Abstract

Although ohmic H-modes have long been produced on TCV and the effects of ELMs at the divertor target studied in some detail, no attempt has yet been made to model the scrape-off layer (SOL) in these plasmas. This paper describes details of the first such efforts in which simulations of the inter-ELM phases using the coupled fluid-Monte Carlo SOLPS5 code (without drifts) are constrained by careful upstream Thomson scattering and Langmuir probe profiles. Simulated divertor profiles are compared with Langmuir probes and fast IR camera measurements at the targets. To account for the very differing transport rates in the edge pedestal and main SOL regions, radial variation of edge transport coefficients has been introduced in the simulations. Similarly, it is found that transport in the main chamber and divertor regions must be separately adjusted to provide an acceptable code-experiment match.

1 Introduction

Numerical modelling of the tokamak scrape-off layer is essential tool for the prediction of conditions to be expected in future fusion reactors. In particular, transient power loads on plasma-facing components due to energetic plasma relaxations, known as edge localised modes (ELMs), are a major cause of concern in ITER since ELM-target interactions may significantly reduce the expected lifetime of the ITER divertor and even the main chamber walls [1, 2]. However, understanding of the details of ELM-SOL-transport and target interactions is still only emerging and considerable effort is required with regard to benchmarking the numerical modelling tools against experimental measurements.

The first step in this exercise is to establish a “steady” state” pre- or inter-ELM model to provide a starting point for the more complex time dependent ELM simulations. This paper describes the results of the first effort to provide this for a TCV type-III ELMing H-mode target plasma using the SOLPS5 fluid-Monte Carlo edge code benchmarked against experimental data obtained upstream in the main SOL and pedestal region and at the divertor targets.

Recent experiments with high power ECRH at the third harmonic have produced large, possibly Type-I ELMs on TCV for the first time, typically exhausting ~ 12% of the plasma stored energy [3], but in standard ohmic H-modes operating close to the L-H transition threshold power, only Type III ELMs are obtained. Typical single null lower (SNL) ohmic H-mode discharges have \( I_p = 400 \, \text{kA}, \, n/n_{GW} \sim 0.3 \) (\( n_{GW} \) is the Greenwald density) and steady ELMing phases with \( f_{\text{elm}} \sim 200 \, \text{Hz} \), where each ELM exhausts only a few 100 J of plasma stored energy (~1-2%). As such these ELMs cannot be compared with larger events seen on bigger machines regarding the magnitude of target power fluxes etc., but their behaviour with respect to transport in the SOL and interactions with the targets appears to be similar. In fact, their benign nature makes the fluid plasma simulation in some ways more appropriate since the ELMs are insufficiently large to require a true kinetic simulation and are likely to be less perturbing in the sense of parallel heat flux limits and variations in sheath transmission coefficients.

2 Experiment

The TCV tokamak (\( R=0.875 \, \text{m}, \, a=0.25 \, \text{m}, \, B_0 = 1.43 \, \text{T} \)), is an all-graphite machine in which a number of open diverted configurations can be achieved. To date, the majority of
ohmic H-modes have been with reversed toroidal field, \( B_\phi \), (ion \( B \times V_B \) drift direction upwards). This is historical and essentially a consequence of H-mode avoidance, since with the more conventional forward \( B_\phi \) operation, ohmic H-mode is easily obtained, even at low plasma current. This usually occurs without frequent ELMs, making density control difficult. This is particularly important for the low density second harmonic ECRH experiments which constitute a large fraction of the TCV experimental programme.

Simulations described here have been performed for a deuterium Type III ELMing H-mode target discharge (#26730) with \( I_p = 430 \) kA, \( f_{\text{elm}} = 230 \) Hz and line averaged electron density, \( \bar{n}_e = 6 \times 10^{19} \) m\(^{-3}\). The magnetic equilibrium reconstruction of this SNL configuration is shown in Fig. 1, illustrating the short high field side (HFS) divertor leg on the central column and low field side (LFS) strike point on the vessel floor. This rather unconventional diverted configuration is characteristic of TCV and is required principally for reasons of vertical stability. The plasma has elongation and triangularity of \( \kappa_{95} = 1.65, \delta_{95} = 0.4 \) respectively, with \( q_{95} = 2.5 \) and stored energy of \( \sim 20 \)kJ.

The time evolution of a few relevant plasma signals are also shown in Fig. 1 along with the location of the edge diagnostics from which data is used here to constrain the code. Two single Langmuir probe (LP) arrays provide good coverage of electron temperature \( T_e \), electron density, \( n_e \) and ion flux density, \( j_{\text{sat}} \) at inner and outer targets [4]. During this particular discharge the probes were operated in fixed negative bias mode, generating \( j_{\text{sat}} \) on a fast timescale. In further, identical discharges, pre-programmed outer divertor strike points sweeps in conjunction with both voltage sweep and constant bias modes, allow profiles on ion flux, \( n_e \) and \( T_e \) with higher spatial resolution to be generated. Outer target heat flux profiles are deduced from the tile surface temperature using vertically viewing infrared (IR) thermography [5]. A fast reciprocating Langmuir probe (RCP) samples the main SOL plasma on the LFS vacuum vessel midplane and, in conjunction with a high resolution edge Thomson scattering (TS) system, provides upstream \( T_e \) and \( n_e \) profiles across the pedestal and SOL regions.

3 Numerical tool (Simulation)

The SOLPS5 package is a sophisticated coupled fluid (B2.5) and Monte Carlo (EIRENE) code modelling the plasma fluid and neutral transport on a simulation grid generated from the measured equilibrium poloidal magnetic flux surfaces from any given tokamak discharge [6]. Experimentally obtained inputs given to the code are magnetic equilibrium, power entering
the SOL (\(P_{\text{SOL}} = P_{\Omega} - P_{\text{RAD}} = 275\) kW in this case - see Fig. 1) and upstream density at the separatrix \((1.6 \times 10^{19} \text{ m}^{-3})\) from edge TS. Coefficients, \(D_{\perp}, \chi_{\perp,i,e}\) controlling the rate of perpendicular particle and energy diffusion are systematically adjusted in order to obtain satisfactory agreement between experimental and simulated midplane profiles (always shown here mapped to the outboard midplane). The transport can also be specified by an adhoc combination of diffusivity and convection, or by convection alone using the convective velocity \(v_{\perp}\), but has not been attempted in this first approach – only \(D_{\perp}, \chi_{\perp,i,e}\) are varied. In the absence of experimental data for the ion temperature profile (though edge charge-exchange measurements will be available in the future), \(\chi_{\perp,i} = \chi_{\perp,e}\) is assumed.

The SOLPS grid extends radially from -2.5 cm to +2 cm on either side of the midplane separatrix and comprises 72 poloidal and 24 radial cells. This grid extent is sufficient to encompass the edge transport barrier (ETB) region, which is rather narrow in these TCV shots (see below). Albedos are set at 1 on wall surfaces. Carbon is dominant impurity in TCV and is included in the simulation, with transport coefficients assigned as for the fuel species. Parallel heat flux limits are set at 10 for ions (ie essentially no ion heat flux limit), 0.3 for electrons and no drifts have been included at this stage.

The modelling attempts described here broadly follow the approach in the JET EDGE2D-Nimbus study in [7], seeking first the closest match to upstream experimental profiles during inter-ELM phases using a step-like Ansatz for \(D_{\perp}, \chi_{\perp,i,e}\) in the edge and SOL regions, but also introducing poloidal variation of the transport coefficients such that the transport is specified differently in the main chamber SOL and divertor regions. This is extremely important in TCV, where the unconventional divertor geometry means that care must be taken in presence of steep H-mode edge barriers to tailor differently the transport in this region compared with core.

### 4 Results and discussion

#### 4.1. Upstream profiles

Fig. 2 compiles the results of this inter-ELM simulation for the upstream profiles of \(T_e\) and \(n_e\) in comparison to edge TS and RCP data. The TS profiles are compilations of a number of laser pulses through the discharge, filtered to exclude ELM events. The composite profile has been fitted using a tanh function which identifies the experimentally measured pedestal
height and width [8] as $3.6 \times 10^{19}$ m$^{-3}$, 1.36 cm and 179 eV, 1.02 cm for $n_e$ and $T_e$ respectively. There is excellent agreement, where the data overlap, between the RCP and TS $T_e$ profiles. For density, the RCP data have been multiplied by a factor of 0.5 to account for the known overestimation due to finite Larmor radius effects which increase the projected collection area of the Langmuir probe pins. No radial shift has been applied to the profiles.

The SOLPS5 model profiles are also shown in Fig. 2, superimposed on the experimental data. This represents an excellent level of agreement and has been obtained using a radial variation of the transport coefficients as also shown in Fig. 2. Whilst $D_\perp$ does not require much variation in the region through the confined and ETB regions, a gradual decrease of $\chi_\perp$ is required from just inside the inner boundary of the simulation region right through the ETB. Both $D_\perp$ and $\chi_\perp$ are increased up to a common value of $1\text{m}^2\text{s}^{-1}$ in the main SOL and it seems clear that the foot of the ETB extends someway (~0.5 cm at the midplane) into the SOL itself. This is similar to the JET findings in [7]. Unlike the analysis in [7], however, no inward pinch nor outward drift has been found necessary to model the experimental profiles, though it is clear that there is a certain arbitrariness to the choice of these coefficients, since closely similar results can be found by introducing a profile of $v_\perp$ and appropriately adjusting those of $D_\perp$ and $\chi_\perp$.

4.2 Target profiles

Fig. 3 presents the measured inner and outer divertor target $j_{\text{sat}}$, $n_e$ and $T_e$ profiles compared with the simulation for the upstream match shown in Fig. 2. At the outer target the experimental parallel ion fluxes have been obtained both from fast voltage sweep of the probes as the divertor leg itself is swept through the steady ELMing phase (see Fig. 1) and by extracting the pre-ELM $j_{\text{sat}}$ value obtained from a coherent ELM average (following the technique reported in [4]) on a probe by probe basis for a case with the outer strike point fixed in time (in a separate, identical discharge). The two techniques provide similar profiles, though the divertor leg sweep clearly has the advantage of offering higher spatial resolution. Data at the inner target are of lower quality – floating potentials of the inner target LP, especially in the strike point region, are very negative (due to the presence of strong thermoelectric currents [4]) and insufficient bias potential often makes it difficult to extract $T_e$ reliably.
In general, the simulation experiment match is again satisfactory, but it should be noted that this has only been possible by “switching off” the transport barrier in the divertor regions and increasing D⊥ and χ⊥i,e in the divertor SOL and private flux region (PFR) from 1 → 6 m²s⁻¹ (cf. 1 m²s⁻¹ in the main chamber SOL – Fig. 2). As can be seen from the model profile widths at the outer target, the PFR transport should probably be decreased to steepen the profile there.

Without the increased divertor transport rates, the code overestimates the experimental outer target j_sat and T_e by more than a factor of 3, but it should be clear that because drifts have not been included in the simulation, it is somewhat artificial to seek too close a match. Drifts very likely are playing a role in TCV, but the situation is complicated by the unconventional divertor geometry combining a short and long divertor leg. In reversed B_ϕ (the case considered here), observations made elsewhere (eg on the JET [9] and Alcator C-Mod [10] tend to find that although T_e at the inner usually stays lower than at the outer, the difference is significantly reduced compared with forward B_ϕ, where T_e is always much higher at the outer target. This is also of course due to toroidal geometry which automatically ensures that more power flows to the outer SOL.

In TCV, the experimental data in Fig. 3 indicate a hotter inner divertor in reversed B_ϕ, but some of this is undoubtedly due to the short inner divertor leg. The code approximately matches the inner target T_e but overestimates that at the outer by about a factor of 2. Density, which is reasonably well matched at both targets, is computed from the probe characteristic fits as n_e = j_sat/e c_s, with the c_s the sound speed assuming T_i = T_e. The code simulations indicate that the latter is a good approximation at the target. Switching on drifts (the subject of planned future work) is very likely to decrease the predicted outer target T_e and may have only a small effect at the inner target (for the geometrical reasons mentioned above). In fact, very recent experimental observations of forward B_ϕ ohmic H-modes, albeit at lower current (I_p = 330 kA) than the discharge considered here have shown that the experimental outer target T_e is increased by almost a factor 2 over the values shown here, which would match these drift-free SOLPS5 simulations.

Fig. 4 compares the experimental LP and predicted perpendicular target power fluxes, P⊥ for both targets where, at the outer target, new data from a vessel floor viewing IR camera have been included [5]. The LP and SOLPS5 estimates are computed according to P⊥ = γj_sat T_e c_s sinα with a the angle of incidence of the total magnetic field at the targets and γ the sheath heat transmission coefficient. The latter has been assumed as 7.5 for the purposes of
Fig. 4, but comparison with the IR profile shows that slightly higher values would be more appropriate in this case [5]. Due principally to the overestimate of target $T_e$, SOLPS5 overestimates the outer target power (~ factor 3) and slightly underestimates the inner target values, but is only a factor 2 above the measured IR profile. The integral experimental power balance (summing the inner and outer target contributions to obtain $P_{\text{SOL}}$) is quite well satisfied but slightly overestimates the expected power. Fig. 4 clearly shows that the majority of the conducted power is found at the inner target in this configuration. This is confirmed by tomographic inversion of chordal radiation measurements which show the strongest radiating zone to be located at the X-point and inner strike regions.

5 Conclusions

First attempts have been made to model the inter-ELM SOL plasma of ohmic ELMing H-mode on TCV using the SOLPS5 coupled fluid-Monte Carlo code package. Simulations are constrained by seeking to match upstream SOL and edge pedestal profile measurements. No such match is possible without introducing radial variations of the particle and heat diffusivity, with low values in the edge transport barrier region and an increase in the SOL. Compared with the main chamber SOL values, both $D_\perp$ and $\chi_{i,i,e}$ must be increased roughly fivefold if outer target experimental profiles of ion flux and $T_e$ are to be even approximately matched. Agreement is reasonable at the inner target, where densities and temperatures are considerably higher. At least part of the reason for the higher code values, particularly of $T_e$, found at the outer target in comparison with experiment is due to the neglect of drift effects in these first simulations. The reasonably good match at the inner target may be an indication that it is the rather unconventional equilibrium, with an extremely short X-point to inner strike point position, which dominates over any drift or divertor physics effects. The encouraging overall model-experiment agreement for this steady state phase provides a good basis for the more complex time dependent modelling of the ELM itself.
