The characteristics of confinement properties and magnetohydrodynamics (MHD) stabilities of the super dense core (SDC) plasmas are intensively studied in the Large Helical Device (LHD) experiment. The SDC plasmas are produced in the configuration with outward shifted magnetic axis and rapid fueling into the core region by pellet injection. The SDC plasmas have high electron pressure due to the large electron density \( n_e \approx 10^{21} \text{[m}^{-3}] \) in the core region which induces a large Shafranov shift \( \Delta/a_{\text{eff}} > 0.5 \). It is useful to apply the production method of the SDC plasmas for obtaining high-beta plasmas with high pressure in the core region. In this study, the characteristics of the ideal MHD instabilities of the SDC plasmas are analyzed by using the 3-D ideal MHD code TERPSICHERE. The calculated equilibrium of the typical SDC plasma with the central beta of \( \beta_0 = 5\% \) solved as the result of the HINT/HINT2 codes shows that a deep magnetic well depth appears around the core region due to the large Shafranov shift. The Mercier criterion \((D_i)\) shows that the plasma is stable all over the plasma region and consequently the low-\( n \) interchange modes do not appear. Although the typical SDC plasma is stable to the interchange mode, it is worthwhile to investigate the other pressure profiles and the magnetic field configurations to know the role of the MHD instabilities on the experimentally obtained SDC plasmas. In the experiment, the SDC plasmas cannot be produced in the configuration with inward shifted magnetic axis. Such configuration tends to be MHD unstable, in which the core resonant interchange modes become unstable in case of relatively low-beta plasma with finite pressure gradient in the core region. We will investigate how the MHD instabilities affect the production of the SDC plasma with steep pressure gradient in the core region in the configuration with inward shifted magnetic axis.

(global) mode and high-n (local) mode. Here, $n$ means the toroidal Fourier mode number. In this study, we have investigated about low-n ideal mode, high-n ideal mode, and resistive high-n mode. The latter mode relates to the plasma transport. The analyses of low-n ideal mode are carried out by using 3-D ideal MHD stability code TERPSICHORE [2]. The Mercier index shows the stability of ideal high-n mode. The resistive high-n mode is examined from local parameters of specific volume, Reynolds number and pressure gradient. The equilibria analyzed here are solved as the result of the HINT/HINT2 codes [3,4].

This paper is organized as follows. Characteristics of MHD stability of experimentally obtained plasmas are described in the following section. In section 3, equilibria with modeled pressure profiles are analyzed to orient the experimental results. Finally, we will discuss and summarize in section 4.

2. Characteristics of MHD stability of experimentally obtained plasmas

Experimentally obtained SDC plasmas have a steep pressure gradient in the core region which corresponds to around the position of the rotational transform $\nu/2\pi = 1/2$. We focus on, therefore, the $m/n = 2/1$ mode as a low-n ideal MHD mode. Here, $m$ means the poloidal Fourier mode number. The analyses of low-n ideal mode are carried out by using 3-D ideal MHD stability code TERPSICHORE. The relationship between the growth rate and $R_{ax}$ is shown in Fig.3. In case of $R_{ax} = 3.6[m]$, the $m/n = 2/1$ mode is unstable with the growth rate $\gamma/\omega_{A} = 1.62 \times 10^{-3}$ and the wide mode structure appears as shown in Fig.3(a). In case of $R_{ax} = 3.65[m]$, the growth rate is $1.74 \times 10^{-3}$ and the width of the structure is narrower than that in case of $R_{ax} = 3.6m$. It is reported that the growth rate of $\gamma/\omega_{A} = 10^{-2}$ is defined as the stability boundary [5]. It can be, therefore, considered that the ideal low-n ($m/n = 2/1$) interchange mode is stable except for the configuration with $R_{ax} = 3.6[m]$.

3. MHD stability of analytical equilibrium

Equilibria with modeled pressure profiles are analyzed to orient the experimental results. Here, three kinds of pressure profiles of parabolic ($\beta = \beta_{0}(1 - \rho^{2})$), peaked ($\beta = \beta_{0}(1 - \rho^{3})$), and broad ($\beta = \beta_{0}(1 - \rho^{3})$) are adopted. The contour lines of Mercier index $D_{1}$ are shown in Fig. 4 where dashed and solid thin lines

![Fig.2 Normalized pressure profiles. Filled and open circles indicate the case of $R_{ax} = 3.60[m]$ and $3.85[m]$ respectively. The steep gradient is seen in $R_{ax} = 3.85[m]$.](image1)

![Fig.4 Contour lines of Mercier index and the position of $\nu/2\pi = 1/2$ surface in $\rho - \beta_{0}$ space. Dashed and solid thin lines indicate $D_{1} = 0$ and 0.2 respectively. Bold solid lines correspond to the position of $\nu/2\pi = 1/2$.](image2)

![Fig.3 Dependence on the growth rate of $m/n = 2/1$ mode of $R_{ax}$. Typical mode structures in case of (a)$R_{ax} = 3.6[m]$ and (b)$R_{ax} = 3.65[m]$ are also shown.](image3)
indicate $D_I = 0$ and 0.2 respectively. Bold solid lines correspond to the position of $\nu/2\pi = 1/2$. In equilibria with $R_{ax} = 3.60$[m] (Fig.4(a)(e)(i)), Mercier unstable regions dominate the $\rho - \beta_0$ space. Mercier unstable region generally narrows with increasing $R_{ax}$. In particular, the equilibrium with peaked profile in $R_{ax} = 3.75$[m] is Mercier stable all over the region (Fig.4(d)).

In order to investigate the global ideal mode, we have analyzed the stability of $m/n = 2/1$ mode which mainly resonates at core region. The low-$n$ ideal mode tends to be unstable when the resonant surface obviously enters the Mercier unstable region. The ideal low-$n$ interchange mode is destabilized (as above mentioned, growth rate becomes $\gamma/\omega_A > 10^{-2}$) in $R_{ax} = 3.60$[m] with peaked and parabolic profiles, in which the mode structures are shown in Fig.5. In each cases, (peaked (Fig.5 (a)) and parabolic Fig.5 (b)), the growth rate is $\gamma/\omega_A = 1.84\times10^{-2}$ and $1.10\times10^{-2}$ respectively. The shape of mode structure is similar to each other, in which the full width at half maximum, $\Delta \rho$, is $\Delta \rho \sim 0.1$ and the position of the peak corresponds to around $\rho = 0.54$. In the other equilibria ($R_{ax} > 3.6$[m]), the low-$n$ mode ($m/n = 2/1$) does not appear.

The orientation of experimental results from the viewpoint of ideal MHD instability is shown in Fig.6. The left figure (Fig.6 (a)) shows the global ideal MHD unstable region by solid lines and the right one (Fig.6 (b)) indicates the unstable region of the local MHD mode. The experimental results of central beta $\beta_0$ are superimposed. The experimentally obtained plasmas generally locate far from the MHD unstable ($m/n = 2/1$ mode) region as shown in Fig.6 (a). Some of experimental results ($R_{ax} = 3.6$[m] and 3.65[ms]), on the other hand, enter the Mercier unstable region as shown in Fig.6(b). These results suggest that the ideal global mode does not affect the beta (gradient) in outward-shifted configuration. High-$n$ ideal mode might influence the MHD characteristics because the unstable region of high-$n$ ideal mode covers the region where the experimental data exists.

4. Discussion and summary

The ideal MHD stability of SDC plasma is investigated. The results show that the SDC plasmas are stable against to the ideal MHD mode. In order to investigate the other MHD stability, we will discuss the possibility of the resistive mode here. The resistive MHD instability is well correlated with the transport via the resistive pressure gradient driven turbulence. The coefficient of the particle diffusion $D$ is defined by the magnetic curvature ($\kappa_n$), Reynolds number ($S$) and pressure gradient ($d\beta/d\rho$) as follows [6-7].
\[ D \propto \frac{\kappa_n}{S} \frac{d\beta}{d\rho} \tag{1} \]

The qualitative behavior of the diffusion against to the \( R_{ax} \) is shown in Fig.7. The deferential of specific volume \( V'' \) is used here instead of \( \kappa_n \) to estimate the coefficient of the particle diffusion. The plot at \( \rho = 0.7 \) of \( R_{ax} = 3.6[m] \) indicates the small value, which comes from the local flating of the pressure gradient. Figure 7 shows that the diffusion by the resistive pressure gradient driven turbulence generally continuously decreases with the \( R_{ax} \). The diffusion at \( \rho = 0.5 \) and 0.6, in particular, goes to zero around \( R_{ax} = 3.7[m] \) where the threshold is seen as shown in Fig.1. In other word, diffusion tends to become large in the inward-shifted configuration. Further analyses about resistive mode are required.
