was purged for 10 min with He before the TPD in order to remove all weakly adsorbed species. Figure 7.5 shows the evolution of AMU 30, 32 and 46 during the TPD. Their overlapping profiles indicated NO<sub>x,ads</sub> species. The concentration ratio from AMU 30 and AMU 32 is illustrated in the inset of Figure 7.5. It approached with increasing temperature a plateau with the value 2. At 723 K all molecules which contributed to the AMU 46 profile were desorbed. The interpretation of this finding is that in the temperature range from 673 to 873 K, where AMU 30 divided by AMU 32 equals 2, only one surface species desorbed contributing to AMU 30 and AMU 32, while at lower temperatures with a non-constant ratio different surface species desorbed contributing to AMU 30, 32 and 46. On that basis, the deconvolution of the TPD profiles resulted in two main surface compounds.

An AMU 32' profile was derived from the experimental AMU 30 profile assuming a constant AMU 30/AMU 32 ratio of 2 and is shown together with the experimental AMU 30 profile in Figure 7.6a. This TPD pattern was assigned to NO<sub>2,ads</sub> as the ratio of NO:O<sub>2</sub> equals 2:1. By subtracting the AMU 32' profile from the experimental AMU 32 profile, the AMU 32'' profile was derived. In order to close the mass balance of the TPD, the AMU 32'' profile was correlated with the experimental AMU 46 profile in Figure 7.6b. The areas below the AMU 46 and AMU 32'' profiles had a ratio of 2:1. In addition, the shapes of the AMU 46 and AMU 32'' profile were similar. Therefore, a common surface species, NO<sub>3,ads</sub>, was proposed for this TPD pattern. Thus, the TPD profiles after the NO<sub>2</sub> interaction could be fully interpreted.

**Figure 7.5:** TPD profiles of AMU 46, 32, 30 after 15 min NO<sub>2</sub> interaction (0.5 vol%) with Fe-ZSM-5<sub>350</sub> at 523 K. Inset: Concentration ratio from AMU 30 and AMU 32 versus temperature.

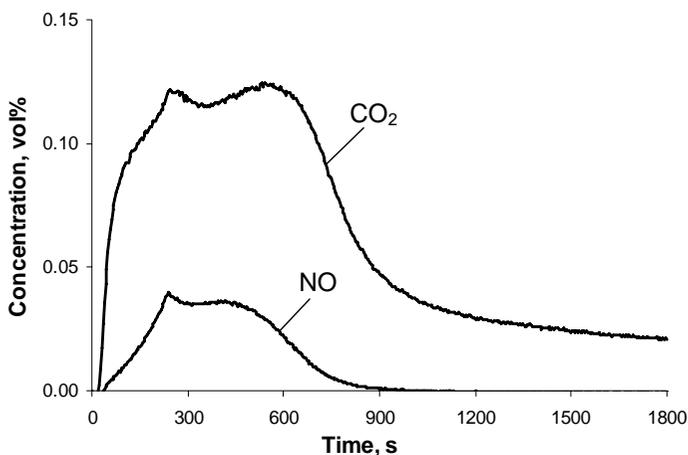

**Figure 7.6:** Assignment of the TPD profiles after 15 min NO<sub>2</sub> interaction (0.5 vol%) with Fe-ZSM-5<sub>350</sub> at 523 K to NO<sub>2,ads</sub> (a) and NO<sub>3,ads</sub> (b) surface species.

First,  $3.0 \cdot 10^{18}$  molecules/g NO<sub>3,ads</sub> species desorbed with a maximum at 623 K contributing to AMU 32 and 46 with the ratio 2:1. Shortly after with a maximum at 623 K  $12 \cdot 10^{18}$  molecules/g NO<sub>2,ads</sub> evolved contributing to AMU 30 and 32 with a ratio 2:1. Consequently, NO<sub>2</sub> adsorption on the zeolite was accompanied by its decomposition via the formation of adsorbed NO<sub>3,ads</sub> and gaseous NO which is qualitatively summarized in the following equation:

(O)<sub>Fe</sub>, formed during N<sub>2</sub>O interaction with Fe-ZSM-5<sub>350</sub>, desorbed during the TPD at lower temperature than the NO<sub>x</sub> species and mainly without the parallel desorption of NO or NO<sub>2</sub> species [3]. Thus, the TPD after NO<sub>2</sub> interaction did not indicate atomic surface oxygen, (O)<sub>Fe</sub>, since the simultaneous desorption of oxygen with NO or NO<sub>2</sub> during TPD runs resulted from decomposing NO<sub>x</sub> surface species. Furthermore, (O)<sub>Fe</sub> loaded from N<sub>2</sub>O possessed high reactivity in the oxidation of CO to CO<sub>2</sub>. The activity of the surface species formed during NO<sub>2</sub> interaction was also characterized by their capacity to oxidize CO. The CO<sub>2</sub> and NO responses during the CO interaction with the NO<sub>2</sub> pre-treated catalyst are presented in Figure 7.7.

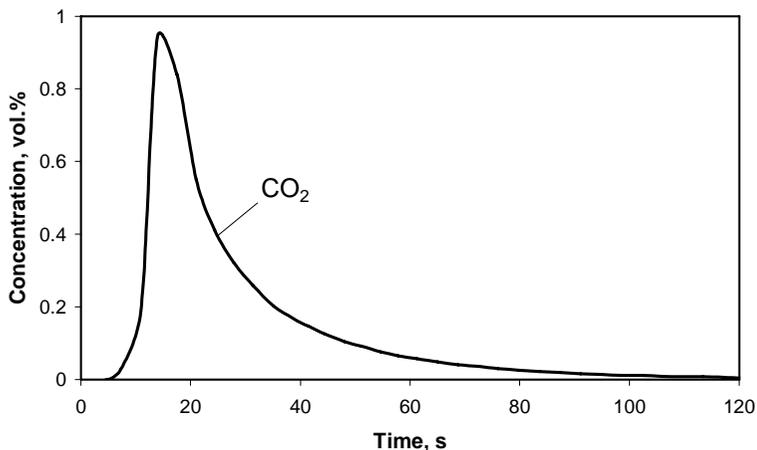

**Figure 7.7:** CO<sub>2</sub> and NO response curves obtained during interaction of 3 vol% CO in He at 523 K with the Fe-ZSM-5<sub>350</sub> after exposure to NO<sub>2</sub> (0.5 vol% NO<sub>2</sub>, 0.5 vol% Ar in He) for 15 min at 523 K.

The formation of CO<sub>2</sub> was slow and still ongoing after 30 min of CO interaction. At the beginning it was accompanied by NO desorption. The integration of the peak area gave the total amount of 25·10<sup>18</sup> molecules/g produced CO<sub>2</sub> and 3.9·10<sup>18</sup> molecules/g desorbed NO. The reason was probably a partial reduction of NO<sub>2,ads</sub>, NO<sub>3,ads</sub> which released NO at the same time:

Figure 7.8 published in [11] shows the CO<sub>2</sub> response curve obtained during interaction of CO with oxygen deposited from N<sub>2</sub>O at 523 K on the Fe-ZSM-5<sub>200</sub> which is very similar to the Fe-ZSM-5<sub>350</sub> apart from the amount of active sites. Intensive

formation of CO<sub>2</sub> was observed and finished within 120 s due to the consumption of reactive oxygen loaded from N<sub>2</sub>O on the NO<sub>x</sub> free surface. However, oxygen loaded from N<sub>2</sub>O on the surface saturated with NO<sub>x,ads</sub> species was not reactive with respect to CO oxidation to CO<sub>2</sub> [3]. Surface NO<sub>x,ads</sub> species probably blocked the sites necessary for CO activation, which may be in the vicinity of the loaded oxygen. Therefore, the formation of  $\alpha$ -oxygen from NO<sub>2</sub> cannot be evidenced with CO oxidation since a large amount of NO<sub>2,ads</sub>+NO<sub>3,ads</sub> were present which would make surface oxygen inactive with respect to CO oxidation to CO<sub>2</sub>.

**Figure 7.8:** CO<sub>2</sub> response curve obtained during interaction of CO (3 vol% CO in He, 523 K) with oxygen deposited from N<sub>2</sub>O on the Fe-ZSM-5<sub>200</sub> catalyst at 523 K. Taken from [11].

### 7.1.3. Summary

The interaction of gaseous NO<sub>2</sub> with Fe-ZSM-5 at 523 K in vacuum and at atmospheric pressure showed the formation of two different NO<sub>x</sub> surface species accompanied by the evolution of gaseous NO (Equation (7.6)). NO<sub>2,ads</sub> and NO<sub>3,ads</sub> species were identified in TPD experiments at atmospheric pressure. The amount of surface species after NO<sub>2</sub> interaction was an order of magnitude higher than the amount of active sites which can be loaded with atomic oxygen from N<sub>2</sub>O. The surface species formed by NO<sub>2</sub> at atmospheric pressure oxidized CO only slowly compared to reactive surface oxygen from N<sub>2</sub>O. TAP experiments clearly showed that the interaction of NO<sub>2</sub> with the Fe-ZSM-5 didn't lead to surface oxygen at 523 K which was active in CO oxidation. This is in line with Sobalik et al. reporting that NO<sub>2</sub> didn't form active oxygen on Fe-ferrites at 473-523 K [12].

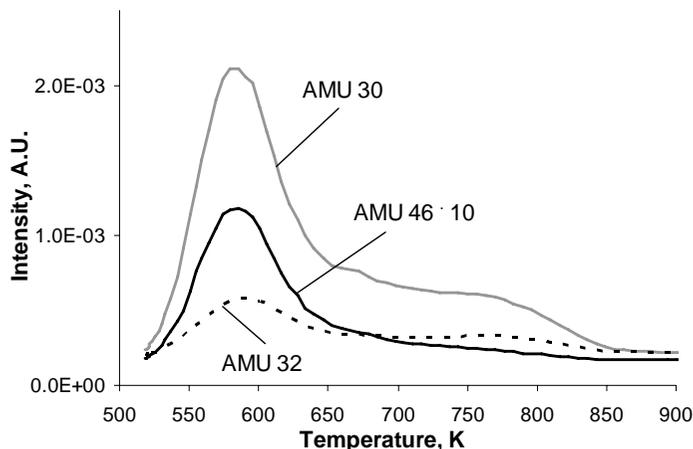

Bulushev et al. showed that oxygen loaded from N<sub>2</sub>O on the surface saturated with NO<sub>x,ads</sub> species was not reactive with respect to CO oxidation to CO<sub>2</sub> [3]. Thus, the

formation of  $\alpha$ -oxygen from NO<sub>2</sub> cannot be evidenced with CO oxidation since a large amount of NO<sub>x,ads</sub> species was present on the catalyst surface after NO<sub>2</sub> interaction.

## 7.2. Role of NO<sub>2</sub> in N<sub>2</sub>O Decomposition

### 7.2.1. Pulse Experiments with TAP Setup under Vacuum

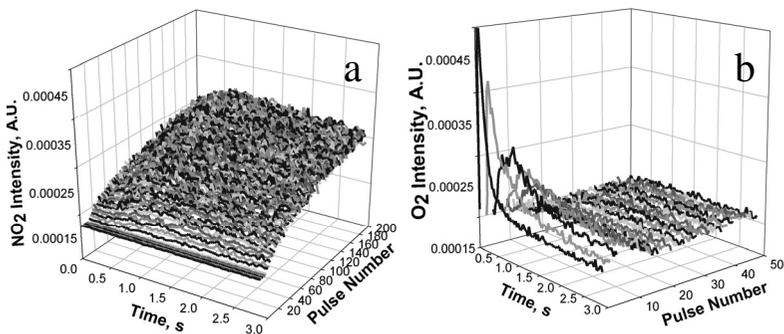

NO<sub>2</sub> was used as pre-treatment in order to study its effect on the N<sub>2</sub>O decomposition. 300 pulses of NO<sub>2</sub> were introduced at the Fe-ZSM-5<sub>5500</sub> at 523 K followed by 600 N<sub>2</sub>O pulses. The subsequent TPD profiles are presented in Figure 7.9. The intensities, maxima and shape of the response were very similar to the ones after 300 pulses of NO<sub>2</sub> (Figure 7.2).

**Figure 7.9:** TPD profiles of AMU 46, 30, 32 after 300 pulses of NO<sub>2</sub> in Ar followed by 600 pulses N<sub>2</sub>O over the Fe-ZSM-5<sub>5500</sub> catalyst at 523 K.

Thus, NO<sub>2</sub> formed surface species on the catalyst at 523 K which were not affected by N<sub>2</sub>O pulses. Active surface oxygen, (O)<sub>Fe</sub>, was not loaded from N<sub>2</sub>O after the NO<sub>2</sub> pre-treatment. Furthermore, the species created on the catalyst after the NO<sub>2</sub>→N<sub>2</sub>O treatment were inactive in CO oxidation (not shown). It seems like the active sites for oxygen loading from N<sub>2</sub>O got already occupied during the NO<sub>2</sub> treatment. It should be mentioned that NO did not block the active sites for oxygen loading from N<sub>2</sub>O but facilitated the oxygen desorption during TPD runs.

The role of NO<sub>2</sub> in N<sub>2</sub>O decomposition was investigated by pulse experiments with the TAP setup. The interaction of NO<sub>2</sub> pulses with the catalyst containing (O)<sub>Fe</sub> loaded from 600 N<sub>2</sub>O pulses at 523 K was studied. The response curves of NO<sub>2</sub> (a) and O<sub>2</sub> (b) are illustrated in Figure 7.10. The first ten NO<sub>2</sub> pulses were completely adsorbed on the catalyst and led to desorption of oxygen which was as well observed while pulsing NO over the N<sub>2</sub>O pre-treated Fe-ZSM-5<sub>5500</sub>. The formed surface species were inactive with respect to CO oxidation.

**Figure 7.10:** NO<sub>2</sub> (a) and O<sub>2</sub> (b) response curves during the introduction of 300 NO<sub>2</sub> pulses at 523 K over Fe-ZSM-5<sub>5500</sub> containing (O)<sub>Fe</sub>.

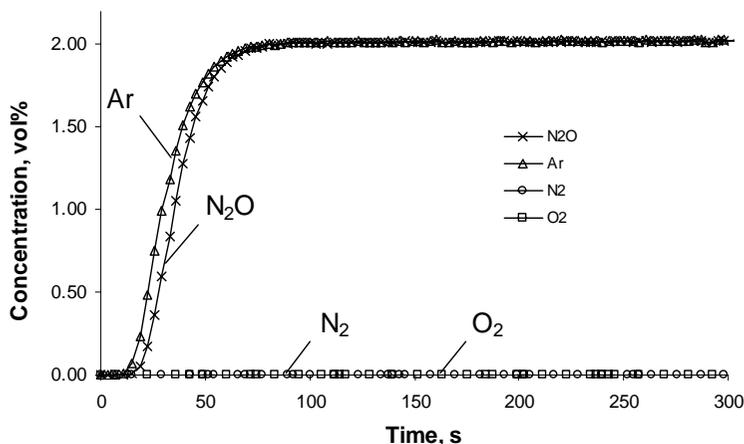

The TPD experiment performed after to the N<sub>2</sub>O → NO<sub>2</sub> pulse sequence gave qualitatively and quantitatively the same result as after pulsing only NO<sub>2</sub> seen in Figure 7.2. Thus, NO<sub>2</sub> provoked the desorption of reactive atomic oxygen loaded from N<sub>2</sub>O and formed the same surface species as on the standard pre-treated catalyst.

Similar but quantitative experiments were performed with the Micromeritics setup at atmospheric pressure in order to further clarify the effect of NO<sub>2</sub> on N<sub>2</sub>O decomposition at 523 K.

## 7.2.2. Quantitative Flow Experiments at Atmospheric Pressure

Whether NO<sub>2</sub> can provide the same effects as NO on the N<sub>2</sub>O decomposition was studied at 523 K in step response and subsequent TPD experiment. As already presented in section 6.1, the slow formation of NO<sub>ads</sub> on the catalyst was observed from N<sub>2</sub>O catalyzing the N<sub>2</sub>O decomposition. Surface NO<sub>ads</sub> can be further oxidized to adsorbed NO<sub>2</sub> species (NO<sub>2,ads</sub>) which led to the facilitation of (O)<sub>Fe</sub> recombination/desorption. The presence of NO<sub>x,ads</sub> formed from NO did not inhibit the surface oxygen loading from N<sub>2</sub>O at 523 K as observed by a transient response method. However, the reactivity of (O)<sub>Fe</sub> toward CO oxidation at low temperatures (< 523 K) was drastically diminished [3].

The temperature of 523 K was low enough to ensure the study of the effect of NO<sub>2</sub> and not of a NO/NO<sub>2</sub> mixture since NO<sub>2</sub> decomposes to O<sub>2</sub> and NO at higher temperatures as seen in Equation (7.1). The Fe-ZSM-5<sub>350</sub> interacted for 15 min with NO<sub>2</sub> at 523 K, was purged for 10 min in He and then exposed to N<sub>2</sub>O. The response curves obtained during the introduction of 2 vol% N<sub>2</sub>O are shown in Figure 6.10.

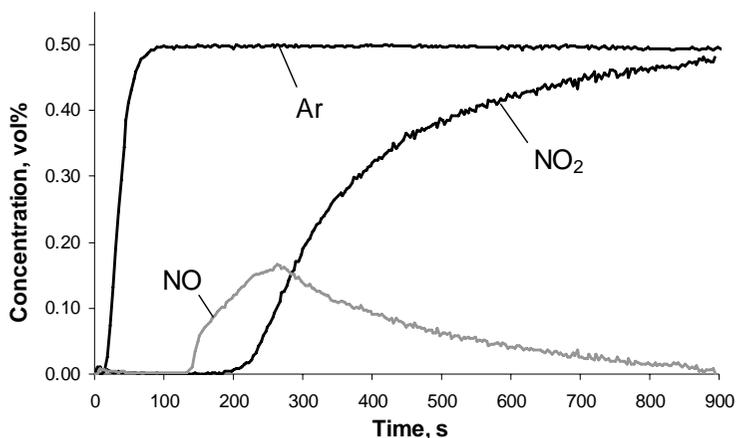

**Figure 7.11:** Response curves of N<sub>2</sub>O, Ar, N<sub>2</sub> and O<sub>2</sub> obtained at 523 K during introduction of the 2 vol% N<sub>2</sub>O, 2 vol% Ar mixture in He on the Fe-ZSM-5<sub>350</sub> catalyst after NO<sub>2</sub> interaction (0.5 vol% NO<sub>2</sub>, 0.5 vol% Ar in He for 15 min at 523 K).

Only N<sub>2</sub>O and Ar appeared at the reactor outlet. The absence of N<sub>2</sub> formation indicated the absence of oxygen loading on the catalyst from N<sub>2</sub>O which was usually observed during the N<sub>2</sub>O interaction with a standard pre-treated catalyst. A delay of the N<sub>2</sub>O to the Ar response showed that N<sub>2</sub>O was reversibly adsorbed. Integration of the area between the two responses (Ar and N<sub>2</sub>O) gave  $2.1 \cdot 10^{18}$  molecules/g of reversible adsorbed N<sub>2</sub>O. The amount of reversible adsorbed N<sub>2</sub>O after NO<sub>2</sub> pre-treatment was close to its value upon N<sub>2</sub>O interaction with the standard pre-treated catalyst ( $2.4 \cdot 10^{18}$  molecules/g). Thus, NO<sub>2</sub> blocked the sites for (O)<sub>Fe</sub> loading from N<sub>2</sub>O but hardly influenced the sites for reversible N<sub>2</sub>O adsorption. The TPD run after the NO<sub>2</sub> followed by N<sub>2</sub>O interaction with the catalyst at 523 K gave qualitatively and quantitatively the same result as already present in Figure 7.5 after NO<sub>2</sub> only interaction. This indicates that N<sub>2</sub>O did not undergo any reaction with the NO<sub>2</sub> pre-treated catalyst. N<sub>2</sub>O was only reversibly adsorbed. NO<sub>2</sub> blocked the active sites for N<sub>2</sub>O decomposition at low temperatures as 523 K.

For a better understanding of a possible role of NO<sub>2</sub> in the N<sub>2</sub>O decomposition mechanism, the interaction of NO<sub>2</sub> with (O)<sub>Fe</sub> loaded from N<sub>2</sub>O was investigated. The

transient responses during NO<sub>2</sub> introduction over the Fe-ZSM-5 which was saturated with (O)<sub>Fe</sub> loaded from N<sub>2</sub>O are shown in Figure 7.12.

**Figure 7.12:** Response curves of N<sub>2</sub>O, Ar and NO obtained at 523 K during introduction of the 0.5 vol% NO<sub>2</sub>, 0.5 vol% Ar mixture in He on the Fe-ZSM-5<sub>350</sub> catalyst after N<sub>2</sub>O interaction (2 vol% N<sub>2</sub>O, 2 vol% Ar in He for 5 min at 523 K).

Ar, the inert tracer, accounted for the hydrodynamic reactor behavior. NO<sub>2</sub> evolution was delayed with respect to Ar. NO was produced and its formation was nearly finished after 15 min. The area between the concentration-time profile of Ar and NO<sub>2</sub> was proportional to the amount of adsorbed/reacted NO<sub>2</sub>:  $40 \cdot 10^{18}$  molecules/g. The integration of the NO response gave the amount of produced NO:  $11 \cdot 10^{18}$  molecules/g. The concentrations of produced N<sub>2</sub>, reversibly adsorbed N<sub>2</sub>O, adsorbed NO<sub>2</sub> and produced NO during transient response experiments with 2 vol% N<sub>2</sub>O or 0.5 vol% NO<sub>2</sub> are summarized in Table 7.2.

During the NO<sub>2</sub> interaction with the oxygen saturated catalyst,  $10 \cdot 10^{18}$  molecules/g of NO<sub>2</sub> less were consumed and  $5 \cdot 10^{18}$  molecules/g of NO less were produced as with the standard pre-treated catalyst. However, the TPD run (not shown) after the N<sub>2</sub>O → NO<sub>2</sub> interaction gave qualitatively and quantitatively the same results as the TPD after NO<sub>2</sub> interaction with the Fe-ZSM-5<sub>350</sub> which is shown in Figure 7.5. Hence, it can be concluded that the loaded oxygen from N<sub>2</sub>O ( $2.7 \cdot 10^{18}$  molecules/g) interacted with NO<sub>2</sub> forming NO<sub>2,ads</sub>, NO<sub>3,ads</sub> species. Therefore, less NO<sub>2</sub> decomposed to provide oxygen for the surface species formation and a smaller amount of NO was produced.

**Table 7.2:** Concentrations of produced or adsorbed molecules during transient response experiments at 523 K with the Fe-ZSM-5<sub>350</sub> catalyst determined with the Micromeritics Analyzer.

Treatment for 15 min	N <sub>2</sub> produced, 10 <sup>18</sup> molec./g	N <sub>2</sub> O rev. ads., 10 <sup>18</sup> molec./g	NO <sub>2</sub> ads., 10 <sup>18</sup> molec./g	NO produced, 10 <sup>18</sup> molec./g
2 vol% N <sub>2</sub> O	2.7	2.4	-	-
0.5 vol% NO <sub>2</sub>	-	-	50	16
2 vol% N <sub>2</sub> O after 15 min 0.5 vol% NO <sub>2</sub>	-	2.1	-	-
0.5 vol% NO <sub>2</sub> after 15 min 2 vol% N <sub>2</sub> O	-	-	40	11

The possibility of having reactive (O)<sub>Fe</sub> left on the catalyst after the N<sub>2</sub>O→NO<sub>2</sub> interaction was tested by CO introduction at 523 K. The response was similar to Figure 7.7 during CO oxidation after NO<sub>2</sub> treatment. Only slow oxidation of CO was observed which was not characteristic for the interaction of CO with reactive (O)<sub>Fe</sub>. This could indicate that the oxygen loaded from N<sub>2</sub>O was completely consumed with NO<sub>2</sub> for the formation of NO<sub>2,ads</sub>,NO<sub>3,ads</sub> species. Furthermore, oxygen loaded from N<sub>2</sub>O on the surface saturated with NO<sub>x,ads</sub> species was shown to be not reactive with respect to CO oxidation to CO<sub>2</sub> [3].

### 7.2.3. Summary

NO<sub>2</sub> pre-treatments inhibited the loading of oxygen from N<sub>2</sub>O in transient response and TAP experiments. The formation of gaseous nitrogen was not observed during the exposure of the NO<sub>2</sub> pre-treated catalyst to N<sub>2</sub>O. NO<sub>2</sub> blocked the sites for oxygen loading from N<sub>2</sub>O but the amount of reversibly adsorbed N<sub>2</sub>O stayed constant compared to the standard pre-treated catalyst. The blockage of the sites which were active in N<sub>2</sub>O decomposition through NO<sub>2</sub> pre-treatment had not been reported so far. Only kinetic analysis of the NO oxidation over MFI zeolites at temperatures from 473 to 623 K revealed the occurrence of a strong reaction inhibition by adsorbed NO<sub>2</sub> [13]. In chapter 6, it is shown that adsorbed NO did not inhibit the surface oxygen loading from N<sub>2</sub>O at 523 K.

NO<sub>2</sub> interaction with (O)<sub>Fe</sub> containing catalyst led to the formation of NO<sub>2,ads</sub>,NO<sub>3,ads</sub> species as upon NO<sub>2</sub> interaction with the standard pre-treated catalyst. The oxygen deposited by N<sub>2</sub>O pre-treatment was consumed for the formation of NO<sub>x,ads</sub> species in experiments at atmospheric pressure. Since oxygen was already present on the catalyst, less oxygen was needed from NO<sub>2</sub> and, therefore, less gaseous NO was

produced during NO<sub>2</sub> interaction with the N<sub>2</sub>O pre-treated Fe-ZSM-5 as compared to a standard pre-treated sample. In TAP experiments oxygen was released during the interaction of NO<sub>2</sub> with (O)<sub>Fe</sub> loaded Fe-ZSM-5<sub>550</sub>. The same phenomenon was observed during the interaction of NO with (O)<sub>Fe</sub>. In contrast to TAP results, the desorption of oxygen was not observed in transient experiments at atmospheric pressure. A possible explanation is that the thin catalyst bed in the TAP reactor was left quickly by formed O<sub>2</sub> whereas during experiments at atmospheric pressure the freed O<sub>2</sub> had the possibility to react further with NO<sub>x,ads</sub> species. More details and the corresponding experiments are given in section 6.3.

### 7.3. Temperature-Programmed Reaction at Atmospheric Pressure

Temperature-programmed reaction is often used to study the reaction dynamics and activation energy. Here, the interaction of N<sub>2</sub>O, NO<sub>2</sub>, N<sub>2</sub>O+NO and N<sub>2</sub>O+NO<sub>2</sub> mixtures were studied by temperature-programmed reaction and compared with each other in terms of reactivity and apparent activation energy. The influence of NO and NO<sub>2</sub> on the reaction system was of special interest.

#### 7.3.1. Treatments before Temperature-Programmed Reaction

Before the TPR experiments, pre-treatments of the Fe-ZSM-5<sub>550</sub> with the N<sub>2</sub>O (1 vol%), NO<sub>2</sub> (0.25 vol%), N<sub>2</sub>O (1 vol%)+NO (0.25 vol%) and N<sub>2</sub>O (1 vol%)+NO<sub>2</sub> (0.25 vol%) in Ar/He mixture at 523 K were performed to load surface species on the catalyst. During the 15 min treatment, different processes took place as listed below: The loading of oxygen, (O)<sub>Fe</sub>, from N<sub>2</sub>O accompanied by N<sub>2</sub> production, the adsorption of N<sub>2</sub>O, NO, and NO<sub>2</sub> on the catalyst, formation of NO and O<sub>2</sub> from NO<sub>2</sub> and vice versa, and the creation of NO<sub>x,ads</sub> species from N<sub>2</sub>O as well as from NO<sub>2</sub>.

The concentrations of produced or adsorbed species are summarized in Table 7.3. They were determined as described in section 7.1 and 7.2. The treatment with N<sub>2</sub>O showed oxygen loading via N<sub>2</sub> evolution as discussed in section 5.2. The exposure of the catalyst to NO<sub>2</sub> resulted in NO production and NO<sub>x,ads</sub> formation such as in Figure 7.4. More interesting were the observations during the N<sub>2</sub>O+NO<sub>2</sub> and N<sub>2</sub>O+NO treatments and will be discussed in detail in the following.

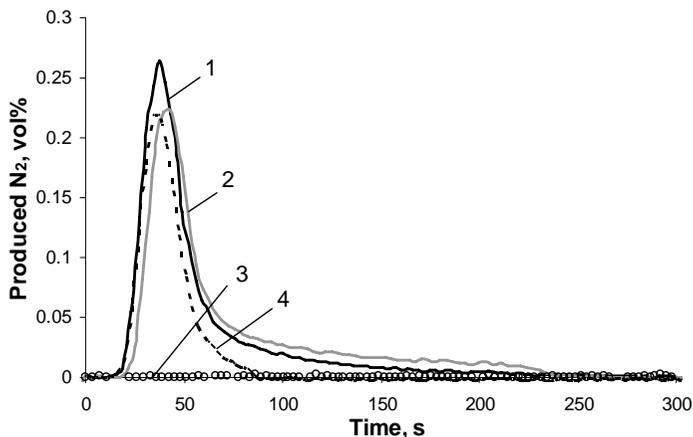

**Table 7.3:** Characteristic concentrations of produced or adsorbed molecules during transient response experiments at 523 K with the Fe-ZSM-5<sub>350</sub> catalyst determined with the Micromeritics Analyzer.

<i>Treatment for 15 min</i>	<i>N<sub>2</sub> produced, 10<sup>18</sup> molec./g</i>	<i>N<sub>2</sub>O rev. ads., 10<sup>18</sup> molec./g</i>	<i>NO ads., 10<sup>18</sup> molec./g</i>	<i>NO<sub>2</sub> ads., 10<sup>18</sup> molec./g</i>	<i>NO prod., 10<sup>18</sup> molec./g</i>
1 vol% N <sub>2</sub> O	2.4	1.3	-	-	-
0.25 vol% NO <sub>2</sub>	-	-	-	33	9.5
1 vol% N <sub>2</sub> O + 0.25 vol% NO	1.5	1.3	5.2	-	-
1 vol% N <sub>2</sub> O + 0.25 vol% NO <sub>2</sub>	2.5	1.5	-	24	12

The most significant reaction, which was the loading of the catalyst with oxygen, (O)<sub>Fe</sub> from N<sub>2</sub>O (Equation (7.8)) will be compared for different transient experiments. It was indirectly observed by the characteristic initial N<sub>2</sub> production from N<sub>2</sub>O which was not accompanied by gaseous oxygen formation. Therefore, the N<sub>2</sub> response profiles obtained during N<sub>2</sub>O interaction with the Fe-ZSM-5<sub>350</sub> at 523 K are summarized in Figure 7.13 for the different cases. Curve (1): N<sub>2</sub>O interacted with the standard pre-treated catalyst. Curve (2): The catalyst was exposed to a mixture of N<sub>2</sub>O+NO<sub>2</sub>. Curve (3): N<sub>2</sub>O interacted with the NO<sub>2</sub> pre-treated catalyst. Curve (4): The catalyst was exposed to a mixture of N<sub>2</sub>O+NO.

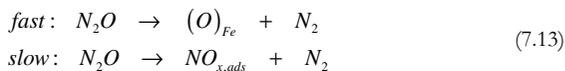

The amount of produced N<sub>2</sub> was about the same during 1 vol% N<sub>2</sub>O interaction (Figure 7.13, curve 1, 2.4·10<sup>18</sup> molecules/g N<sub>2</sub>) and during 1 vol% N<sub>2</sub>O+0.25 vol% NO<sub>2</sub> interaction (Figure 7.13, curve 2, 2.5·10<sup>18</sup> molecules/g N<sub>2</sub>) with the standard pre-treated catalyst. The amount of reversibly adsorbed N<sub>2</sub>O on the Fe-ZSM-5<sub>350</sub> was also the same for the N<sub>2</sub>O and the N<sub>2</sub>O+NO<sub>2</sub> mixture. Thus, the loading of active sites with oxygen was fully achieved even in the presence of 0.25 vol% NO<sub>2</sub>. However, pre-adsorbed NO<sub>2</sub>, which was discussed in section 7.2, completely inhibited the oxygen loading from N<sub>2</sub>O (Figure 7.13, curve 3, no N<sub>2</sub> evolution). Only reversible adsorption of N<sub>2</sub>O takes place. The loading of surface oxygen from the N<sub>2</sub>O+NO<sub>2</sub> mixture showed that the interaction

of N<sub>2</sub>O with the catalyst was faster than the blockage of the active sites by surface species formed from NO<sub>2</sub>.

**Figure 7.13:** Response curves of N<sub>2</sub> obtained at 523 K during introduction of 1 vol% N<sub>2</sub>O, 1 vol% Ar in He (1), 1 vol% N<sub>2</sub>O, 0.25 vol% NO<sub>2</sub>, 1.25 vol% Ar in He (2), 2 vol% N<sub>2</sub>O, 2 vol% Ar in He after NO<sub>2</sub> interaction (0.5 vol% NO<sub>2</sub>, 0.5 vol% Ar in He for 15 min at 523 K) (3) and 1 vol% N<sub>2</sub>O, 0.25 vol% NO, 1.25 vol% Ar in He (4) over the Fe-ZSM-5<sub>350</sub> catalyst.

The loading of oxygen from N<sub>2</sub>O took also place during the treatment with N<sub>2</sub>O+NO. The amount of formed N<sub>2</sub> was  $1.5 \cdot 10^{18}$  molecules/g (Figure 7.13, curve 4) in contrast to  $2.4 \cdot 10^{18}$  molecules/g (Figure 7.13, curve 1) when only N<sub>2</sub>O was interacting with the catalyst. In the presence of NO the N<sub>2</sub> evolution from N<sub>2</sub>O was finished within 100 s (curve 4) while a tailing up to 250 s was observed during the interaction of N<sub>2</sub>O only (curve 1). Thus, in the presence of NO, pathways leading to a slow formation of N<sub>2</sub> from N<sub>2</sub>O were absent. The slow creation of NO<sub>*x,ads*</sub> species from N<sub>2</sub>O was evidenced in section 6.1. The loading of (O)<sub>Fe</sub> and the formation of NO<sub>*x,ads*</sub> species from N<sub>2</sub>O was accompanied by N<sub>2</sub> formation as seen in the following equations:

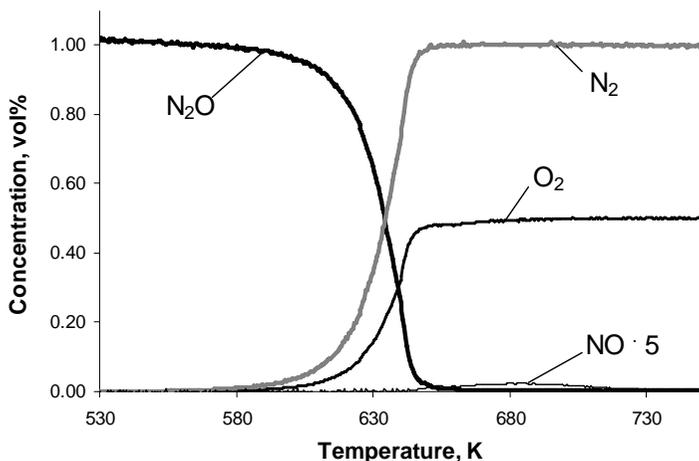

These NO<sub>*x,ads*</sub> species which were usually formed by N<sub>2</sub>O in a slow process were probably created faster by simple adsorption of NO from the N<sub>2</sub>O+NO mixture accompanied by a diminished N<sub>2</sub> release.

### 7.3.2. Temperature-Programmed Reaction Profiles

In this section the responses of the temperature-programmed reactions of N<sub>2</sub>O, NO<sub>2</sub>, N<sub>2</sub>O+NO and N<sub>2</sub>O+ NO<sub>2</sub> are presented and discussed. The catalyst was exposed to the reaction mixture of the TPR for 15 min at 523 K prior to the temperature ramp of 10 K/min from 523 to 873 K. The pre-treatment with the different reaction mixtures is discussed in the previous section.

Figure 7.14 shows the conversion of 1 vol% N<sub>2</sub>O versus temperature. The decomposition to N<sub>2</sub> and O<sub>2</sub> started above 577 K and reached 100% at 650 K.

**Figure 7.14:** Temperature-programmed reaction profiles observed during the passage of 1 vol% N<sub>2</sub>O, 1 vol% Ar mixture in He over the Fe-ZSM-5<sub>350</sub> catalyst.

The ratio of N<sub>2</sub>/O<sub>2</sub> remained equal to two during the entire studied temperature range and the amount of detected NO or NO<sub>2</sub> around 683 K was negligible:

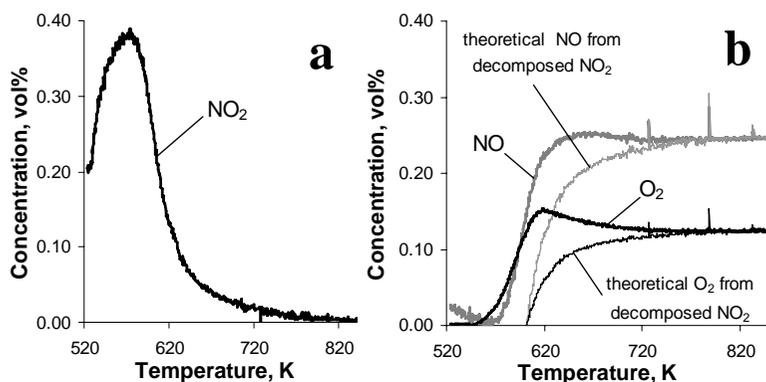

Surface oxygen was already loaded during the 15 min of N<sub>2</sub>O pre-treatment accompanied by the formation of  $2.4 \cdot 10^{18}$  molecules/g of N<sub>2</sub>.

The TPR profiles of 0.25 vol% NO<sub>2</sub> is shown in Figure 7.15. Upon heating the catalyst, an excess of NO<sub>2</sub> was observed due to desorption of reversibly adsorbed NO<sub>2</sub> accumulated on the catalyst during the pre-treatment. At higher temperature NO<sub>2</sub> decomposed to NO and O<sub>2</sub>:

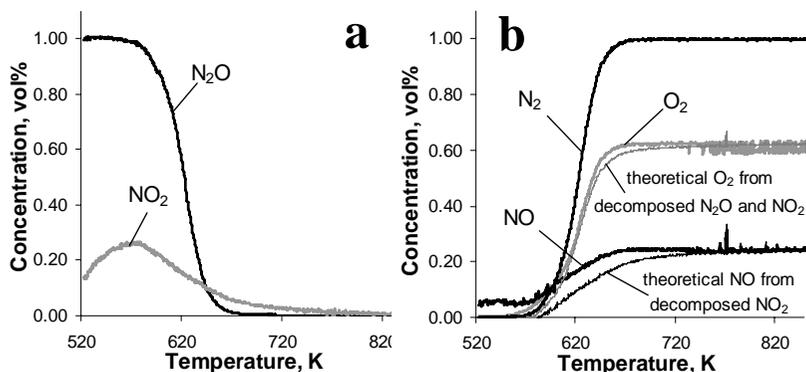

Based on this equation the theoretical profiles for the produced NO and O<sub>2</sub> were calculated from the amount of decomposed NO<sub>2</sub> and are illustrated in Figure 7.15b. It is seen by the difference of the experimental and calculated responses that the evolved amount of NO and O<sub>2</sub> was over-stoichiometric with respect to the decomposed amount of NO<sub>2</sub>. The excess of NO and O<sub>2</sub> was assigned to the desorption of NO<sub>x,ads</sub> species which were accumulated on the catalyst during the pre-treatment.

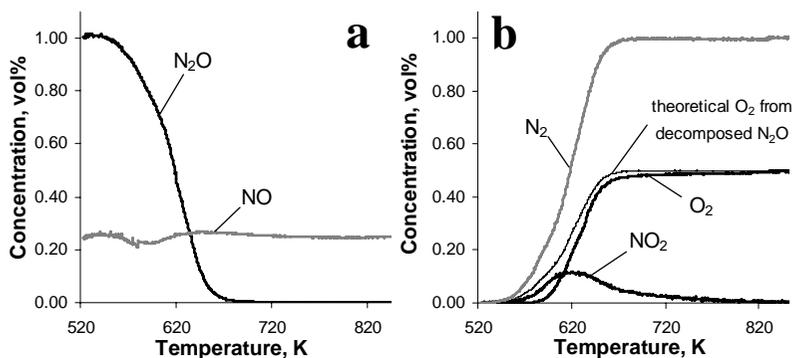

**Figure 7.15:** Temperature-programmed reaction profiles observed during the passage of 0.25 vol% NO<sub>2</sub>, 0.25 vol% Ar mixture in He over the Fe-ZSM-5<sub>350</sub> catalyst. Reactant (a), products (b).

The effect of NO<sub>2</sub> on the N<sub>2</sub>O decomposition was investigated in a TPR using a mixture of 0.25 vol% NO<sub>2</sub> and 1 vol% N<sub>2</sub>O. The responses in Figure 7.16 show the stoichiometric decomposition of N<sub>2</sub>O to N<sub>2</sub> starting at 570 up to 688 K for 100% conversion. NO<sub>2</sub> decomposed with progressing temperature to NO and O<sub>2</sub>. Thus, NO was formed during the TPR. The concentrations of NO<sub>2</sub> as well as NO were always changing. A stoichiometric decomposition of NO<sub>2</sub> as in Equation (7.15) was assumed and the corresponding profiles for the produced NO and O<sub>2</sub> were calculated from the amount of decomposed NO<sub>2</sub>. The stoichiometric decomposition of N<sub>2</sub>O (Equation (7.14)) was also accounted for the determination of the theoretically produced amount of O<sub>2</sub>. Figure 7.16b includes the calculated O<sub>2</sub> and NO responses in which the N<sub>2</sub>O and NO<sub>2</sub> decomposition was considered. As already observed at the NO<sub>2</sub> TPR, an excess of NO desorbed between 523 K and 723 K whereas an excess of O<sub>2</sub> was hardly observed in the N<sub>2</sub>O+NO<sub>2</sub> TPR. NO originated from NO<sub>ads</sub> species accumulated on the catalyst during the pre-treatment.

**Figure 7.16:** Temperature-programmed reaction profiles observed during the passage of 0.25 vol% NO<sub>2</sub>, 1 vol% N<sub>2</sub>O, 1.25 vol% Ar mixture in He over the Fe-ZSM-5<sub>350</sub> catalyst. Reactants (a), products (b).

Since NO was constantly formed during N<sub>2</sub>O-NO<sub>2</sub>-TPR, a N<sub>2</sub>O-NO-TPR was performed for comparison. Figure 7.17 illustrates the TPR profiles of 1 vol% N<sub>2</sub>O and 0.25 vol% NO. N<sub>2</sub>O decomposed stoichiometrically to N<sub>2</sub> from 543 to 693 K. Based on a stoichiometric decomposition of N<sub>2</sub>O (Equation (7.14)), the theoretical O<sub>2</sub> response was calculated and illustrated in Figure 7.17b.

**Figure 7.17:** Temperature-programmed reaction profiles observed during the passage of 0.25 vol% NO, 1 vol% N<sub>2</sub>O, 1.25 vol% Ar mixture in He over the Fe-ZSM-5<sub>350</sub> catalyst. Reactants (a), products (b).

A deficit of the produced oxygen was observed by comparing the theoretical with the experimental O<sub>2</sub> response. Obviously, oxygen reacted partially with NO forming NO<sub>2</sub>. For the amount of evolved NO<sub>2</sub> during the experiment an equivalent amount of

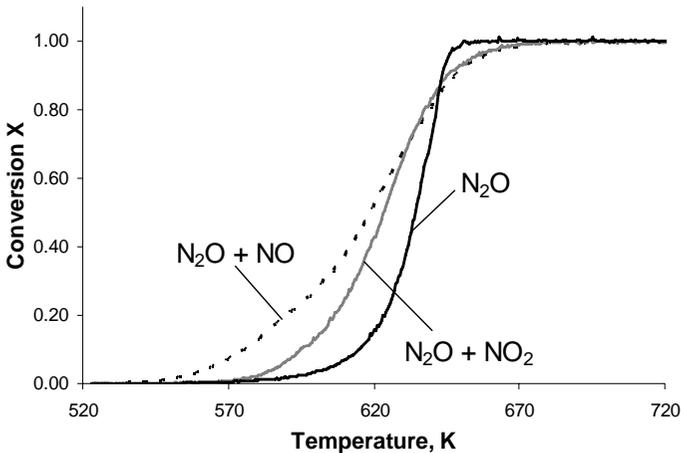

NO had to be consumed. The consumption of a small amount of NO was observed by the sink in the NO response around 598 K in Figure 7.17a. The outstanding amount of NO for the NO<sub>2</sub> formation was probably already adsorbed on the catalyst during the pre-treatment. The accumulation of NO during the pre-treatment as well as the O<sub>2</sub> consumption was shifted to fewer time/temperature compared to the appearance of NO<sub>2</sub> (desorption maximum at 623 K). It can be concluded that NO<sub>2</sub> was formed on the catalyst surface and not in a gas phase reaction.

### 7.3.3. Apparent Activation Energy

In this section the N<sub>2</sub>O conversion as function of the temperature is compared for different reaction mixtures: 1 vol% N<sub>2</sub>O + 1 vol% Ar, 1 vol% N<sub>2</sub>O + 0.25 vol% NO + 1.25 vol% Ar, 1 vol% N<sub>2</sub>O + 0.25 vol% NO<sub>2</sub> + 1.25 vol% Ar in He. The apparent activation energy is presented.

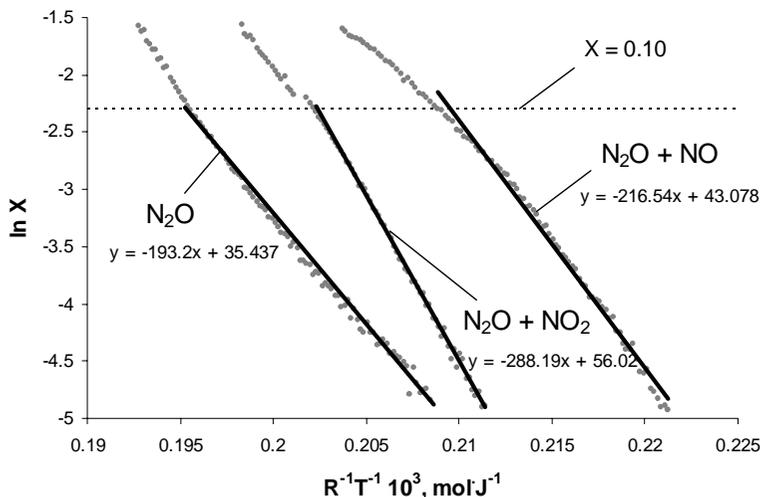

Figure 7.18 shows the relation between conversion and temperature of the N<sub>2</sub>O decomposition over Fe-ZSM-5<sub>350</sub> for different mixtures (N<sub>2</sub>O, N<sub>2</sub>O+NO and N<sub>2</sub>O+NO<sub>2</sub>). It can be seen that the conversion increased with the increase of the temperature and reaches 100% at 673 K for all three mixtures. The addition of NO<sub>2</sub> and NO to N<sub>2</sub>O decreased the temperature whereas the decomposition started by 8 and 34 K lower, respectively.

**Figure 7.18:** Temperature dependence of N<sub>2</sub>O conversion of the Fe-ZSM-5<sub>350</sub> for different reaction mixtures: 1 vol% N<sub>2</sub>O + 1 vol% Ar, 1 vol% N<sub>2</sub>O + 0.25 vol% NO + 1.25 vol% Ar, 1 vol% N<sub>2</sub>O + 0.25 vol% NO<sub>2</sub> + 1.25 vol% Ar in He.

The N<sub>2</sub>O+NO and N<sub>2</sub>O+NO<sub>2</sub> curve overlapped at temperatures higher than 623 K. The reason is that the concentration profiles of NO and NO<sub>2</sub> during the TPR were about the same above 623 K for the N<sub>2</sub>O+NO and N<sub>2</sub>O+NO<sub>2</sub> mixture. At lower temperatures the NO and NO<sub>2</sub> concentration profiles for the two mixtures were significantly different as can be seen in Figure 7.16 and Figure 7.17. The promoting effect of NO is clearly seen in Figure 7.18 by higher conversions at the same temperature for the N<sub>2</sub>O+NO mixture compared to N<sub>2</sub>O only. NO<sub>2</sub> was also enhancing the N<sub>2</sub>O decomposition but to a lower extent. Since the interconversion of NO<sub>2</sub> and NO took place, they coexisted on the catalyst or in the reaction mixture and it was difficult to determine in which way NO or NO<sub>2</sub> contributed to the N<sub>2</sub>O decomposition.

The N<sub>2</sub>O conversion obtained during temperature-programmed reaction of only N<sub>2</sub>O and mixtures of N<sub>2</sub>O+NO and N<sub>2</sub>O+NO<sub>2</sub> from 539 K to 623 K are shown in the form of an Arrhenius plot in Figure 7.19.

**Figure 7.19:** Arrhenius plot generated from the results of Figure 7.18 for the N<sub>2</sub>O decomposition over Fe-ZSM-5<sub>350</sub> for different reaction mixtures: 1 vol% N<sub>2</sub>O + 1 vol% Ar, 1 vol% N<sub>2</sub>O + 0.25 vol% NO + 1.25 vol% Ar, 1 vol% N<sub>2</sub>O + 0.25 vol% NO<sub>2</sub> + 1.25 vol% Ar in He.

A differential flow reactor was considered with a constant rate at all points within the reactor. Since rates were concentration-dependent it was only reasonable for small conversions ( $X \leq 0.10$ ). Our results in the transient period [14] and other investigators' results [15, 16] indicated that the N<sub>2</sub>O decomposition is a first-order reaction ( $n=1$ ). On the basis of Equation (7.17) the apparent activation energy was calculated from the slope

of the straight line and the preexponential factor from the axis intercept, respectively. The results are summarized for the different reaction mixtures in Table 7.4.

$$c_{N_2O_0} \cdot \frac{\Delta X}{\tau_{res}} = A e^{(-E_a/RT)} \cdot c_{N_2O}^n \quad (7.17)$$

For N<sub>2</sub>O decomposition the apparent activation energy was found to be E<sub>a</sub> = 193 kJ/mol. This value agreed with those published by Kiwi-Minsker et al.: 169 kJ/mol [14], Bell and coworkers: 179 kJ/mol [17] and 185 kJ/mol [18], Perez-Ramirez et al.: 161 kJ/mol [4], Zhu et al.: 136-213 kJ/mol [19] and Sang et al.: 194 kJ/mol [5].

The addition of NO or NO<sub>2</sub> caused an increase in the rate of N<sub>2</sub>O decomposition. However, the apparent activation energy was higher for the mixtures than for pure N<sub>2</sub>O, 217 kJ/mol for N<sub>2</sub>O+NO and 288 kJ/mol for the N<sub>2</sub>O+NO<sub>2</sub> mixture. The increase of the activity in the presence of NO was not reflected in a decrease in E<sub>a</sub> as was observed by Perez-Ramirez et al.: 106 kJ/mol [4] and Sang et al.: 165 kJ/mol [5]. Simultaneously with E<sub>a</sub> increased the preexponential factor. The higher activity was, thus, explained by the compensation effect, resulting in an increase of the preexponential factor in the order of ~10<sup>5</sup>-10<sup>9</sup>.

**Table 7.4:** Apparent Arrhenius Parameters for First-Order Kinetic Fits for N<sub>2</sub>O decomposition obtained from the results of Figure 7.18.

Reaction Mixture	(X = 0 - 0.10)	
	E <sub>a</sub> , kJ mol <sup>-1</sup>	ln A (A: s <sup>-1</sup> )
N <sub>2</sub> O	193	35
N <sub>2</sub> O+ NO	217	43
N <sub>2</sub> O + NO <sub>2</sub>	288	56

### 7.3.4. Summary

Temperature-programmed reaction at atmospheric pressure of N<sub>2</sub>O showed the expected stoichiometric decomposition into N<sub>2</sub> and O<sub>2</sub>. The reaction started above 577 K and reaches 100% conversion at 650 K. The formation of gaseous NO or NO<sub>2</sub> was negligible. The TPR of NO<sub>2</sub> showed its decomposition with increasing temperature to NO and O<sub>2</sub>. The TPR with a mixture of N<sub>2</sub>O+NO<sub>2</sub> and N<sub>2</sub>O+NO was accompanied by the interconversion of NO<sub>2</sub>↔NO which made an assignment of effects to NO and NO<sub>2</sub>, respectively, very difficult. In addition, NO<sub>x</sub> surface species were formed during the pre-treatment of 15 min in the reaction mixture. The desorption of the accumulated surface species interfered with the processes of the TPR.

NO<sub>2</sub> was formed in the TPR with the N<sub>2</sub>O+NO mixture. It is interesting to note that the release of NO<sub>2</sub> was time/temperature delayed with respect to the consumption of NO from the N<sub>2</sub>O+NO mixture indicating a surface instead of a gas-phase reaction.

During the pre-treatment with the N<sub>2</sub>O+NO<sub>2</sub> mixture at 523 K, (O)<sub>Fe</sub> loading took place to the full extent. As discussed above, the catalyst pre-treated with NO<sub>2</sub> did not uptake oxygen from N<sub>2</sub>O since the active sites were blocked by NO<sub>2,ads</sub>, NO<sub>3,ads</sub> species. It can be concluded that the loading of (O)<sub>Fe</sub> from N<sub>2</sub>O was faster than the adsorption and formation of NO<sub>2,ads</sub>, NO<sub>3,ads</sub> species from NO<sub>2</sub>.

During the simultaneous introduction of N<sub>2</sub>O and NO at 523 K, (O)<sub>Fe</sub> was loaded which was measured by the N<sub>2</sub> release. The amount of produced N<sub>2</sub> was only about 60% compared to surface oxygen loaded from N<sub>2</sub>O in the absence of NO. In the presence of NO, pathways leading to a slow formation of N<sub>2</sub> from N<sub>2</sub>O were absent. The slow formation of NO<sub>ads</sub> species accompanied by N<sub>2</sub> evolution from N<sub>2</sub>O was reported in [14]. These NO<sub>x,ads</sub> species which were usually formed by N<sub>2</sub>O in a slow process were probably created faster by simple adsorption of NO from the N<sub>2</sub>O+NO mixture accompanied by a diminished N<sub>2</sub> release.

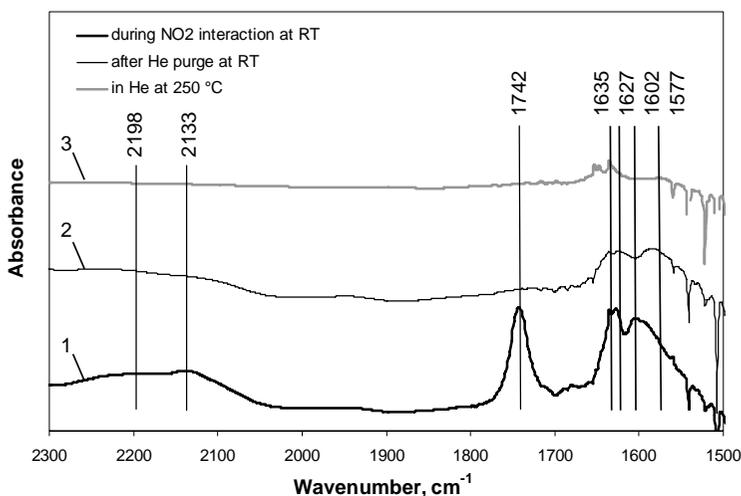

The apparent activation energy for N<sub>2</sub>O decomposition calculated from a TPR experiment was 193 kJ/mol. The temperature-programmed reaction might not be in steady state during the whole experiment since N<sub>2</sub>O formed NO<sub>x,ads</sub> species only slowly [20] which co-catalysed the N<sub>2</sub>O decomposition. Nevertheless, the apparent activation energy was close to the value (169.4 ± 5.5 kJ/mol) obtained by steady-state measurements with the same Fe-ZSM-5<sub>350</sub> catalyst [14].

It was observed that the addition of sub-stoichiometric amount of NO and NO<sub>2</sub>, respectively, caused an increase in the rate of N<sub>2</sub>O decomposition. The increase in activity was not reflected in a decrease in the apparent activation energy as it was the case in [4, 5] by ca. 40-60 kJ/mol. On the contrary, the activation energy increased by 22 kJ/mol and 73 kJ/mol due to the addition of NO and NO<sub>2</sub>, respectively. Simultaneously, the apparent preexponential factor increased in the order of ~10<sup>5</sup>-10<sup>9</sup>. Thus, the higher activity can be explained by the compensation effect.

## 7.4. NO<sub>2</sub> DRIFTS in Situ

Adsorbed NO<sub>x</sub> species were formed from NO<sub>2</sub> during contact with Fe-ZSM-5 catalysts at 523 K. The formation of these species was further investigated by infrared spectroscopy. The zeolite was exposed to a flow of 20 ml (STP)/min of 0.5 vol% NO<sub>2</sub>, 0.5 vol% Ar in He. The DRIFT spectra presented in Figure 7.20, spectrum 1 were obtained after 15 min of NO<sub>2</sub> interaction with the zeolite at room temperature in the presence of gaseous NO<sub>2</sub>. It shows absorption frequencies at 2198, 2133, 1742, and

between 1635 and 1577 cm<sup>-1</sup>. The bands at 2198 and 2134 cm<sup>-1</sup> were assigned to [NO<sup>+</sup>][N<sub>2</sub>O<sub>4</sub>] and NO<sup>+</sup>, respectively [21-24]. The 1744 cm<sup>-1</sup> band was unambiguously assigned to N<sub>2</sub>O<sub>4</sub> [21, 22, 24]. The band at 1635 and 1627 cm<sup>-1</sup> was attributed to some form of adsorbed NO<sub>2</sub> [21, 24]. The frequencies around 1602 cm<sup>-1</sup> were assigned to nitro and nitrate groups [21, 24] while the low intensity band at 1577 cm<sup>-1</sup> with low intensity was attributed to adsorbed NO<sub>3</sub> groups [21, 22, 24]. The assignments for the FT-IR bands are summarized in Table 7.5. The band assignment for frequencies below 1650 cm<sup>-1</sup> was not evident since many NO<sub>x</sub> species (NO<sub>2</sub>, NO<sub>2</sub><sup>-</sup>, NO<sub>3</sub><sup>-</sup>) adsorbed at about 1650-1600 cm<sup>-1</sup> [25]. Bands in the range of 1920–1750 cm<sup>-1</sup> attributed to mononitrosyl and dinitrosyl complexes with Fe(II) on zeolite did not appear upon NO<sub>2</sub> interaction. In summary, strong bands for NO<sup>+</sup> and N<sub>2</sub>O<sub>4</sub> were observed while the bands of the nitro and nitrate groups were not well resolved and their assignment was ambiguous.

**Figure 7.20:** DRIFT spectra obtained during NO<sub>2</sub> interaction (0.5 vol%, 15 min) at room temperature (1), subsequent He purge (5 min) at room temperature (2) and the spectra at 523 K in He (3).

The spectra of the adsorbed species after a He purge of 5 min is also presented in Figure 7.20, spectrum 2 in order to see the difference between strongly and weakly adsorbed species. The bands of N<sub>2</sub>O<sub>4</sub> and NO<sup>+</sup> disappeared upon the He purge and the bands of the nitro and nitrate groups decreased in intensity. The spectra upon heating to 523 K (Figure 7.20, spectrum 3) in He showed only very weak bands at 1635 and 1577 cm<sup>-1</sup> assigned to adsorbed NO<sub>2</sub> and NO<sub>3</sub> species, respectively.

In this case DRIFTS was not a suitable way to study the formation of NO<sub>x,ads</sub> species on the Fe-ZSM-5<sub>350</sub> during NO<sub>2</sub> interaction at 523 K and their desorption at higher temperatures since the bands of the nitrite and nitrate groups had a very low

intensity already at low temperatures as 523 K. The sample size was only 50 mg and the concentration of active sites with  $2.7 \cdot 10^{18}$  sites/g was very low. This showed again the general problem of characterizing Fe-ZSM-5 active in N<sub>2</sub>O decomposition due to the small concentration of active sites.

**Table 7.5:** Summary of the assignment of the different FT-IR bands.

<i>Band position (Wavenumber, cm<sup>-1</sup>)</i>	<i>Assignment to adsorbed</i>	<i>Reference</i>
2198	[NO <sup>+</sup> ][N <sub>2</sub> O <sub>4</sub> ]	[21, 22]
2133	NO <sup>+</sup>	[21-24]
1742	N <sub>2</sub> O <sub>4</sub>	[21, 22, 24]
1711	N <sub>2</sub> O <sub>4</sub>	[22]
1635	NO <sub>2</sub>	[21, 24]
1627	NO <sub>2</sub>	[21, 24]
1602	NO <sub>2</sub>	[21, 24]
	NO <sub>3</sub>	
1577	NO <sub>3</sub>	[21, 22, 24]

DRIFT spectroscopy was applied to further elucidate the interaction of NO<sub>2</sub> with the Fe-ZSM-5<sub>350</sub>. The idea was to study the formation of surface species by NO<sub>2</sub> and to observe their stability upon heating the catalyst. However, already at 523 K the intensities of nitro/nitrate groups were very weak. Additional bands of interest in the range of 2300 to 1500 cm<sup>-1</sup> were not observed, which made the method not suitable to study the interaction of NO<sub>2</sub> with the particular catalyst. At room temperature strong bands for NO<sup>+</sup> and N<sub>2</sub>O<sub>4</sub> were observed while the bands of the nitro and nitrate groups were not well resolved and their assignment was ambiguous.

# Chapter 8

## **H<sub>2</sub>O INTERACTION WITH Fe-ZSM-5**

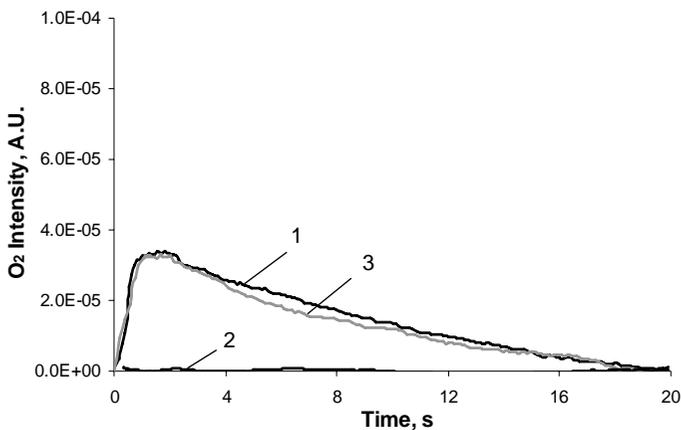

A significant deactivation during N<sub>2</sub>O decomposition was several times observed upon water introduction into the reaction mixture [1-5]. The water inhibition was studied theoretically and compared with experimental results by Heyden et al. [6, 7]. The authors concluded that water impurity (< 100 ppm) may strongly affect the kinetics of N<sub>2</sub>O decomposition. Water is often already present in reaction mixtures as an impurity. This chapter addresses the water effect on N<sub>2</sub>O decomposition over isomorphously substituted Fe-ZSM-5 at different temperatures. It is aimed on further understanding under which conditions water inhibits the N<sub>2</sub>O decomposition and the reaction steps involved. Vacuum conditions and small amounts of reactants in the TAP setup facilitate the de-hydroxylation of the catalyst compared to atmospheric pressure experiments.

## 8.1. H<sub>2</sub>O Influence on Catalytic Activity

### 8.1.1. Transient Experiments under Vacuum

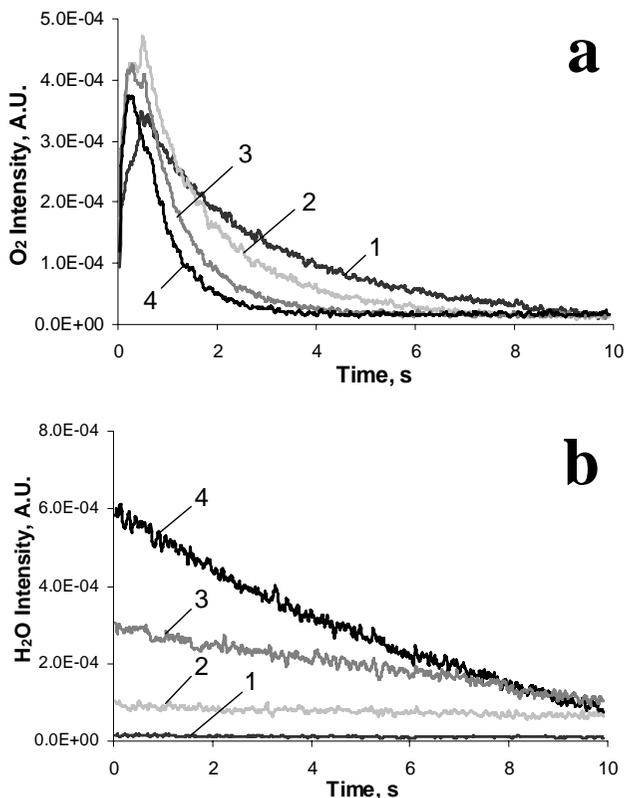

The effect of water on the activity of the Fe-ZSM-5<sub>5500</sub> catalyst was studied in vacuum under transient conditions at different temperatures using the TAP system. At temperatures below 600 K N<sub>2</sub>O decomposed via N<sub>2</sub> evolution and atomic surface oxygen loading. The decomposition proceeded until the catalyst was saturated with oxygen and stopped completely thereafter. Consequently, a catalytic activity measurement was not possible at low temperatures. H<sub>2</sub>O pulses subsequently to N<sub>2</sub>O pulses provoked the partial desorption of oxygen and transformed the residual surface oxygen. This experiment gives valuable information about the interaction of (O)<sub>Fe</sub> with water and is described in detail in section 8.2.

At 703 K N<sub>2</sub>O decomposed over Fe-ZSM-5<sub>5500</sub> by forming gaseous N<sub>2</sub> and gaseous O<sub>2</sub>. The O<sub>2</sub> response from a N<sub>2</sub>O pulse over the dry catalyst is shown in Figure 8.1, curve 1. Subsequently to the introduction of about 100 N<sub>2</sub>O pulses for reaching a representative conversion, the Fe-ZSM-5<sub>5500</sub> was saturated with water at 703 K followed by N<sub>2</sub>O pulsing during two hours. The catalyst was completely deactivated upon the introduction of water. No oxygen release was observed during N<sub>2</sub>O interaction with the catalyst (Figure 8.1, curve 2). However, during continuous N<sub>2</sub>O pulsing thereafter, H<sub>2</sub>O desorbed and 95% of the initial conversion was recovered after 2 h (Figure 8.1, curve 3). Thus, the effect of water on the catalyst at 703 K can be considered reversible in vacuum.

**Figure 8.1:** O<sub>2</sub> responses during the introduction of N<sub>2</sub>O pulses at 703 K over dry Fe-ZSM-5<sub>5500</sub> (1), over the catalyst saturated with water (2) and after 2h of N<sub>2</sub>O pulsing over the wet catalyst (3).

The effect of water on the N<sub>2</sub>O decomposition at 803 K was studied with the same catalyst using a pump-probe experiment. After the standard pre-treatment of the Fe-ZSM-5<sub>5500</sub> about 100 pulses of N<sub>2</sub>O were introduced to the reactor every 20 s to acquire a representative conversion. Afterwards, pulses of N<sub>2</sub>O (80 vol% N<sub>2</sub>O in Ar) and H<sub>2</sub>O were consequently fed to the reactor. N<sub>2</sub>O was introduced at  $t = 0$  s time and H<sub>2</sub>O was pulsed after a delay at  $t = 10$  s. The total cycle time was 20 s. The N<sub>2</sub>O decomposition to N<sub>2</sub> (not shown) and O<sub>2</sub> (Figure 8.2a) was observed in agreement with the steady-state results. Under these conditions water adsorbed reversibly and gave a very broad peak. A part of this H<sub>2</sub>O peak starting from the moment of N<sub>2</sub>O introduction, is seen in Figure 8.2b. The area under the peak was proportional to the water amount present on the surface before the N<sub>2</sub>O pulse.

**Figure 8.2:** Oxygen (a) and water (b) responses obtained at 803 K during N<sub>2</sub>O interaction (0 s) with the Fe-ZSM-5<sub>5500</sub> catalyst containing different amounts of water: without H<sub>2</sub>O (1), with increasing amount of water (2), (3), (4).

The oxygen response area decreased with increasing surface water amount. A difference of approximately two times was observed between the oxygen response area without water (curve 1) and with maximal water coverage (curve 4). This indicates that water blocked considerably active iron sites for the reaction even though it was only reversibly adsorbed at 803 K. At the conditions of the experiment Ar, N<sub>2</sub>O and N<sub>2</sub> peaks (not shown) were quite narrow (< 0.5 s) as compared with the oxygen peak, which was quite broad and sharpened with increasing amount of H<sub>2</sub>O (from 10 to 4 s, Figure 8.2a). The shape of the oxygen responses provide valuable qualitative information on the reaction mechanism and is discussed in section 8.3.

### 8.1.2. Steady-state Experiments at Atmospheric Pressure

To study the effect of water on N<sub>2</sub>O decomposition under steady-state conditions, experiments were performed with the Micromeritics AutoChem 2910 setup at atmospheric pressure. A water pulse of 2  $\mu$ l was introduced into the reaction mixture passing through the Fe-ZSM-5<sub>500</sub> catalyst at different temperatures after the steady-state was attained within 65 min. The conversions before and after water introduction are presented in Table 8.1. It is seen that with the dry catalyst the increase of the temperature from 523 to 673 K increased the conversion up to about 100%. Water introduction led to the complete deactivation of the catalyst towards N<sub>2</sub>O decomposition.

**Table 8.1:** Water effect on the steady-state conversion during the N<sub>2</sub>O decomposition (2 vol% N<sub>2</sub>O in Ar, total flow rate 20 ml/min) over Fe-ZSM-5<sub>500</sub> (0.4 g).

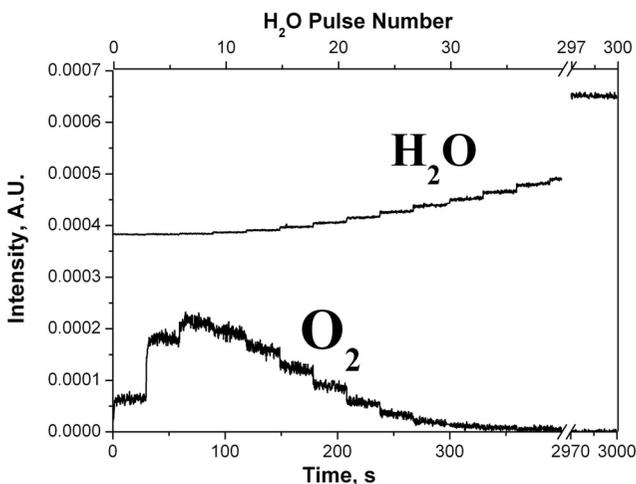

Temperature, K	Conversion after 65 min in the reaction mixture	
	Before H <sub>2</sub> O introduction	After H <sub>2</sub> O introduction
523	0	0
603	0.15	0
673	1.0	0

### 8.1.3. Summary

In summary, the presence of H<sub>2</sub>O decreased the catalyst activity in N<sub>2</sub>O decomposition at any studied temperature (523–803 K) in experiments with the TAP and the Micromeritics setup. The de-hydroxylation of the catalyst was facilitated in vacuum. The effect of water on the N<sub>2</sub>O decomposition at 703 K led to complete deactivation but it was reversible. At 803 K the N<sub>2</sub>O conversion was diminished to about the half in N<sub>2</sub>O/H<sub>2</sub>O pump probe experiments. Water injection on the catalyst at atmospheric pressure (523-673 K) inhibited completely the N<sub>2</sub>O decomposition.

## 8.2. Interaction of H<sub>2</sub>O with Surface Oxygen loaded from N<sub>2</sub>O

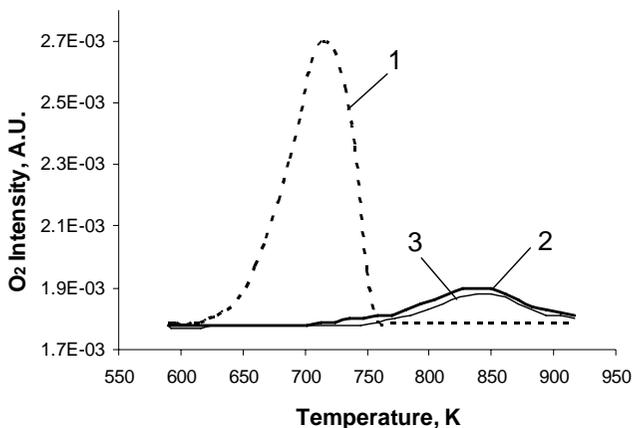

The interaction of H<sub>2</sub>O with surface oxygen loaded from N<sub>2</sub>O was studied with the Fe-ZSM-5<sub>5500</sub> at 593 K using the TAP reactor. At these conditions the formation of surface atomic oxygen (O)<sub>Fe</sub> and gaseous N<sub>2</sub> from N<sub>2</sub>O took place, but the formation of gaseous oxygen was not observed. The active sites were loaded with oxygen by multiple N<sub>2</sub>O pulsing. Afterwards, pulses of water were introduced. It is seen in Figure 8.3 that the first water pulses provoked an O<sub>2</sub> release. This suggests the competitive adsorption of water on the iron sites containing oxygen. Oxygen evolved as a very broad peak. After 30 pulses of water oxygen did not desorb anymore, while water continued to accumulate on the catalyst until the saturation after ca. 300 pulses.

**Figure 8.3:** Oxygen desorption provoked by water pulses after oxygen loading from N<sub>2</sub>O on the Fe-ZSM-5<sub>5500</sub> catalyst in the TAP reactor at 593 K.

A TPD experiment was performed in order to investigate residual surface species after the water treatment of the (O)<sub>Fe</sub> containing catalyst. Figure 8.4 summarizes TPD profiles of O<sub>2</sub> evolution for different pre-treatments at 593 K. Curve 1 shows the TPD profile of oxygen after (O)<sub>Fe</sub> loading from N<sub>2</sub>O. Curve 2 illustrates the O<sub>2</sub> evolution in the TPD after the interaction of H<sub>2</sub>O with the (O)<sub>Fe</sub> containing catalyst. As indicated by a shift of the temperature of maximal desorption rate from 715 to 849 K the presence of water clearly transformed the residual adsorbed oxygen. Kiwi-Minsker et al. reported as well that the oxygen recombination/desorption was more difficult from the water saturated surface as from the dry catalyst [8].

It was shown earlier that (O)<sub>Fe</sub> loaded from N<sub>2</sub>O possessed high reactivity in CO oxidation already at low temperatures (423-473 K) [9]. The surface oxygen transformed by H<sub>2</sub>O was inactive in CO oxidation as seen by the absence of CO<sub>2</sub> formation during CO interaction (not shown). Curve 3 in Figure 8.4 shows the TPD profile of the O<sub>2</sub> evolution after the N<sub>2</sub>O→H<sub>2</sub>O→CO treatment of the Fe-ZSM-5<sub>5500</sub> at 593 K. It is almost identical to curve 2 confirming the inactivity of the surface oxygen with respect to CO oxidation.

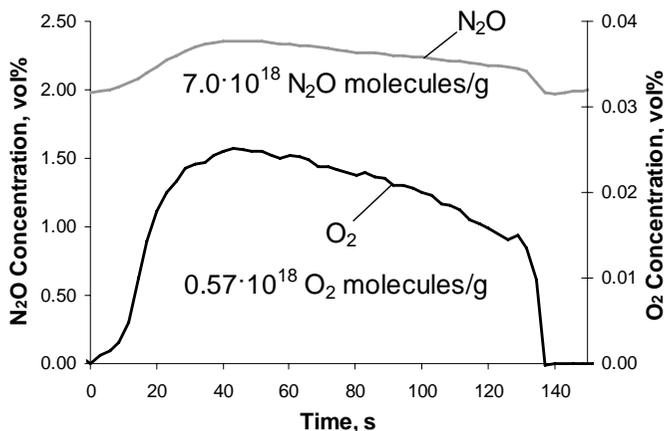

**Figure 8.4:** TPD profiles of oxygen after its loading from N<sub>2</sub>O (1), after N<sub>2</sub>O interaction followed by water saturation (2) and after N<sub>2</sub>O interaction followed by water saturation and CO treatment (3) at 593 K of the Fe-ZSM-5<sub>5500</sub>.

Thus, water interaction with (O)<sub>Fe</sub> at 593 K provoked the evolution of O<sub>2</sub> and transformed residual oxygen into an inactive form which can not oxidize CO to CO<sub>2</sub>. The observations upon the interaction of H<sub>2</sub>O with (O)<sub>Fe</sub> containing zeolite are summarized in the following equation:

Similar experiments were performed in the Micromeritics AutoChem 2910 setup with the Fe-ZSM-5<sub>5500</sub> catalyst at 523 K. 2 μl water were injected in the reaction mixture consisting of 2 vol% N<sub>2</sub>O, 2 vol% Ar in He after surface oxygen loading for 2.5 min It is seen in Figure 8.5 that O<sub>2</sub> and N<sub>2</sub>O were desorbed upon the water pulse. H<sub>2</sub>O was detected at the reactor outlet 140 s after the injection (not shown). Thus, water adsorption was accompanied by the evolution of 0.57·10<sup>18</sup> molecules/g oxygen and the desorption of N<sub>2</sub>O which was only weakly adsorbed and amounts 7.0·10<sup>18</sup> molecules/g. Important is that the amount of oxygen induced by water adsorption (1.1·10<sup>18</sup> atoms/g)

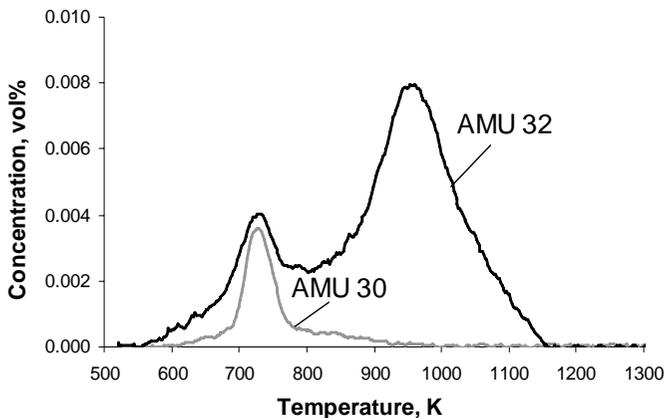

was less than the amount of loaded oxygen ( $3.5 \cdot 10^{18}$  atoms/g). Hence, water substituted only a part of the loaded ( $O$ )<sub>Fe</sub> leading to its desorption as O<sub>2</sub>.

**Figure 8.5:** O<sub>2</sub> and N<sub>2</sub>O desorption provoked by the injection of 2  $\mu$ l water into the reaction mixture of 2 vol% N<sub>2</sub>O, 2 vol% Ar in He after oxygen loading from N<sub>2</sub>O on the Fe-ZSM-5<sub>5500</sub> catalyst at 523 K.

A TPD run was performed after the water assisted oxygen desorption in order to study the residual surface species. Figure 8.6 shows the AMU 32 and AMU 30 TPD. NO<sub>x,ads</sub> species desorbed around 729 K contributing to AMU 30 and AMU 32. NO<sub>x,ads</sub> species were known to be slowly formed from N<sub>2</sub>O as reported in [1, 10] and acted as co-catalyst [11, 12] in N<sub>2</sub>O decomposition. They were stronger attached to the catalyst than water. Supplementary, oxygen was desorbed showing a broad peak with a maximum at 959 K similar to the profile when oxygen loading was performed on the water saturated surface which was inactive in CO oxidation [8, 13]. Water participated in the transformation of the active iron sites into inactive ones.

It can be concluded that water affected ( $O$ )<sub>Fe</sub> by provoking its partial desorption as O<sub>2</sub> and transforming the residual oxygen into an inactive form as already summarized in Equation (8.1). Very good agreement was found between the TAP reactor data obtained at vacuum conditions and catalytic data at atmospheric pressure. NO<sub>x,ads</sub> species formed from N<sub>2</sub>O resisted the water treatment while weakly adsorbed N<sub>2</sub>O desorbed during the water pulse at atmospheric pressure.

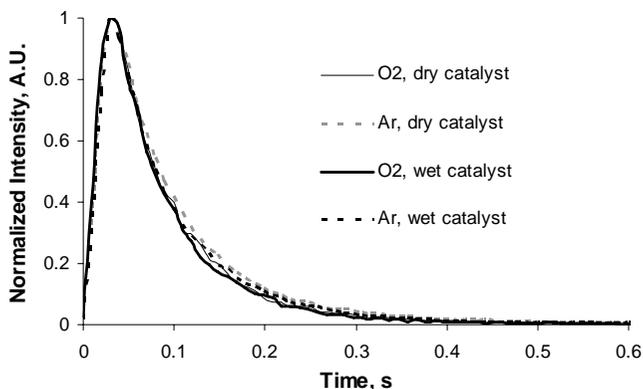

**Figure 8.6:** TPD profiles of AMU 32 and 30 after oxygen loading from 2 vol% N<sub>2</sub>O, 2 vol% Ar in He for 2.5 min on the Fe-ZSM-5<sub>5500</sub> catalyst at 523 K followed by the injection of 2  $\mu$ l water into the reaction mixture.

### 8.3. Effect of H<sub>2</sub>O on Oxygen Desorption during N<sub>2</sub>O Decomposition

N<sub>2</sub>O/H<sub>2</sub>O pump probe experiments with the Fe-ZSM-5<sub>5500</sub> at 803 K which are presented in section 8.1 showed a diminished N<sub>2</sub>O conversion over the wet zeolite. In Figure 8.2 it can be seen that the area of the O<sub>2</sub> response becomes smaller with increasing amount of H<sub>2</sub>O on the catalyst. However, the oxygen responses shifted also to lower times with increasing surface water amount. To understand the reasons of the broad shape of the O<sub>2</sub> response on the dry surface and narrow on the wet one, O<sub>2</sub>/Ar pulses were introduced on the dry and wet catalyst at the same temperature. It is seen in Figure 8.7 that the Ar and O<sub>2</sub> responses were similar and extremely narrow (< 0.4 s) independently on the water pre-treatment. Hence, oxygen re-adsorption did not take place on the zeolite and mass transport of oxygen did not play an important role in the conditions of N<sub>2</sub>O decomposition on the dry as well as on the wet surfaces. The results indicate that the oxygen recombination/desorption is the rate-determining step of N<sub>2</sub>O decomposition which is discussed in detail in chapter 5.

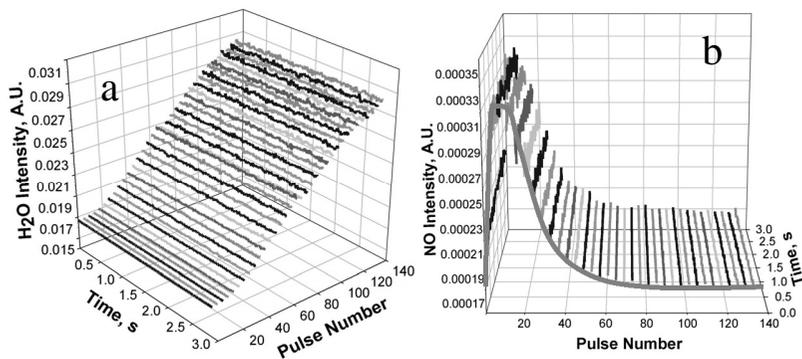

However, the O<sub>2</sub> response shift to lower times on the wet surface points out a larger rate constant of the oxygen recombination/desorption in the presence of water. The latter is in line with the observed water assisted oxygen desorption taking place at temperatures as low as 523 K and 593 K (section 8.2) contrary to normal oxygen desorption, which was not observed below 600 K in TAP experiments.

**Figure 8.7:** Height-Normalized oxygen and argon responses obtained during introduction of the O<sub>2</sub>/Ar mixture on the dry and wet Fe-ZSM-5<sub>500</sub> catalyst at 803 K.

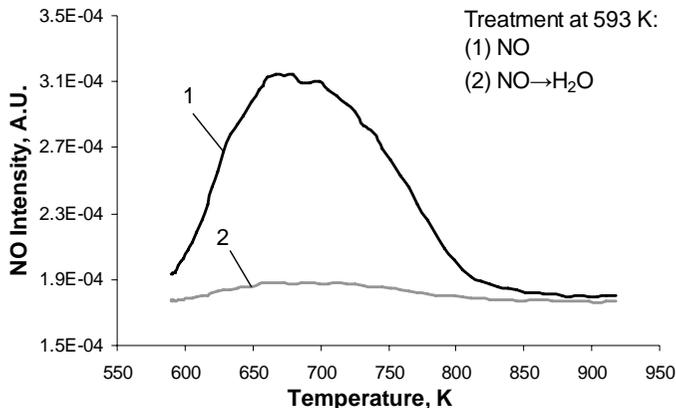

#### 8.4. H<sub>2</sub>O Assisted NO Desorption

The effect of water on adsorbed NO was investigated with the TAP setup at 593 K. NO adsorbs strongly on Fe(II) and is, therefore, frequently used as a probe molecule. Depending on the coordinative unsaturation of the Fe(II) sites NO can adsorb as mono-, di- and trinitrosyl [14, 15]. The Fe-ZSM-5<sub>500</sub> was loaded with NO by 600 NO pulses. Consequent water pulses provoked the desorption of NO as seen in Figure 8.8.

**Figure 8.8:** Water pulses (a) provoke NO desorption (b) from the NO containing Fe-ZSM-5<sub>500</sub> catalyst at 593 K. Grey line: guide for eyes.

H<sub>2</sub>O desorbed in a very broad peak and accumulated on the catalyst over 140 pulses. NO desorbed as well in a very broad peak during the first 40 water pulses. This observation points out the preference of the H<sub>2</sub>O molecules for certain sites which were occupied by NO<sub>ads</sub>. NO TPD profiles before and after water interaction with the NO containing Fe-ZSM-5<sub>5500</sub> are compared in Figure 8.9. Evidently, the main part of NO<sub>ads</sub> was desorbed during water pulsing.

**Figure 8.9:** NO TPD profiles after introducing 600 NO pulses (1) and 600 NO pulses followed by 140 H<sub>2</sub>O pulses (2) over the Fe-ZSM-5<sub>5500</sub> catalyst at 593 K.

The affinity of H<sub>2</sub>O and NO to the Fe-ZSM-5 was further investigated by pulsing NO over the wet Fe-ZSM-5<sub>5500</sub> at 593 K. Figure 8.10 illustrates the NO pulses responses. Clearly, NO passed the TAP-reactor within 3 s when the catalyst was saturated with water. NO pulses over the dry zeolite (not shown) were much broader and need more than 10 s to traverse the reactor. The large mean residence time of NO was the result of reversible ad- and desorption processes with the catalyst. The reduced mean residence time of NO with the wet Fe-ZSM-5 indicated less interaction of NO with the catalyst. A possible explanation is that water blocked sites which participate in dry conditions in NO adsorption. In accordance with the reduced NO affinity to the wet catalyst are IR spectroscopy data from Pirngruber et al. [16]. They concluded that de-hydroxylation of Fe-ZSM-5 prepared by CVD created vacancies in the coordination sphere of iron that allowed the adsorption of two or even three molecules of NO on one site.

It can be concluded that there was competitive adsorption of H<sub>2</sub>O and NO on the same sites while water had a stronger affinity to the Fe-ZSM-5 than NO. H<sub>2</sub>O provoked the desorption of NO<sub>ads</sub> and occupied different sites. NO interacted only weakly with the wet catalyst since sites for NO adsorption were already saturated by water.

NO<sub>x,ads</sub> species formed by N<sub>2</sub>O interaction with the catalyst at atmospheric pressure were not desorbed by water as described in section 8.2, Figure 8.6. Thus, water desorbed NO<sub>ads</sub> but not NO<sub>x,ads</sub> species showing the strong bonding of the NO<sub>x,ads</sub> species to the catalyst.

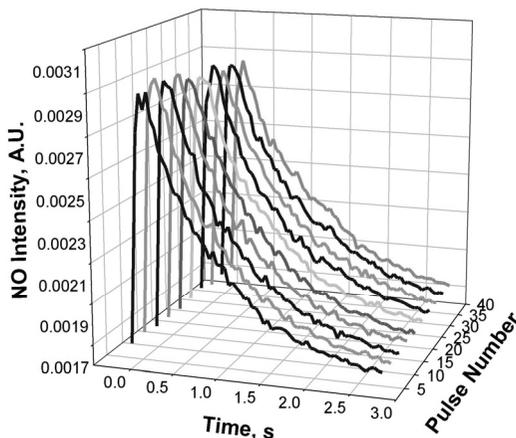

Figure 8.10: NO pulses over the water containing Fe-ZSM-5<sub>5500</sub> catalyst at 593 K.

## 8.5. Summary

Adsorbed water strongly influenced the N<sub>2</sub>O decomposition inhibiting it completely at least at temperatures  $\leq 673$  K. The latter occurred because the oxygen recombination/desorption, considered as the rate-determining step of N<sub>2</sub>O decomposition, did not take place from the water saturated surface rendering the zeolite catalyst inactive toward N<sub>2</sub>O decomposition [1]. During TAP experiments only small amounts of water were dosed and the water desorption was facilitated due to vacuum conditions. Therefore, the recovery of the initial catalyst activity at 703 K was observed 2 h after water treatment. The effect of water at this temperature can be considered reversible.

The observed partial desorption of the loaded (O)<sub>Fe</sub> as O<sub>2</sub> at 523-593 K induced by water adsorption, indicated its competition with water for the same adsorption sites. During N<sub>2</sub>O/H<sub>2</sub>O pump probe experiments at 803 K oxygen desorbed significantly faster with increasing water amount on the catalyst suggesting as well the water assisted O<sub>2</sub> desorption. At the same time, the catalyst activity decreased to about the half of the initial N<sub>2</sub>O conversion over the dry zeolite.

At 523 and 593 K only a part of oxygen loaded from N<sub>2</sub>O was desorbed from the catalyst by water. The residual adsorbed oxygen desorbed during TPD experiments with

the TAP setup at 849 K instead of 715 K for oxygen loaded from N<sub>2</sub>O on the dry catalyst. However, the most important is that the oxygen on the wet catalyst can not oxidize CO to CO<sub>2</sub>. It means that the active sites were transformed into an inactive form in the presence of water. The oxygen which stayed on the catalyst seemed to participate in the Fe(II) oxidation to the hydroxylated Fe(III) species, as proposed in a simplified scheme reported in [13]. These Fe(III) species were inactive in N<sub>2</sub>O decomposition and could be activated again by high-temperature treatment in He or in vacuum.

Other reaction steps were also influenced by water adsorption. Reversibly adsorbed N<sub>2</sub>O at atmospheric pressure desorbed upon H<sub>2</sub>O interaction. NO<sub>x,ads</sub> species formed during N<sub>2</sub>O interaction at 523 K remained on the catalyst while NO<sub>ads</sub> desorbed during water treatment. Water adsorbed strongly on several sites of the zeolite and was able to provoke the desorption of reversibly adsorbed N<sub>2</sub>O, NO<sub>ads</sub> and a part of (O)<sub>Fe</sub>.

NO showed much weaker interaction with the wet catalyst than with the dry one at 593 K. This is understood as NO can adsorb among others on Fe(II) sites, which become highly coordinative saturated by adsorbed water.

Good agreement was found between the TAP reactor data obtained at vacuum conditions and steady-state data at atmospheric pressure. The results on water assisted O<sub>2</sub> desorption and catalyst deactivation by water were published by us [17].

# Chapter 9

## CONCLUSIONS AND PERSPECTIVES

### 9.1. Conclusions

Mechanistic aspects of the  $\text{N}_2\text{O}$  decomposition to  $\text{N}_2$  and  $\text{O}_2$  over Fe-ZSM-5 containing small amounts of active iron were studied with transient pulse experiments in vacuum and transient flow experiments at atmospheric pressure. Both approaches showed that the mechanism strongly depends on the reaction temperature, but in all cases the reaction proceeds via atomic surface oxygen loading and gaseous  $\text{N}_2$  formation from  $\text{N}_2\text{O}$  as a first step. A complete saturation of the active sites can be attained by  $\text{N}_2\text{O}$  exposure at low temperatures ( $T < 600$  K in vacuum,  $T < 523$  K at atmospheric pressure) where oxygen is stored and does not desorb. On that basis, the concentration of sites active in surface atomic oxygen loading from  $\text{N}_2\text{O}$  were determined in pulse experiments using the TAP setup. The concentration of active sites was found to be the same as in a flow experiment with the Micromeritics analyzer.

The mechanism of surface atomic oxygen recombination and desorption as  $\text{O}_2$  depends on the temperature. At high temperature ( $T > 773$  K) the atomic surface oxygen recombines probably directly and desorbs as  $\text{O}_2$ . The oxygen recombination/desorption was found to be delayed to  $\text{N}_2\text{O}$  decomposition and  $\text{N}_2$  evolution at 803 K which

indicates that oxygen formation is the rate-determining step. A curve fit of the oxygen desorption response resulted in a first order dependence of the oxygen desorption rate on the oxygen surface coverage.

In the range of 523 to 773 K, the  $O_2$  formation is facilitated by NO. The formation of  $NO_{x,ads}$  species was observed during the interaction of  $N_2O$  with the zeolite at 593 K. The temperature of maximum desorption rate of oxygen in TPD experiments decreases with increasing amount of  $NO_{x,ads}$  species. The effect is enhanced by pre-adsorbed NO on the catalyst. Adsorbed  $NO_x$  acts as co-catalyst and facilitates the desorption of oxygen which is in general accepted as the rate-determining step of the  $N_2O$  decomposition.

$NO$  pulses over the catalyst containing atomic surface oxygen provoke the recombination and desorption of atomic surface oxygen at low temperatures (523 K and 593 K) where the desorption of  $O_2$  is not observed during  $N_2O$  interaction with the Fe-ZSM-5<sub>5500</sub>.  $NO$  adsorbs in large amounts at the same time on the catalyst on adjacent sites to the  $N_2O$  decomposing sites since the reloading of oxygen from  $N_2O$  takes place without any difficulty.

$N_2O/NO$  pump-probe experiments at 661 K demonstrated an accelerated oxygen desorption at the time of the  $N_2O$  pulse due to adsorbed  $NO/NO_x$  species. The subsequent  $NO$  pulse accelerate the desorption of the residual surface oxygen at 661 K and 803 K. Adsorbed  $NO$  accommodates oxygen from  $N_2O$  forming higher oxidized nitrogen oxide species which decompose back to  $NO_{ads}$  and molecular oxygen. Thus, the recombination of surface oxygen loaded from  $N_2O$  is accelerated by a  $NO/NO_x$  redox cycle.

In general,  $NO_2$  is considered as intermediate of the catalytic cycle of  $N_2O$  decomposition and functions as intermediate oxygen storage. At temperatures above 600 K the interconversion of  $NO_2 \leftrightarrow NO$  takes place whereas at lower temperature  $NO_2$  compared to  $NO$  shows a different effect on the oxygen loading from  $N_2O$ .

The interaction of gaseous  $NO_2$  with Fe-ZSM-5 at 523 K in vacuum and at atmospheric pressure showed the formation of two different  $NO_x$  surface species accompanied by the evolution of gaseous  $NO$ . In general, oxygen loaded from  $N_2O$  on the surface saturated with  $NO_{x,ads}$  species is not reactive with respect to  $CO$  oxidation to  $CO_2$ . Therefore, the formation of  $\alpha$ -oxygen from  $NO_2$  could not be evidenced with  $CO$  oxidation since a large amount of  $NO_{x,ads}$  species is present on the catalyst surface after  $NO_2$  treatment.

$NO_2$  pre-treatments inhibit the loading of oxygen from  $N_2O$  in transient response experiments.  $NO_2$  blocks the sites for oxygen loading from  $N_2O$  but the amount of reversible adsorbed  $N_2O$  stays constant compared to the standard pre-treated catalyst. Unlike the surface species formed upon  $NO_2$  treatment, adsorbed  $NO$  doesn't prevent the surface oxygen loading from  $N_2O$  at 523 K.

$NO_2$  interaction with  $(O)_{Fe}$  containing catalyst leads to the formation of  $NO_{2,ads}, NO_{3,ads}$  species as upon  $NO_2$  interaction only. The oxygen deposited by  $N_2O$  pre-

treatment is consumed for the formation of  $\text{NO}_{\text{s,ads}}$  species in experiments at atmospheric pressure.

Adsorbed water strongly influences the  $\text{N}_2\text{O}$  decomposition inhibiting it completely at least at temperatures  $\leq 673$  K. During TAP experiments only small amounts of water were dosed and the water desorption is facilitated due to vacuum conditions. Therefore, the recovery of the initial catalyst activity at 703 K was observed 2 h after water treatment. The effect of water at this temperature is considered reversible.

The observed partial desorption of the loaded atomic surface oxygen as  $\text{O}_2$  at 523 and 593 K induced by water adsorption, indicates the competition of water for the same adsorption sites. During  $\text{N}_2\text{O}/\text{H}_2\text{O}$  pump-probe experiments at 803 K oxygen desorbs significantly faster with increasing water amount on the catalyst suggesting as well the water assisted  $\text{O}_2$  desorption. At the same time, the catalyst activity decreases to about the half of the initial activity of the dry zeolite.

At 523 and 593 K only a part of oxygen loaded from  $\text{N}_2\text{O}$  is desorbed from the catalyst by water. The residual adsorbed oxygen desorbs during TPD experiments with the TAP setup at 849 K instead of 715 K for oxygen loaded from  $\text{N}_2\text{O}$  on the dry catalyst. However, the most important is that the oxygen on the wet catalyst can not oxidize CO to  $\text{CO}_2$ . It means that the active sites are transformed into an inactive form in the presence of water. The oxygen which stays on the catalyst seems to participate in the Fe(II) oxidation to the hydroxylated Fe(III) species. These Fe(III) species are inactive in  $\text{N}_2\text{O}$  decomposition and could be activated again by high temperature treatment in He or in vacuum.

Very good agreement was found between the TAP reactor data obtained under vacuum and results obtained by transient flow experiments at atmospheric pressure. It follows that the mechanism of the  $\text{N}_2\text{O}$  decomposition over Fe-containing ZSM-5 depends strongly on the reaction temperature as well as on the presence of other gases such as NO,  $\text{H}_2\text{O}$  and  $\text{NO}_2$ .

## 9.2. Perspectives

It would be interesting to further investigate the interaction of  $\text{NO}_2$  with the Fe-ZSM-5 using the TAP setup in particular whether atomic surface oxygen can be generated from  $\text{NO}_2$  such as from  $\text{N}_2\text{O}$ .  $\text{NO}_2$  interacts with the catalyst via NO evolution and oxygen loading. Since a large amount of  $\text{NO}_{2,\text{ads}}$ / $\text{NO}_{3,\text{ads}}$  species is also formed on the catalyst, the loaded oxygen could not be tested for its reactivity in CO oxidation to  $\text{CO}_2$ . Active surface oxygen from  $\text{N}_2\text{O}$  was shown to be inactive with respect to CO oxidation in the presence of  $\text{NO}_{\text{s,ads}}$  species. The dosing of small amounts of  $\text{NO}_2$  with the TAP setup could separate the formation of active surface oxygen and of

$\text{NO}_{\text{s,ads}}$  species. This could give useful information on the fate of the deposited oxygen from  $\text{NO}_2$ .

The study of another iron containing zeolite, for example BEA framework, would be beneficial to get more information on the influence of the host matrix on the catalyst properties. A comparison with the MFI-type zeolite could reveal further mechanistic aspects, in particular concerning the desorption of oxygen and the effect of  $\text{NO}$ ,  $\text{NO}_2$  and  $\text{H}_2\text{O}$  on the  $\text{N}_2\text{O}$  decomposition.

# CURRICULUM VITAE

## EDUCATION

2002-2007

### **PhD in Chemical Engineering**

- Swiss Federal Institute of Technology Lausanne (EPFL), Switzerland, Laboratory of Chemical Reaction Engineering
- "Study of N<sub>2</sub>O Decomposition over Fe-ZSM-5 with Transient Methods"

2000-2002

### **Master of Science in Chemical Engineering, with distinction**

- University of Erlangen-Nuremberg, Germany
- Diploma thesis: "Entwicklung einer Druck- und Kleinstvolumenstrom-Regelung für in situ DRIFTS im pressure gap"

1996-2000

### **Engineering Diploma in Technical Chemistry, with distinction**

- University of Applied Sciences Nuremberg, Germany
- Diploma thesis: "Neuartiges Nanoliter-Injektionssystem auf Piezo-Mikromanipulator-Basis für die Kapillarelektrophorese"
- Awards from Bavarian Ministry of Science and Max Buchner Foundation for excellent diploma thesis

## PROFESSIONAL EXPERIENCE

2002-2007

### **Assistant/Researcher at the EPFL, Lausanne, Switzerland**

- Supervised one master and two semester theses
- Assisted the course: Advanced Chemical Reaction Engineering
- Coached practical laboratory work in Chemical Engineering

1999

### **6-month internship at Degussa-Hüls AG, Theodore, AL, USA**

- Acquired and evaluated production process data
- Performed laboratory experiments for plant start-up
- Developed analytical procedures
