ABSTRACT

We study the market partition between two distinct firms that deliver services to waiting-time sensitive customers. In our model, the incoming customers select a firm on the basis of its posted price, the expected waiting time and its brand. More specifically, we quantify by a cost any departure from the ideal brand expected by each incoming customer. Considering that the two underlying queueing processes operate under high traffic regimes, we analyze the market sharing dynamics by using a diffusion process. As a function of control parameters, such as the waiting and brand departure costs or the incoming traffic intensity, we are able to analytically characterize a transition between an Hotelling-like regime (dominated by brand considerations) and a deadline type regime (dominated by waiting time considerations). The market sharing dynamics is described by the time evolution of a boundary point, which time evolution belongs to the class of noise-induced phase transitions, so far widely discussed in physics, chemistry and biology.

Keywords: Stochastic Processes, Linear City Game Model, Heavy Traffic Queueing Dynamics, Multiplicative Noise, Noise-Induced Phase Transition.

1. Introduction

In his original contribution [7], H. Hotelling did consider the case where two vendors supply an identical product that is perceived homogenous by incoming customers. However, the vendors being separated in geographical space, transportation costs to be added to the mill prices charged by the vendors are generated. In presence of two vendors, it exists an inner market boundary point, for which the mill price plus the transportation costs from both suppliers break even. This seminal modeling framework, often referred as linear city game, has stimulated a wealth of contributions with the goal to relax some of the oversimplifying hypothesis of the original model. In particular, the introduction of elastic demands (i.e. customers are not prepared to pay prohibitive prices) for the product has been discussed in [10]. Note that the original Hotelling’s model is basically deterministic - it indeed does not incorporate random perturbations which actually may corrupt the prices and then affect the customers’ decision process. Among the numerous potential noise sources, one of the simplest and most natural way to incorporate randomness is to consider the situations where the customers’ decision to select one of the vendors depends on the expected time delay before service. This simple and realistic situation has been recently proposed by G. Cachon and P. Harker in [2, 3]. As these authors clearly emphasized in [2], the resulting inherent analytical complexity implies that rather seldom are the models dealing with firms that simultaneously compete with both prices and processing rates. The aim of this note is to investigate a class of simple models for which explicitly analytical considerations can partly be worked out. While in [2] the firms are assumed to adjust their processing rates to guarantee a fixed expected time cost, our class of models takes into account the fluctuations of the waiting times and therefore keeps full track of the randomness induced by the underlying queueing processes. Note that the adjusting processing rates assumption proposed in [2] allows a discussion based only on averages. Contrary to [2], where no variance effects enter into the description of the model (i.e. this is effectively a “pseudo-stochastic” model), our approach explicitly emphasizes the role played by the fluctuations variance - also called in the sequel the “volatility” of the underlying noise sources. As discussed in [5], the introduction of waiting costs in the queueing dynamics leads to the concept of externalities (i.e. the costs induced on later incomers by a customer who is just joining the queue). In the class of models to be discussed here, these externalities trigger the random dynamics controlling the boundary point which defines the market partition. While, for Hotelling-like models, the interest is paid directly on the competition between the servers (see for instance [1, 3, 10]), in the present study we exclusively focus on the market sharing dynamics.

Service models where distance and quality of service enter into consideration find, among others, a perfect practical framework in the secondary health care market. More precisely, let us consider patients who wait for non-urgent operations, that can be mid-term planned. As said in [9], where an application of the standard Hotelling model to the secondary health care market is proposed, patients may accept meeting monetary and non-monetary costs inherent to distance, if they expect a positive return in terms of enhanced quality of service. Furthermore, the quality of service perceived by the patients combines different aspects, including the time to wait for the operation to take place. Another situation will be met when car drivers who enter into a city centre are offered alternative choices between several parking lots (here we focus on two lots). It is nowadays common to post in real time, at the entrance of the city, the number of available parking spaces of each parking lot. The actual time required to complete a parking action, which here plays the role of the waiting time, is clearly monotonously decreasing with the number of available spaces of the parking lot. Hence, the selection of the best parking lot does not only depend on its location, but also on its current content.

In section 2, we show that, for heavy traffic regimes of the underlying queueing processes, the boundary point partitioning the market interval is governed by a scalar stochastic differential equation with multiplicative noise source. For this dynamics, it is possible to explicitly calculate the associated stationary probability measure. The multiplicative character of the noise source offers the possibility to observe a so-called noise-induced phase transition, which manifests itself by a change of the modal character of the stationary probability measure - in the
simplest case realized here, a transition from uni- to a bimodal probability density. In the present context, the transition between these two regimes relates to a transition between a regime where the Hotelling’s spatial (i.e. the brand) character dominates in the decision taken by the incoming customers and a regime where the time delays dominate. In section 3, we explicitly work out a simple, though fully representative, example from our class of models. For this particular choice of the dynamics, we are also able to fully calculate the relaxation rate (i.e. the transient regimes) characterizing the approach towards the final statistical equilibrium. The relaxation process is strongly dependent on the relative importance of the externalities arising in the associated queueing processes. Finally, a short account devoted to simulation experiments explicitly comforts our analytical findings.

2. Model

As in [2], our starting point will be a two servers Hotelling model where two service providers $S_1$ and $S_2$ are located in a (linear) market confined on a segment $\Omega := [-\Delta, +\Delta] \subset \mathbb{R}$, $\Delta > 0$. The positions of the service providers are respectively denoted by $-\Delta \leq x_1 \leq 0$ and $0 \leq x_2 \leq +\Delta$ and, to simplify the presentation (an extension to asymmetric cases is proposed in [4]), are assumed to be symmetric with respect to the center of the market, i.e. $x_1 = -x_2$ and $L = 2x_2$ denotes the distance between $S_1$ and $S_2$. The servers $S_1$ and $S_2$ offer homogenous services and both charge an equal price $p$. Departing now from the original Hotelling’s model, we add queueing processes in front of $S_1$ and $S_2$ and following [5], we will attach waiting costs to any customer lining in the queues before being served. Taking into account waiting costs thus confers a dynamical character to the original Hotelling’s model. Specifically, our dynamic model exhibits the following features and obeys to the following rules:

a) Arrivals dynamics. Incoming customers follow a Poisson rule with rate $\Lambda$, hence the average time between two arrivals will be $\Lambda^{-1}$.

b) Spatial distribution of the arrivals. Incoming customers arrive at a random location $x \in \Omega$ drawn from a uniform probability density $U(\Omega)$ with support on $\Omega$.

c) Services dynamics. Both servers $S_i$, $i = 1, 2$, have generally distributed service times with rate $\mu_i$, hence the average service time will be $\mu_i^{-1}$, $i = 1, 2$.

d) Traffic intensity. The traffic into the system is limited to $\rho := \frac{\Lambda}{\mu_1 + \mu_2} < 1$. This ensures that the system is globally stable, i.e. the global incoming rate is less than the global service rate. In the sequel, we shall assume that both servers share a common rate $\mu = \mu_1 = \mu_2$.

e) Queueing processes. When an incoming customer finds both $S_1$ and $S_2$ busy, he/she will wait for service and line up in a queue. The capacity of the queue is assumed to be unlimited and the service discipline is first-in-first-out (FIFO). In view of points a) and c), we hence consider M/G/1 queues.

f) Customer information gathering. Upon his/her arrival at $x \in \Omega$, each incoming customer knows:

1) his/her relative distance $|x - x_1|$ and $|x - x_2|$ to $S_1$ and $S_2$.

2) the contents $N_i(t)$ and $N_2(t)$ of both queues ($t \in \mathbb{R}^+$ being the arrival time). In other words, both queue contents are observable to any incoming customer.

g) Cost structures. There are two types of costs incurred by any customer, namely:

1) the waiting time cost (WTC), characterized by a cost parameter $c_w$ with physical unit $[\text{dollar} / \text{time unit}]$.

2) the brand departure cost (BDC), quantified by a cost parameter $c_b$ with physical unit $[\text{dollar} / \text{brand distance unit}]$.

h) Decision policy. Upon arrival and based on information regarding:

1) the observed queue lengths $N_1(t)$ and $N_2(t)$,

2) his/her relative position to $S_1$ and $S_2$,

3) the values of the costs $c_w$ and $c_b$,

any incoming customer decides which server $S_1$ or $S_2$ he/she will join.

1) The observed queue lengths $N_1(t)$ and $N_2(t)$,

2) his/her relative position to $S_1$ and $S_2$,

3) the values of the costs $c_w$ and $c_b$,

Different from the original Hotelling’s idea, waiting times confer to the above class of models an explicit dynamic character.

When served by $S_i$, an incoming customer feels a utility function $U_i(x)$, $i = 1, 2$ and $x$ is the customer’s initial position which enters into the decision policy. In words, the functions $U_i(x)$ quantify the gain realized by a customer choosing server $S_i$ when its entering location is $x$. Specifically, for linear waiting and transportation costs, the utility functions read as:

$$U_i(x) = a - p - c_t |x - x_i| - c_w \mathbb{E}(W_i|N_i(t))$$

with $a$ being a systematic reward due to the service and $\mathbb{E}(W_i|N_i(t))$ standing for the conditional expected waiting time at $S_i$ when $N_i(t)$ already waiting customers are observed. As $\mu^{-1}$ is the average service time, this last conditional expectation is readily given by:

$$\mathbb{E}(W_i|N_i(t)) = \frac{N_i(t)}{\mu}.$$
suggests to introduce a time-dependent boundary position $Y_t \in [-\Delta, +\Delta]$ to be a separation point implicitly defined by:

$$U_1(Y_t) = U_2(Y_t).$$

Hence, our strictly increasing (BDC) costs which we assume from now on imply that $Y_t$ dynamically separates the two monopolies held by $S_1$ and $S_2$. A sketch of the situation is given in Fig. 2. As $Y_t$ is a function of the two stochastic processes $N_1(t)$ and $N_2(t)$, it will be itself a stochastic process.

Let $\lambda_i(t, Y_t)$ denotes the partial incoming rate of customers feeding $S_i$ at time $t$ and hence:

$$\lambda_1(t, Y_t) + \lambda_2(t, Y_t) = \Lambda, \quad \forall t \in \mathbb{R}^+.$$  

(3)

In view of the assumption b) (i.e. spatially uniform arrival on $\Omega = [-\Delta, +\Delta]$), the partial traffic flows feeding $S_1$ and $S_2$ result from the Bernoulli “thinning” of the incoming Poisson flow with global rate $\Lambda$. The branching probability is given by $P = \frac{\Delta + Y_t}{2\Delta}$ and it is well known that the thinning produces two independent Poisson processes with partial rates:

$$\lambda_1(t, Y_t) = \frac{\Delta + Y_t}{2\Delta} \Lambda \quad \text{and} \quad \lambda_2(t, Y_t) = \frac{\Delta - Y_t}{2\Delta} \Lambda.$$  

(4)

Let $A_i(t)$, $D_i(t)$ and $N_i(t)$ respectively denote the numbers of arrivals, departures and the population in $S_i$ at time $t$. From now on, we restrict ourselves to heavy traffic regimes characterized by $\rho = \frac{\lambda}{\mu} = 1 - \epsilon$, with $\epsilon$ small. Writing

$$N_i(t) = A_i(t) - D_i(t),$$

in heavy traffic the server $S_i$ has very long busy period and hence the process $N_i(t)$ does almost never vanish, $i = 1, 2$. This implies that the departure and arrival processes are almost independent. In heavy traffic regimes, it is well established (see in particular [8]) that both queue contents at time $t$ are well approximated by diffusion processes of the form ($i = 1, 2$):

$$N_i(t) = \int_0^t [\lambda_i(s, Y_s) - \mu] ds + \int_0^t V_i(s, Y_s) dB_{i,s}$$

(5)

where $B_{1,t}$ and $B_{2,t}$ are independent standard Brownian motions and the terms $V_i(t, Y_t)$ denote the state-dependent "volatilities" given by:

$$V_i(t, Y_t)^2 = \lambda_i(t, Y_t)^3 \sigma_{a,i}^2 + \mu^3 \sigma_{s,i}^2 \quad i = 1, 2,$$  

(6)

with $\sigma_{a,i}^2$ (resp. $\sigma_{s,i}^2$) being the variance of the inter-arrival times (resp. the variance of the service times) for server $S_i$. Using Eqs.(3) to (6) and the fact that $B_{1,t}$ and $B_{2,t}$ are independent, we therefore can write:

$$N_2(t) - N_1(t) = -\frac{\Lambda}{\Delta} \int_0^t Y_s ds + \int_0^t V(s, Y_s) dB_{s},$$

(7)

with $B_t$ being a standard Brownian motion and $V^2(t, Y_t) = V_1(t, Y_t)^2 + V_2(t, Y_t)^2 = \Lambda + \mu^3 (\sigma_{a,1}^2 + \sigma_{s,2}^2)$. Remember that for Poisson processes, we have $\sigma_{a,i}^2 = \lambda_i(t, Y_t)^{-2}$.

When the utility functions are given by Eq.(1), the time-dependent boundary point will obey, $\forall t \in \mathbb{R}^+$:

$$Y_t = \begin{cases} \frac{w_1}{2\rho} D_{2,1}(t) & \text{if} \ c_tL \geq \frac{\rho}{\Lambda} |D_{2,1}(t)| \\ -\Delta & \text{if} \ c_tL < \frac{\rho}{\Lambda} |D_{2,1}(t)| \end{cases}$$

(8)

where $D_{2,1}(t) = N_2(t) - N_1(t)$. Note that when $c_tL \geq \frac{\rho}{\Lambda} |(N_2(t) - N_1(t))|$, then $Y_t \in [x_1, x_2] \subset [-\Delta, +\Delta]$. Indeed in this case, the brand departure cost from one server to the other (i.e. $c_tL$) is greater than the difference between the waiting time costs of the two servers (i.e. $\frac{\rho}{\Lambda} |(N_2(t) - N_1(t))|$). Hence, a customer located near the server having the longest queue will choose this server anyway. When $c_tL < \frac{\rho}{\Lambda} |(N_2(t) - N_1(t))|$, then any customer in the whole interval $[-\Delta, +\Delta]$ will join the server having the shortest queue. Indeed, the difference between the content of the queues is such that the relative gain in waiting time cost is greater than the brand departure cost from one server to the other. A representation of the dynamics induced by Eq.(8) for a particular choice of the control parameters is found in Fig. 3.
an odd (due to the symmetry of the problem), effective monotonously increasing one-to-one, $C^2(\mathbb{R})$ function:

$$f(\cdot) : \mathbb{R} \rightarrow [-1, +1]$$

fulfilling:

$$Y_t = \Delta f (\gamma (N_2(t) - N_1(t)))$$

with:

$$\gamma := \frac{c_{uw}}{\mu L e_t}$$

being a non-dimensional parameter quantifying the respective importance of the different costs. Note that in Eq.(11), the time unit is measured in average service time. While we restrict here our study to symmetric configurations, the derived methodology is extended in [4] to non-symmetric cases, that might arise when we consider:

1) asymmetric positions ($x_1 \neq -x_2$) and/or
2) different service rates ($\mu_1 \neq \mu_2$) and/or
3) unequal posted prices ($p_1 \neq p_2$).

Indeed, it is shown in [4] that the range of functions

$$f(x) = \sqrt{\frac{\beta}{\alpha}} \left( \frac{K e^{\sqrt{-\alpha^2 x}} - e^{-\sqrt{-\alpha^2 x}}}{K e^{\sqrt{-\alpha^2 x}} + e^{-\sqrt{-\alpha^2 x}}} \right)$$

can be considered in the present model ($\alpha < 0$, $\beta \geq 0$, $-\frac{\beta}{\alpha} \leq 1$ and $K > 0$) and that these functions are perfectly suitable for treating any possible non-symmetric configuration.

As $f$ is invertible, Eq.(10) can be written as:

$$f^{-1} \left( \frac{Y_t}{\Delta} \right) = \gamma (N_2(t) - N_1(t)).$$

Using Eq.(7), Eq.(12) becomes:

$$f^{-1} \left( \frac{Y_t}{\Delta} \right) = -\frac{\gamma \Lambda}{\Delta} \int_0^t Y_s ds + \gamma \int_0^t V(s, Y_s) dB_s.$$  

Differentiating, we obtain:

$$(f^{-1})' \left( \frac{Y_t}{\Delta} \right) dY_t = -\gamma \Lambda Y_t dt + \Delta \gamma V(t, Y_t) dB_t,$$

which can be written as:

$$dY_t = -\frac{\gamma \Lambda Y_t}{(f^{-1})' \left( \frac{Y_t}{\Delta} \right)} dt + \frac{\Delta \gamma V(t, Y_t)}{(f^{-1})' \left( \frac{Y_t}{\Delta} \right)} dB_t.$$  

In our settings (remember that we deal with M/G/1 queues),

$$V(t, Y_t) = \sqrt{\Lambda + \mu^2 (\sigma_{11}^2 + \sigma_{22}^2)}$$

does not depend on $Y_t$ nor on $t$. We can thus write Eq.(15) as:

$$dY_t = -\frac{\gamma \Lambda Y_t}{(f^{-1})' \left( \frac{Y_t}{\Delta} \right)} dt + \frac{\Delta \gamma V}{(f^{-1})' \left( \frac{Y_t}{\Delta} \right)} dB_t.$$  

The stochastic differential equation (SDE) given by Eq.(16) describes the effective dynamics of the boundary position $Y_t$. The White Gaussian noise $dB_t$ being merely the limit of finitely correlated processes, we assign to the underlying stochastic integral relative to Eq.(16) the Stratonovitch’s interpretation. Hence, the transition probability density $P(y, t \mid y_0, t_0)$ describing the solution of the SDE (16) reads as:

$$\frac{\partial}{\partial t} P(y, t \mid y_0, t_0) = \mathcal{F} P(y, t \mid y_0, t_0),$$

with Fokker-Planck operator taking here the form, [6]:

$$\mathcal{F}(\cdot) := \frac{\partial}{\partial y} \left[ \frac{\gamma \Lambda y}{(f^{-1})' \left( \frac{y}{\Delta} \right)} \right] + \frac{1}{2} \frac{\partial^2}{\partial y^2} \left[ g(y) \frac{\partial}{\partial y} g(y) \right],$$

where

$$g(y) = \frac{\Delta \gamma V}{(f^{-1})' \left( \frac{y}{\Delta} \right)}.$$  

The stationary probability density function $P_s(y)$ solving Eq.(17), with vanishing left hand side, reads as:

$$P_s(y) = \mathcal{N} \left( f^{-1}(y) \right) \exp \left\{ -\frac{2 \Lambda}{\Delta^2 V^2} \int_0^y u (f^{-1}(u) - f(0)) du \right\},$$

for $y \in [-\Delta, +\Delta]$, with $\mathcal{N} < \infty$ a normalization constant.

Our assumptions of identical prices and identical dynamic of the servers imply an even parity of the stationary measure (i.e. $P_s(y) = P_s(-y)$). In particular, studying the curvature $\mathcal{R}(0)$ of $P_s(y)$ at $y = 0$ directly furnishes information regarding the modularity of $P_s(y)$. From Eq.(18), we directly obtain:

$$\text{sign} \{ \mathcal{R}(0) \} = \text{sign} \left\{ -\gamma V^2 f''(0) - 2 \Lambda (f^{-1})'(0) (f'(0))^3 \right\}.$$

For given functions $f$, we observe that the sign of the curvature $\mathcal{R}(0)$ directly depends on the values of the (control) external parameters (here $c_{uw}, e_t, \Lambda, \Lambda$ and $\mu$) of our class of models. This clearly shows the possibility to observe noise-induced phase transitions and an explicit illustration is worked out in section 3 to follow.

### 3. Explicit Illustration

Belonging to the previous class of models, the particular choice

$$Y_t = \Delta \tanh \left( \gamma (N_2(t) - N_1(t)) \right)$$

leads to very simple algebra. A particular representation of Eq.(20), put into comparison with the dynamics induced by Eq.(8), is found in Fig. 3.

For this particular case, the SDE (16), describing the effective boundary point dynamics, becomes:

$$dY_t = -\gamma \Lambda Y_t \left( 1 - \left( \frac{Y_t}{\Delta} \right)^2 \right) dt + \Delta \gamma V \left( 1 - \left( \frac{Y_t}{\Delta} \right)^2 \right) dB_t.$$  

In view of Eq.(18), the corresponding stationary probability density function simply becomes:

$$P_s(y) = \mathcal{N} \left( 1 - \left( \frac{y}{\Delta} \right)^2 \right)^{\frac{1}{2\gamma^2 \pi}}$$

for $y \in [-\Delta, +\Delta]$, where $\mathcal{N}$ is the normalization constant given here by:

$$\mathcal{N}^{-1} = \Delta \int_0^1 t^{-\frac{1}{2}} \left( 1 - t \right)^{\frac{1}{2\gamma^2 \pi}} dt = \Delta B \left( \frac{1}{2}, \frac{\Lambda}{\gamma V^2} \right),$$
For the choice given in Eq. (20), we can also study the rate of approach to the equilibrium. Indeed, by introducing the change of variables:

\[ t \mapsto \tau = \gamma^2 V^2 t, \quad X_t \mapsto Y_t = \Delta \tanh(X_t), \]

the dynamics given by Eq. (20) reduces to:

\[ dX_t = -\frac{\Lambda}{\gamma V^2} \tanh(X_t) + dW_t = -2K \tanh(X_t) + dW_t. \]  

and the time-dependent solution \( P(x, t \mid x_0, 0) \) of the associated Fokker-Planck is known for long (see for instance [11]). As an illustration, let us mention that for the situations where the dimensionless parameter \( K := \frac{\gamma^2 V^2}{2\Delta} \in \mathbb{N} \), the explicit form simplifies somewhat and is given by [11]:

\[
P(x, t \mid x_0, 0) = \frac{1}{1 + z^2} \cdot \left[ 1 + z^2 \right]^{K/2} e^{-K^2 \tau} e^{-\frac{(x-x_0)^2}{\tau}} + \frac{1}{\pi(1 + z^2)} \sum_{n=0}^{K-1} \frac{(K-n)}{n!} (2K + 1 - n) e^{-n(2K-n)^2 \theta_n(x_0) \theta_n(x)} f_n(x, x_0, t),
\]

with the definitions:

\[
\sinh(z) := x,
\]

\[
f_n(x, x_0, t) := \frac{1}{\sqrt{\pi}} \int_{-(K-n)\sqrt{\tau}}^{(K-n)\sqrt{\tau}} e^{-z^2} dz
\]

and the polynomials:

\[
\theta_n(x) := (-1)^n 2^{-n} \Gamma(K - n + \frac{1}{2}),
\]

\[
\cdot (1 + x^2) K^\frac{1}{2} \frac{d^n}{d(1 + x^2)^n} (1 + x^2)^{-K - \frac{1}{2}}.
\]

In particular, the long time scale \( 1/t_{relax} \) governing the approach to the stationary state given by Eq. (22) is determined by the spectral gap between 0 and the first non vanishing eigenvalue of the Fokker-Planck equation (17) (remember that the vanishing eigenvalue corresponds to the stationary probability measure given by Eq. (18)). It follows that:

\[
1/t_{relax} = \begin{cases} 
2(K-1) \gamma^2 V^2 & \text{if } K \geq 1, \\
K^2 \gamma^2 V^2 & = \frac{\Lambda^2}{\Delta^2} & \text{if } K < 1.
\end{cases}
\]

From Eq. (27), we can draw the following remarks:

a) **Spectral characteristics of the Fokker-Planck equation.** In view of Eq. (27), there are two relaxation regimes governed by the spectral properties of the associated Fokker-Planck equation (17). As discussed in [11], for \( K \geq 1 \) the spectrum exhibits both discrete and continuum parts whereas for \( K < 1 \) only the continuum part survives.

b) **Regime transitions.** Note that the transition from unimodal to bimodal densities given in Eq. (22) by \( \left( \frac{\gamma V^2}{\Delta} - 1 \right) \gamma^2 V^2 = 0 \) coincides with the transition in the relaxation regimes given by Eq. (27).

c) **Rate of approach to the equilibrium.** When discrete eigenvalues exist, the asymptotic time relaxation towards the single mode stationary probability density (given by Eq. (22)) is faster compared to the relaxation rate associated with the purely continuum spectrum which drives the system to the bimodal density (given by Eq. (22)). This can be intuitively understood in limiting regimes. Indeed, note first that for the pure Hotelling case, the boundary position probability density is delta-peaked in the middle of the market interval, (remember that we did focus in this paper on fully symmetric configurations) and the relaxation time to reach this equilibrium is vanishingly small - this corresponds to the deterministic scheduling which commands to “join the closest server”. For dominating Hotelling’s type regimes, the **externalities** (i.e. the waiting costs affecting...
incomers arriving behind a customer entering into service) have little influence on the equilibrium probability density which describes the boundary point - this produces a fast relaxation towards the statistical equilibrium, which will be close to the limiting delta-peaked density. In the contrary, when the deadline type regime strongly dominates, a new incomer strongly modifies the dynamical state of the system and hence strongly perturbs the underlying probability measure, thus implying a long relaxation time to the statistical equilibrium. Note that for \( K = 0 \) in Eq.(27), a situation realized when \( c_t \to \infty \), the relaxation time diverges to infinity, meaning that no statistical equilibrium exists - this corresponds to the purely deterministic scheduling which commands to “join the server exhibiting the shortest queue”.

3.2. Simulation Experiments

We have simulated the dynamics of the boundary position \( Y_t \) in the particular case where \( Y_t \) fulfills Eq.(20). Simulations have been realized using the Enterprise Dynamics discrete events simulator. Each customer, upon arrival, determines on which side of the boundary point \( Y_t \) (dynamically given by Eq.(20), with regard to the current content of the queues) is his/her (un)derlying position and he/she joins the queue hence chosen. We have computed an estimation of the stationary probability density function of the boundary position \( Y_t \) after \( 10^5 \) customers have passed through the system. The simulation experiments performed for different values of the control parameters (here \( \gamma \), \( \Lambda \) and \( \mu \)) confirm the presence of the noise-induced phase transition given by the analytical model. The particular result of such a simulation, put into comparison with the analytical curve given by Eq.(22), can be seen in Fig. 5.

![Simulated and analytical stationary probability density function](image)

*Fig. 5: Simulated and theoretical stationary probability density function of the time-dependent boundary position \( Y_t = \Delta \cdot \tanh(\gamma (N_\Omega(t) - N_\Sigma(t))) \) when \( \Delta = 1, \Lambda = 1.9, \mu = 1 \) (\( \rho = 0.95 \)), \( \gamma = 5 \cdot 10^{-2} \) and the service time processes are Poisson.*

4. Conclusion

Besides covering actual aspects of services, the addition of waiting costs to the original Hotelling’s model confers dynamic and stochastic dimensions to a so far mostly static and deterministic elementary industrial organization problem. In the simplest configurations obtained for fixed and symmetric services, we already observe the central role played by the underlying random queue dynamics, which is here used to model the waiting processes. In particular for heavy traffic regimes, the Hotelling inner market boundary point obeys to a *time-dependent stochastic diffusion process* with multiplicative noise. Such multiplicative fluctuations, generated by state dependent “volatility” terms, are well known to give rise to *noise induced phase transitions*, a phenomena which cannot be derived by deterministic analysis alone.
