Humans and animals learn by modifying the synaptic strength between neurons, a phenomenon known as synaptic plasticity. These changes can be induced by rather short stimuli (lasting, for instance, only a few seconds), yet, in order to be useful for long-term memory, they should remain stable for months or years.

Experimentalists study synaptic plasticity by applying a vast variety of protocols. In the present thesis we focus on protocols that fall under two main categories: (i) Those that induce synaptic modifications that last for only a few hours ("early phase" of plasticity) (ii) Those that allow synapses to undergo a sequence of steps that transforms the rapid changes occurring during the "early phase" into a stable memory trace ("late phase" of plasticity).

The goal of this thesis is to better understand synaptic plasticity across these different phases, early and late, by creating compact mathematic models to describe the plasticity mechanisms. Our approach allows for a synthetic view of the field as well as the exploration of functional consequences of learning. In this direction, we propose a model for the induction of synaptic plasticity that depends on the presynaptic spike time and non-linearly on the postsynaptic voltage. The model is able to reproduce a broad range of experimental protocols such as voltage-clamp experiments and spike-timing experiments. Since the voltage is a key element in the model, we describe the neuronal activity by using a compact neuron model that faithfully reproduces the voltage time course of pyramidal neurons. In addition, this model of the induction of synaptic plasticity is combined with a trigger process for protein synthesis, and the final stabilization mechanism in order to describe the "late phase". In this combinatory form, it is able to explain experimental phenomena known as tagging experiments and to make testable predictions. A study of functional consequences of the induction model reveals selectivity in the inputs, independent component analysis computation and a tight relation between connectivity and coding.

In parallel a top-down approach finding independent components is used to derive a rate-based learning rule which shows structural correlations with the induction model. This unified model across different time scales allowing the stabilization of synapses is crucial to understand learning and memory processes.
in animals and humans, and a necessary ingredient for any large-scale model of the brain.

Acknowledgments

First of all, I would like to thank sincerely my supervisor, Prof. Wulfram Gerstner, for his great guidance all along my PhD. He had always good suggestions for further investigations and gave me a lot of his time. He has a really broad vision of the field and an amazing knowledge of the literature. I learned a lot working with him and he trusted me sending me to give talks in major conferences. I would like to also thank my collaborators Prof. André Longtin from Ottawa and Jean-Pascal Pfister for the common work on Independent Component Analysis, Dr. Eleni Vasilaki and Lars Büsing for the model on the early phase of plasticity, Lorric Ziegler for working together on the TagTriC model. Moreover I would like to thank all my colleagues for the productive discussions at the white board, the nice lunches, coffee breaks at the university but also all the time spent outside the working context. Finally I thank gratefully my friends and my family for their never ending trust, support and care.

Chapter 1

INTRODUCTION

1.1 EXPERIMENTAL BACKGROUND

Animals have an incredible ability to learn and memorize experiences during their life. Memory, or at least a part of memory, is believed to be stored in the connections between the neurons, the synapses. They potentially offer a very large memory capacity since there are about 100 to 500 trillions, i.e. $10^{14}$ synapses in a human brain. Moreover, the synapses have been shown to be plastic, i.e. their strength is variable. The basic idea of how synapses change was already proposed by Hebb in 1949 in his postulate "When an axon of cell $j$ repeatedly or persistently takes part in firing cell $i$, then $j$’s efficiency as one of the cells firing $i$ is increased" (Hebb 1949). It is only about 25 years later that synaptic potentiation was measured experimentally in anesthetized rabbits (Bliss and Gardner-Medwin 1973). A few years later synaptic depression was measured (Lynch, Dunwiddie, and Gribkoff 1977).

Two neurons can be connected via chemical and/or electrical (gap junctions) synapses. A chemical synapse is placed between the axon of a presynaptic neuron and a dendrite of the postsynaptic neuron forming an unidirectional connection. This type of synapse is the main focus of the thesis; the electrical one is not considered here. A simplified view of the synaptic communication mechanism is the following: When a presynaptic spike arrives at the presynaptic terminal, neurotransmitters, typically glutamate for excitatory synapses, are released. They can bind at the postsynaptic side to different receptors like N-methyl D-aspartate (NMDA) or $\alpha$-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors. AMPA receptors then open and let sodium ions flow into the cell resulting in a depolarization of the postsynaptic membrane potential. The NMDA receptor opens only if at the same time (a) the glutamate binds to the receptors and (b) the postsynaptic cell is depolarized freeing the magnesium block (see Fig 1.1). This depolarization of the postsynaptic cell can typically come from the back-propagating action potential. The NMDA receptor therefore is seen as a coincidence detector between presynaptic and postsynaptic activities. The opening of these receptors allows calcium to enter the synapse. Despite the detailed description of the mechanisms that allow synaptic commu-
Figure 1.1: Cartoon of a glutamatergic synapse. When a presynaptic spike arrives at the synapse, neurotransmitters are released in the synaptic cleft. They can bind to the NMDA receptor and if at the same time the postsynaptic cell is depolarized, the channel opens. Calcium enters the cell which induces a molecular cascade that phosphorylates the Ca\textsuperscript{2+}/calmodulin-dependent protein kinases (CaMKII), which in turn acts on the AMPA receptor activation. Neurotransmitters can also directly bind to AMPA receptor, in which case the channel opens allowing sodium to enter, leading to a depolarization which is called excitatory postsynaptic potential (EPSP).

Synaptic plasticity measurements

The typical measurement of synaptic strength is the amplitude or the slope of the excitatory postsynaptic potential (EPSP), i.e. the potential response to a single (or a group of coincident) presynaptic spike(s). Synaptic plasticity can be separated in two distinct phenomena: short-term plasticity where changes
persist during few hundreds of milliseconds and long-term plasticity that lasts more than 30 minutes. Short-term plasticity is believed to be presynaptically expressed (Markram, Wu, and Tsodyks 1998; Gupta, Wang, and Markram 2000) and is partly caused by the limited number of neurotransmitters at the synapse. It is well modeled by a reservoir that partially empties with some probability at the time of a presynaptic spike and recovers with a certain time constant (Markram and Tsodyks 1996; Abbott, Varela, Sen, and Nelson 1997). This however is not the interest of this thesis. Here the focus is on long-term plasticity, which can be induced by different types of protocols.

(a) Simultaneous voltage clamp and presynaptic stimulations (Ngzahayo, Schachner, and Artola 2000; Ling, Benardo, Serrano, Blace, Kelly, Crary, and Sacktor 2002) (Fig. 1.2A). When the cell is slightly depolarized the synaptic weight is depressed, whereas it is potentiated when the cell is highly depolarized.

(b) Extracellular presynaptic stimulations at different frequencies (Kelso, Ganong, and Brown 1986; Dudek and Bear 1993; O’Connor, Wittenberg, and Wang, 2005) (Fig. 1.2B). Low frequency stimulation leads to depression, whereas high frequency leads to potentiation.

(c) Pairing of presynaptic and postsynaptic spikes at different time lags (Fig. 1.2C). Typically in pyramidal cells pre-post pairing results in potentiation whereas post-pre in depression (Markram, Lübke, Frotscher, and Sakmann 1997; Bi and Poo 1998). However, it seems that in spiny-stellate neurons (Egger, Feldmeyer, and Sakmann 1999) and in synapses from pyramidal cells onto fast spiking interneurons (Lu, Li, Zhao, ming Poo, and Zhang 2007), pre-post and post-pre pairing both lead to depression; in a cerebellum-like structure of the electrical fish, the temporal order seems to be reversed, i.e. pre-post pairing leads to depression and post-pre to potentiation (Bell, Han, Sugawara, and Grant 1997); and in synapses of parallel fibers onto cartwheel cells, only pre-post pairing leads to depression (Tsounopoulos, Kim, Oertel, and Trussell 2004).

(d) Pairing at different frequencies (Markram, Lübke, Frotscher, and Sakmann 1997; Sjöström, Turrigiano, and Nelson 2001) (Fig. 1.2D). Pre-post pairing at low frequency does not change the synaptic weight, increasing the frequency leads to potentiation. Synaptic plasticity can also be induced with different patterns like triplets of spikes (Froemke and Dan 2002), bursts (Nevian and Sakmann 2006; Gustafsson, Wigstrom, Abraham, and Huang 1987), quadruplets (Wang, Gerkin, Nauen, and Bi 2005) or even natural spike trains (Froemke and Dan 2002). There is also a difference if the presynaptic stimulation is done extracellularly (many inputs at the same time, slices more active) or intracellularly.

(e) Synaptic tagging experiments (Frey and Morris 1997). These experiments provide evidence for another separation of time scales for long-term plasticity. The early phase of long-term plasticity lasts 2 to 3 hours and is induced by tetanic stimulation for potentiation (Fig. 1.2E). The late phase, or consolidation phase, however lasts more than 10 hours (i.e. the time of those experiments)
and is induced by a stronger extracellular tetanus that also stimulates dopaminergic fibers (Fig. 1.2F). Neuronal modulation is thus important in the process of consolidation (Reymann and Frey 2007).

1.2 Theoretical Background

1.2.1 Rate Models

The first models of synaptic plasticity in line with Hebb's principle ("Who fires together wires together") depend on the correlation of presynaptic and postsynaptic activities, typically the firing rates. The next improvements were to subtract a baseline so that the weight can also be depressed (covariance rule (Sejnowski and Tesauro 1989)), add weight dependency, like hard bounds, soft bounds, add normalization to induce competition between weights (Miller and MacKay 1994). Multiplicative normalization was introduced in Oja's rule (Oja 1982) which performs Principle Component Analysis (PCA). At the same time the Bienenstock, Cooper, Munro (BCM) rule became influential (Bienenstock, Cooper, and Munro 1982). It has a nonlinearity in the postsynaptic firing rate and a sliding threshold as homeostasis. It exhibits properties of selectivity in the inputs. Those rate based rules were used in artificial neuron networks like Hopfield networks (Hopfield 1982) and Boltzmann machines (Hinton and Sejnowski 1983), for map formation (von der Malsburg 1973; Kohonen 1990; Bednar and Miikkulainen 2000), receptive field development (Linsker 1986; Bi-ennenstock, Cooper, and Munroe 1982), among others.

1.2.2 Spike Models

In 1996 a theoretical work looking at precise temporal coding (Gerstner, Kempter, van Hemmen, and Wagner 1996) suggested that synaptic plasticity should depend on the time between the presynaptic and the postsynaptic spikes. In parallel Markram et al. were able to show the spike timing dependence experimentally in neocortical slices (Markram, Lübke, Frotscher, and Sakmann 1997). From then on, Spike-Timing-Dependent Plasticity (STDP) models became influential (Gerstner, Kempter, van Hemmen, and Wagner 1996; Kempter, Gerstner, and van Hemmen 1999; Senn, Tsodyks, and Markram 2001; Song, Miller, and Abbott 2000; van Rossum, Bi, and Turrigiano 2000; Rubin, Lee, and Sompolinsky 2001; Güttig, Abarzovich, Rotter, and Sompolinsky 2003a; Kar-markar and Buonomano 2002). These models typically use local variables, i.e. the weight change depends on a presynaptic and postsynaptic trace. Every time a presynaptic spike occurs, the weight decreases by an amount corresponding to
Hyperpolarized: no weight change
Slightly depolarized: depression
Highly depolarized: potentiation

Figure 1.2: Different experimental protocols. A. Voltage clamp experiment. The postsynaptic voltage is clamped at the soma during extracellular presynaptic stimulation. If the voltage is hyperpolarized, no weight change is recorded; for slight depolarization, depression is observed; for strong depolarization, potentiation occurs. Figure redrawn from (Artola, Bröcher, and Singer 1990). B. Presynaptic frequency dependence. Extracellular presynaptic spike trains at different frequencies are induced. Low frequency stimulation yields depression whereas high frequency stimulation results in potentiation. Figure redrawn from (Dudek and Bear 1993). C. STDP experiment. Pairs of presynaptic and postsynaptic spikes are elicited. The lag between the presynaptic spike and the postsynaptic spike varies. Pre before post pairing induces Long Term Potentiation (LTP) whereas post before pre leads to Long Term Depression (LTD). Figure redrawn from (Bi and Poo 1998). D. Pairing frequency experiment. Here the lag between the pre and postsynaptic spike is constant (pre-post (black), post-pre(grey)) but the frequency between the pairing varies. Pre-post at low frequency does not lead to any weight change whereas increasing frequency allows more potentiation. Figure redrawn from (Sjöström, Turrigiano, and Nelson 2001). E. Weak tetanus stimulation. Few extracellular high frequency trains stimulated presynaptically yield LTP that lasts 2 to 3 hours. F. Strong tetanus stimulation. However, if more spikes are induced, the potentiation is stable for longer than 10 hours. Figure redrawn from (Sajikumar and Frey 2004a).
the postsynaptic trace (see section on "Standard Pair-Based Models" and Fig. 1.3B). If a postsynaptic spike occurs, the synapse is potentiated proportionally to the presynaptic trace (see section on "Standard Pair-Based Models" and Fig. 1.3A). We can assume the traces are such that all the spikes are considered, i.e. all-to-all interactions (Fig. 1.3E) or only the nearest neighbor spike (Fig. 1.3F). However the weights can not grow indefinitely, i.e. some kind of bounds should exist. In addition, a dependence of plasticity on the actual strength of the synapses was measured experimentally (Bi and Poo 1998; Turcigiano and Nelson 2004). Theoretically also, some STDP models explored different possibilities for weight dependencies (van Rossum, Bi, and Turcigiano 2000; Güttig, Aharonov, Rotter, and Sompolinsky 2003b) and homeostasis (Turcigiano and Nelson 2004). Great effort has also been put into the study of computational consequences of STDP, for example studying the implications for plastic networks (Roberts and Bell 2000; Mehta, Quirk, and Wilson 2000; Song, Miller, and Abbott 2000; Izhikevich 2004; Legenstein, Naege, and Maass 2005; Guyonneau, VanRullen, and Thorpe 2005; Iglesiasa, Erikssonb, Grize, Tomassini, and Villa 2005; Morrison, Aertsen, and Diesmann 2007; Izhikevich and Edelman 2008). Another step leads to exploration beyond spike pair interactions (Senn, Tsodyks, and Markram 2001; Froemke and Dan 2002; Pfister and Gerstner 2006; Güttig and Sompolinsky 2006). Experimental evidences show that intracellular stimulation of pre-post pairing at low frequency does not induce any weight change. Moreover, if the frequency between the pairings is increased, potentiation increases (Markram, Lübke, Froesch, and Sakmann 1997; Sjöström, Turcigiano, and Nelson 2001). This is not consistent with the traditional view of STDP models where building blocks of plasticity are composed of pairs of pre-post and post-pre spikes. Therefore non-linear models were developed to describe those experiments where triplet interaction of spikes are considered (Senn, Tsodyks, and Markram 2001; Pfister and Gerstner 2006) (see section on "Triplet Model" and Fig. 1.3C,D) or discount factors on the "efficacy" of successive spikes (similar to including a model of short-term plasticity). This last model is based on extracellular inductions of triplets of spikes (Froemke and Dan 2002).

**Standard Pair-Based Models**

For the LTD part, standard pair-based models assume that presynaptic spike arrival at synapse $i$ induces depression of the synaptic weight $w_i$ by an amount that is proportional to $\tilde{y}_i$, an exponential low-pass filtered version of the postsynaptic spike train $Y(t)$ with a time constant $\tau_-$ (see Fig 1.3B, trace post): \[ \tau_- \frac{d}{dt} \tilde{y}_i(t) = -\tilde{y}_i(t) + Y(t). \]

where $Y(t)$ is expressed as the series of short pulses at time $t^n$ with $n$ an index that counts the spike, $Y(t) = \sum_n \delta(t-t^n)$. The variable $\tilde{y}$ is an abstract variable
Figure 1.3: Different types of models. A. LTP with standard STDP model. The synaptic weight is potentiated at the time of the postsynaptic spike by an amount corresponding to the presynaptic trace. B. LTD with standard STDP model. The synaptic weight is depressed at the time of the presynaptic spike by an amount corresponding to the postsynaptic trace. C. LTP with triplet rule from (Pfister and Gerstner 2006) minimal model. The synaptic weight is potentiated at the time of the postsynaptic spike by an amount corresponding to the product of a presynaptic and a postsynaptic trace. D. LTD with triplet rule. Same than standard STDP model. E. All-to-all interaction of spikes. The trace jumps from a fix amount when a spike occurs and decays otherwise, leading to cumulative effect from all the previous spikes. F. Nearest-neighbor interaction of spikes. The trace jumps to a fix value when a spike occurs and decays otherwise. Only the previous spike affects the trace.
which could, for instance, reflect the level of calcium concentration (Lisman 1989) or the release of endocannabinoids (Sjöström, Turrigiano, and Nelson 2004), the back-propagating action potential, though such an interpretation is not necessary for this type of phenomenological rules. Similarly, the presynaptic spike train is described as a series of short pulses at time $t_n$ with $i$ is the index of the synapse, $X_i(t) = \sum_n \delta(t - t_n)$. The depression is then modeled as the following update rule (see Fig 1.3B):

$$\frac{d}{dt} w_i^- = -A_{\text{LTD}}(w_i^-) X_i(t) y,$$

(1.1)

where $A_{\text{LTD}}$ is the amplitude for depression.

For the LTP part, the temporal evolution of the presynaptic low pass filter $\bar{x}_i(t)$ is described by (see Fig 1.3A, trace pre):

$$\tau_+ \frac{d}{dt} \bar{x}_i(t) = -\bar{x}_i(t) + X_i(t),$$

where $X_i$ is the spike train defined above. The quantity $\bar{x}_i(t)$ could for example represent the amount of glutamate bound to postsynaptic receptors (Karmarkar and Buonomano 2002; Pfister and Gerstner 2006) or the number of NMDA receptors in an activated state (Senn, Tsodyks, and Markram 2001). The potentiation is then described by the following equation (see Fig 1.3A):

$$\frac{d}{dt} w_i^+ = +A_{\text{LTP}}(w_i^+) Y(t) \bar{x}_i(t),$$

(1.2)

where $A_{\text{LTP}}$ is the amplitude for potentiation.

These types of model can reproduce the spike-timing-dependent learning window (see 1.2C) but not the pairing frequency dependence (see 1.2D) nor the voltage clamp experiment (see 1.2A).

**Triplet Model**

The minimal triplet model (Pfister and Gerstner 2006) describes the depression the same way as the standard pair-based models. However, the potentiation takes into account triplet interactions of spike, 2 postsynaptic spikes and one presynaptic spike (see Fig 1.3C). The model defines a second type of postsynaptic trace $\bar{y}_2$ that decays with a time constant $\tau_2$ that is typically in the order of 100ms. It can for example represent calcium concentration in the cell. The synapse is potentiated at a time of a postsynaptic spike from an amount that is proportional of the presynaptic spike trace $\bar{x}_i(t)$ (see Fig 1.3C, trace pre) and proportional also to this second postsynaptic spike trace $\bar{y}_2$ (see Fig 1.3C, trace post 2). The potentiation is written:
\[
\frac{d}{dt} w_i^+ = +A_{LTP}(w_i^+) Y(t) \bar{x}_i(t) \bar{y}_2.
\]

where \(A_{LTP}\) is the amplitude for potentiation.

This model is able to reproduce the frequency experiment (see 1.2D) but not the voltage clamp experiment (see 1.2A) since it depends only on the time of the spike and not on the postsynaptic membrane potential.

1.2.3 Biophysical Models

There have been a few attempts to describe the plasticity with its biophysical quantities such as (i) the voltage (Abarbanel, Huerta, and Rabinovich 2002), (ii) the Calcium/Calmodulin-Dependent Protein Kinase II (CaMKII) phosphorylation and bistability (Lisman 1985; Lisman 1989; Zhabotinsky 2000; Okamoto and Ichikawa 2000; Miller, Zhabotinsky, Lisman, and Wang 2005; Graupner and Brunel 2007), (iii) the calcium concentration (Karmarkar, Najarian, and Buonomano 2002; Karmarkar and Buonomano 2002; Shouval, Bear, and Cooper 2002; Abarbanel, Gibb, Huerta, and Rabinovich 2003; Rubin, Gerkin, Bi, and Chow 2005; Cai, Gavornik, Cooper, Yeung, and Shouval 2007) (see section "Calcium Model"), glutamate binding, AMPA receptors (Saudargiene, Porr, and Wörgötter 2003), NMDA receptors (Senn, Tsodyks, and Markram 2001) (see section "STM model") etc. For a detailed description of the biophysical models, please read Chapter 2.7.2-4 of (Graupner 2008).

STM Model

The STM model (Senn, Tsodyks, and Markram 2001) takes into account the dynamics of the NMDA receptor. Those receptors can be in 3 different states: rest, up or down. In absence of spikes, NMDA receptors are in the rest state, but they can be up-regulated when a presynaptic spike occurs or down-regulated with a postsynaptic spike. A notion of two types of second messengers is introduced in the model so that when a postsynaptic spike occurs, second messengers type 1 can be up-regulated only if the NMDA receptors are in the up states already. Inversely, the second messengers type 2 can be down-regulated if there is a presynaptic spike and if the NMDA receptors are already in the down state. Finally LTP appears when there is a postsynaptic spike and the second messengers type 1 are in the up state, LTD occurs at the time of a presynaptic spike if the second messengers type 2 are down regulated (see Fig 1.4A). This model takes into account pair interaction of spikes and also triplet interactions of spikes, i.e., 1 presynaptic spike and 2 postsynaptic ones for potentiation and 2 pre- and 1 postsynaptic spike for depression. It reproduces frequency dependence experiment (see experiment 1.2D, model 1.4C) as well as STDP experiment (see experiment 1.2 C, model 1.4B) but not the voltage clamp.
Figure 1.4: A. STM model. Simulation of the model reproducing B. STDP experiment. C. pairing frequency experiment. Figure redrawn from (Senn, Tsodyks, and Markram 2001).

The calcium model by Shouval et al. (Shouval, Bear, and Cooper 2002) describes concentration of calcium in the postsynaptic cell as a measure for plasticity. Indeed, low calcium concentration is not affecting the synapse but intermediate concentration leads to LTD whereas high concentration leads to LTP (see 1.5A). In order to compute the calcium concentration in the cell, the calcium current flows through the NMDA receptors only if the presynaptic spike is paired with a back propagating action potential.

It reproduces the voltage clamp experiment (see experiment 1.2A, model 1.5B), as well as the presynaptic stimulation frequency (see experiment 1.2B, model 1.5C) and the STDP experiment (see experiment 1.2C, model 1.5D). However, it predicts a LTD part in the pre-post side of the STDP curve due to the shape of the back propagating action potential.
Figure 1.5: Calcium model from Shouval et al. A. Weight change as a function of calcium concentration. Simulation of the model reproducing B. the voltage clamp experiment, C. presynaptic frequency stimulation experiment, D. STDP experiment. Figure redrawn from (Shouval, Bear, and Cooper 2002).
1.2.4 Consolidation Models

As mentioned above, synaptic tagging experiments (Frey and Morris 1997) revealed two phases of long-term synaptic plasticity: the early phase, which induces a change that lasts 2 to 3 hours (Fig. 1.2E) and the late phase, which lasts more than 10 hours (Fig. 1.2F). However, standard STDP models as well as the more detailed biophysical models typically describe only the early phase of long-term plasticity and assume the changes to be long lasting. As an aside note we will mention the cascade model (Fusi, Drew, and Abbott 2005) (see section "Cascade Model"), which has different degrees of plasticity associated with different states, one of which could be interpreted as the maintenance phase described by the tagging experiments. Moreover, in the model of (Graupner and Brunel 2007) describing the CaMKII bistability, it is not clear if this bistability reflects the maintenance or the CaMKII is only part of the early phase of plasticity.

Cascade Model

The cascade model (Fusi, Drew, and Abbott 2005) is designed to optimize the memory capacity in a network. It proposes a bistable synapse that can take a weak value or a strong value. However the synapse can be in different plastic states for each value, called metastates. For example, if the synapse is already weak and undergoes a LTD protocol, it will keep the same weak efficacy but will go to a lower metastate where the synaptic weight is harder to change, i.e. less plastic (see Fig 1.6).

1.2.5 Optimal Models

A completely different approach in developing learning models is the so-called top-down or optimality approach. In this framework, models are designed to perform a given task (e.g. Independent Component Analysis), maximize some quantities such as reward (Florian 2007), precision of spike timing (Pfister, Toyoizumi, Barber, and Gerstner 2006), transmission of information (Bell and Sejnowski 1995; Toyoizumi, Pfister, Aihara, and Gerstner 2005), sparseness (Olshausen and Field 1996), slowness (Wiskott and Sejnowski 2002; Sprekeler, Michaelis, and Wiskott 2007) etc. They can have the constraints of being online and local in order to be biologically plausible. They thus ideally take the form of a typical Hebbian learning rule or an STDP model. The obvious goal is that the top down and the bottom up models (inspired directly from the experiments) are consistent with each other.
Figure 1.6: A cascade model. Bistable synapse (weak or strong) in different metastates that reflect different levels of plasticity (increasing numbers mean less plastic). Dashed box corresponds to a cascade model with two levels. Figure redrawn from (Fusi, Drew, and Abbott 2005). B. For a comparison we show the TagTríc model. The total weight is the addition of the early weight which is a 3-states value and the late weight, a bistable value. For details of the model see Chapter 4 and (Clopath, Ziegler, Vasilaki, Buesing, and Gerstner 2008).
1.2.6 Reinforcement Learning Models

A different type of models has the feature of selecting which "synaptic experiences" should be remembered and which not. It is the reward modulated learning or reinforcement learning (Sutton and Barto 1998). These models have been derived from a top-down reward maximization approach. Learning typically occurs if a coincidence of presynaptic and postsynaptic activity is paired with a reward signal. Later on Schultz et al. (Schultz, Dayan, and Montague 1997; Schultz and Dickinson 2000) suggested a candidate for encoding the reward prediction error, the neuromodulator dopamine. Moreover, dopamine was shown in some synapses to be necessary for STDP (Pawelak and Kerr 2008). Rate-based models were shown to be functionally useful for learning (Williams 1992; Foster, Morris, and Dayan 2000; Sheynikhovich, Chavarriaga, Srour, Arleo, and Gerstner 2009). Recently, spiking versions, i.e. reward modulated STDP became fashionable, derived from an optimal framework (Seung 2003; Xie and Seung 2004; Pfister, Toyozumi, Barber, and Gerstner 2006; Florian 2007) or from a phenomenological approach (Izhikevich 2007).

1.3 Aim of this thesis

The goal of the thesis is to better understand learning and memory. We used a theoretical approach. Aiming at a synthetic view of synaptic plasticity, we constructed mathematical models validated by experimental data. The models developed are so-called minimal ones, i.e. they are complex enough to describe the phenomena studied but not more complex. The biophysical details are not taken into account for the following reasons: (i) to keep flexibility across systems, (ii) to avoid overfitting and (iii) to have intuitive, understandable and if possible analytically tractable models. However, we do associate abstract variables to possible biophysical candidates, without being bound to it. This thesis presents a compact model of synaptic plasticity across different time scales, faithfully reproducing the different types of experimental data described above. The early and the late phase of long term plasticity is taken into account. Short term plasticity effects are neglected.

The model for the early phase of plasticity (Clopath, Vasilaki, Buesing, and Gerstner xxxx) depends on the voltage of the postsynaptic neuron to reproduce voltage clamp experiments (Artola, Bröcher, and Singer 1990; Ngeza-hayo, Schachner, and Artola 2000). Indeed no postsynaptic spike is required for synaptic potentiation whereas the time course of the voltage seems to be relevant. Thus a proper description of the voltage is essential and thus we propose an adequate neuron model that fits the biological data properly (Clopath, Jolivet, Rauch, Luescher, and Gerstner 2007). Note that by construction standard
STDP models (Gerstner, Kempter, van Hemmen, and Wagner 1996; Kempter, Gerstner, and van Hemmen 1999; Senn, Tsodyks, and Markram 2001; Song, Miller, and Abbott 2000; van Rossum, Bi, and Turrigiano 2000; Güttig, Aharonov, Rotter, and Sompolinsky 2003a; Karmarkar and Buonomano 2002) cannot reproduce the voltage dependence of plasticity experiment because they consider only spike times. In addition our model incorporates triplet interactions of spikes (Senn, Tsodyks, and Markram 2001; Pfeister and Gerstner 2006) in order to reproduce the frequency dependence (Markram, Lübke, Frotscher, and Sakmann 1997; Sjöström, Turrigiano, and Nelson 2001) (as described above). Finally, functional implications of this model are studied such as network connectivity under different coding schemes and Independent Component Analysis.

Synaptic plasticity is such a fascinating topic to study because it is considered as the basis of learning and memory. Long lasting changes are thus relevant to study. However standard STDP models (Gerstner, Kempter, van Hemmen, and Wagner 1996; Kempter, Gerstner, and van Hemmen 1999; Senn, Tsodyks, and Markram 2001; Song, Miller, and Abbott 2000; van Rossum, Bi, and Turrigiano 2000; Güttig, Aharonov, Rotter, and Sompolinsky 2003a; Karmarkar and Buonomano 2002) and even biophysical models looking at bistability of CAMKKII (Lisman 1989; Miller, Zhabotinsky, Lisman, and Wang 2005; Graupner and Brunel 2007) do not tackle the problem of late phase plasticity and maintenance. This thesis presents a minimal rule describing the long lasting changes measured by synaptic tagging experiments. Another type of model considering maintenance is the cascade model (Fusi, Drew, and Abbott 2005). We therefore expect to find some structural similarities between ours and the cascade model. In addition, reinforcement learning models, or reward modulated learning have also the property of selecting what should be learned. We thus expect our model of synaptic tagging to depend on neuromodulation. The model presented in this thesis (Clopath, Ziegler, Vasilaki, Buesing, and Gerstner 2008) contains a triggering of plasticity related proteins and a bistable maintenance variable. It describes faithfully the synaptic tagging experiments and captures cross tagging as well.

As introduced in the "theoretical background" section, there are two main approaches for modeling: (i) Either the model is derived from the biology, i.e. the phenomenological model or the biophysical model, which might be exhibiting some functions. (ii) Or the model is derived from a given function, i.e. the optimal or top-down model and then structural similarities to biology can be drawn. Ideally, the two methods should give rise to similar models. In the last part of the thesis, we derive a top-down model performing one of the functions solved by the induction model, that is Independent Component Analysis. This last model is a rate-based learning rule (Clopath, Longtin, and Gerstner 2008) and the link to the model for the early phase of plasticity is discussed in the
1.4 Road-map of this Dissertation

In this dissertation, the following four chapters contain the different papers published during the thesis. Each chapter starts with an introduction and a link to the general aim of the thesis. The last chapter summarizes the results and offers some opening for future work.

**Chapter 2: Single cell modeling - the Adaptive Exponential Integrate and Fire Model**

This chapter presents a neuron model, the Adaptive Exponential Integrate and Fire model, and compares it to voltage traces of layer V pyramidal cells under random current injections.

Paper published in Neurocomputing 2007

**Chapter 3: Model of the induction of long-term synaptic plasticity and its functional implications**

This chapter proposes a model for the early phase of plasticity that depends nonlinearly on the postsynaptic voltage. It reproduces various plasticity experiments and is used to explore different computational roles.

Paper under review in Nature Neuroscience 2009

**Chapter 4: A model for the late phase of long term synaptic plasticity**

This chapter presents a model for synaptic tagging experiments that includes the model for the early phase of plasticity presented above (Chapter 3) and describes the maintenance phase. It faithfully reproduces synaptic tagging and cross tagging experiments.

**Chapter 5: A top down approach to a rule performing Independent Component Analysis**

This chapter shows the derivation of a top down model performing Independent Component Analysis (ICA). It is a Hebbian rate-based rule and it is tested against standard ICA benchmarks. Noteworthy this model shares common functional properties with the induction model presented in Chapter 3.

Paper published in NIPS 2008

**Chapter 6: Conclusions and Future Work**
SINGLE CELL MODELING - THE ADAPTIVE EXPONENTIAL INTEGRATE AND FIRE MODEL

To study synaptic plasticity between neurons, we need an accurate model describing their activity. Indeed, the synaptic plasticity models presented in this thesis not only depend on the exact spike timing but also on the whole voltage time course. Therefore, we present in the following paper (Clopath, Jolivet, Rauch, Luescher, and Gerstner 2007) how well the Adaptive Exponential Integrate and Fire (AdEx) model reproduces voltage traces of layer V pyramidal cells under random current injection.

The AdEx model (Brette and Gerstner 2005) is a simple Integrate and Fire type model augmented by an exponential term (Fourcaud-Trocmé, Hansel, van Vreeswijk, and Brunel 2003) which describes the activation of a rapid sodium current. It allows an accurate prediction of the spike times. Actually, the exact shape of the neuron nonlinearity was measured from experimental data where an exponential was found to be the best fit (Badel, Lefort, Brette, Peter and Gerstner, and Richardson 2008). Moreover, the model has an additional variable which describes the spike-triggered adaptation and the subthreshold adaptation. It was shown to fit accurately a more detailed Hodgkin-and-Huxley model (Hodgkin and Huxley 1952; McCormick, Wang, and Huguenard 1993), i.e. prediction of 96% of spike times (Brette and Gerstner 2005). We were wondering how well this model is in reproducing voltage traces of real neurons. It turns out that the model reproduces up to 96% (average 60%) of the spikes and matches accurately the subthreshold voltage. Later on, we showed that this model can account for different spiking regimes (Naud, Marcille, Clopath, and Gerstner 2008), like irregular spiking, bursting etc.

This model has 2 variables and 7 parameters, it therefore is a good trade-off between complexity and accuracy. Overfitting is avoided and the computational time is reasonable when used to test functional implications in long plasticity experiments.
Predicting neuronal activity with simple models of the threshold type: Adaptive Exponential Integrate-and-Fire model with two compartments

Abstract

An adaptive Exponential Integrate-and-Fire (aEIF) model was used to predict the activity of layer-V-pyramidal neurons of rat neocortex under random current injection. A new protocol has been developed to extract the parameters of the aEIF model using an optimal filtering technique combined with a black-box numerical optimization. We found that the aEIF model is able to accurately predict both subthreshold fluctuations and the exact timing of spikes, reasonably close to the limits imposed by the intrinsic reliability of pyramidal neurons.

Keywords: Adaptation; Exponential integrate-and-fire; Neuron; Spike timing

1. Introduction

Electrophysiological data can be described by detailed conductance-based models (Hodgkin–Huxley-type models [6]). However, those models are rather complex, which implies that they are difficult to analyze and costly to implement numerically. Moreover, it is unclear how many details of conductance-based models are really necessary for the reproduction of experimental spike patterns [4,13]. For those reasons, simple phenomenological spiking neurons such as Integrate-and-Fire models are highly popular.

The adaptive Exponential Integrate-and-Fire (aEIF) model used in this paper generalizes the standard leaky Integrate-and-Fire model in several directions: the strict threshold is replaced by a more realistic smooth threshold zone as in the Exponential Integrate-and-Fire neuron [2]. Furthermore, addition of a second variable captures subthreshold resonance or adaptation [7,15]. The aEIF model showed convincing performances when compared to more detailed models [1], but so far, has never been tested on recordings of real neuron.

In this report, we will test the performances of the aEIF model on layer-V neocortical pyramidal neurons under random current injection.

2. Model

The aEIF is defined by [1]

$$C \frac{du(t)}{dt} = - g_L (u(t) - E_L) + g_L A_T \exp \left( \frac{u(t) - V_T}{A_T} \right) - w + I,$$

(1)

$$\tau_w \frac{dw(t)}{dt} = a(u(t) - E_L) - w(t),$$

(2)

where $C$ is the membrane capacitance, $g_L$ the leak conductance, $E_L$ the resting potential, $A_T$ the slope factor and $V_T$ the threshold potential (Fig. 1). Note that formally, $E_L$ is not exactly the resting potential because of the

exponential term. The variable $w$ describes the level of adaptation of the neuron and $a$ represents the relevance of the exponential term. The variable $w$ describes the level of adaptation of the neuron and $a$ represents the relevance of adaptation of the neuron and $a$ represents the relevance of subthreshold adaptation. The exponential term describes the early activation of voltage-gated sodium channels.

Formally the model is said to generate a spike if the potential $u$ grows rapidly to infinity. In practice, a spike event is recorded when the voltage reaches a threshold $V_{peak} = 20 \text{mV}$. The exact value is not critical because $V_{peak}$ only shifts spike times by a fraction of millisecond. After the spike has been triggered, $u$ is reset to the resting potential $E_L$ and the variable $w$ is increased by an amount $b$, which accounts for spike-triggered adaptation.

The original aEIF model is a point neuron model i.e. without spatial structure. However, in this study, we decided to take into account the coupling of the soma with the dendrites. Therefore, we used a two-compartment model (one somatic compartment coupled to a passive dendritic compartment) defined by

$$\frac{du_s}{dt} = -g_L(u_s - E_L) - \frac{g_c}{p}(u_s - u_d) + g_L \alpha \exp \left( \frac{u_s - V_T}{\alpha} \right) - w + I,$$

$$\frac{du_d}{dt} = -g_L(u_d - E_L) - \frac{g_c}{1-p}(u_d - u_s),$$

$$\tau_w \frac{dw}{dt} = a(u_s - E_L) - w,$$ (5)

where $u_s$ is the membrane voltage in the somatic compartment, $u_d$ the membrane voltage in the dendritic compartment, $g_c$ the coupling conductance and $p = \text{somatic area}$/total area. The two-compartment model is motivated by experimental results. Indeed, the linear response kernel is best fitted by a double exponential (see below point 3(i)), suggesting a coupling between soma and a passive dendrite acting as current sink [8].

3. Parameter fitting

Recordings of layer-V pyramidal neurons of rat neocortex were used to determine parameters of the model. The neurons were recorded intracellularly in vitro while stimulated at the soma by a randomly fluctuating current generated by an Ornstein–Uhlenbeck (OU) process (autocorrelation time 1 ms). Both mean and variance of the OU process were varied in order to sample the response of the neurons to various levels of tonic and time-dependent inputs. Details of the experimental procedure can be found in [14].

Our method to extract the parameters of the aEIF model is based on the following steps:

(i) Passive membrane properties ($C$, $g_L$, $g_c$, $p$, $E_L$): In the subthreshold regime (where the exponential term can be neglected), Eqs. (3) and (4) can be integrated [3],

$$u(t) = \int_0^t \kappa_\infty(s) I(t - s) \, ds.$$ (6)

In the non-adapted state $w = 0$, we find

$$\kappa_\infty(s) = \frac{1}{C}[p e^{-s/\tau_e} + (1-p) e^{-s/\tau_c}].$$ (7)

where $\tau_e = C/g_L$ is the somatic membrane time constant and $\tau_c = (p(p - 1)C)/(p(p - 1)g_L - g_c)$ is the coupling time constant. The kernel $\kappa_\infty$ is extracted by the Wiener–Hopf optimal filtering technique [8]. This step involves a comparison of the subthreshold fluctuations with the corresponding input current. This yields a “raw” filter $\kappa_{exp}$ (Fig. 2). The filter $\kappa_{exp}$ is well fitted by the double exponential $\kappa_\infty$ derived from our two-compartment model. $C$, $g_L$, $g_c$, $p$ were extracted from the double exponential fit $\kappa_\infty$ (Eq. (7)) of $\kappa_{exp}$, $E_L$ from the resting value at the beginning of the recording.

(ii) Slope factor: The slope factor determines the sharpness of the threshold. In the limit $\Delta_T \to 0$, the model becomes a standard leaky Integrate-and-Fire model. As the threshold has a region of fuzziness, we decided to fix the slope factor at $\Delta_T = 2 \text{mV}$ so as to restrict the number of parameters to be optimized. This value seems reasonable and is close to the value found for the Wang–Buszaki model [2].

(iii) Subthreshold adaptation: According to systems theory, it is not possible to extract the subthreshold adaptation $a$ from our data set. Therefore, we set $a$ to zero. Indeed, the Laplace transformed system has one pole and one zero that mask each other (i.e. the determinant of the identifiability matrix is
close to zero), preventing the system to be fully characterizable [10].

(iv) Voltage reset: After a spike has been triggered, the voltage is simply reset to the resting potential $E_L$.

(v) Optimization: Finally, the remaining parameters, $V_T$, $\tau_m$, $b$ were optimized using the simulated annealing technique optimizing the firing rate and maximizing the coincidence factor $\Gamma_{n \rightarrow m}$. We minimized the following expression:

$$2 \frac{|v_{\text{data}} - v_{\text{sim}}|}{v_{\text{data}}} = \Gamma_{n \rightarrow m},$$

where $v_{\text{data}}$ is the firing rate of the neuron data and $v_{\text{sim}}$ is the firing rate of the simulated data. $\Gamma_{n \rightarrow m}$ is defined by [9]

$$\Gamma_{n \rightarrow m} = \frac{N_{\text{coinc}} - \langle N_{\text{coinc}} \rangle}{2(N_{\text{data}} + N_{\text{aEIF}}) N},$$

where $N_{\text{data}}$ is the number of spikes in the reference spike train (recordings of pyramidal cells), $N_{\text{aEIF}}$ is the number of spikes in the predicted spike train (generated with the aEIF model with the same driving current), $N_{\text{coinc}}$ is the number of coincident spikes with precision $\Delta = 2\text{ ms}$ and $\langle N_{\text{coinc}} \rangle$ is the number of coincidences generated by a homogeneous Poisson process with the same rate $v_{\text{sim}}$ as the spike train generated with the aEIF model. Finally, the normalization $N = 1 - 2v_{\text{sim}}\Delta$ allows $\Gamma_{n \rightarrow m}$ to reach 1 only if the spike train of the aEIF model reproduces exactly the spike train of the cell. $\Gamma_{n \rightarrow m}$ will be 0 if the similarity between the two spike trains is not better than between that two random spike trains generated by homogeneous Poisson processes at the same rate. In order to test the robustness of the method, we picked one cell and repeated the parameter optimization by simulated annealing 10 times. We found that the $V_T$ is very robust within errors less than 3%. The parameters $b$ and $\tau_m$ are strongly correlated. While individual variance is high their product $b\tau_m$ is stable.

4. Results

The data set consists of four different neurons. For each cell, a set of 10 different input currents with different means and variances are injected. Each input trace is repeated four times. Fig. 3 shows a direct comparison between predicted and recorded spike trains for a typical neuron. Both spike trains are almost indistinguishable (Fig. 3A; for clarity reasons, the predicted spike train has been shifted upward). Even when zooming in the subthreshold regime, differences are in the range of a few millivolts only (Fig. 3B). The spike dynamics is correctly predicted apart from a short period of time just after the spike is emitted (Fig. 3C). This is due to the reset value of the voltage which is set to the resting potential.

The model performances were evaluated using the coincidence factor $\Gamma_{n \rightarrow m}$ (Eq. (8)). Our model is facing natural limits of prediction because cortical pyramidal neurons respond with very different reliability depending on the type of stimulation they receive [11]. As we cannot expect our model to yield better predictions than the intrinsic reliability of the neuron, we consider the intrinsic reliability of the neuron as an upper bound. The intrinsic reliability can be easily measured since the same input has been injected four times in the same cell. The reliability of neurons does not vary significantly with the mean of the injected current. However, it strongly depends on the variance of the current [8,11]. In the case of low variance, the spike timing is not controlled by the stimulus anymore. Therefore, we abandon the data with low variance ($\sigma < 150$ pA). Intrinsic reliability is characterized by the factor $\Gamma_{n \rightarrow n}$ in analogy to Eq. (8). The subscript $n \rightarrow n$ means that the neuron is compared to itself across two different trials with the same realization of the input. We remark that data with high variance input are more likely to resemble an in vivo situation than low variance input data. For data used below, the intrinsic reliability varies from $\Gamma_{n \rightarrow n} = 75\%$ to as low as $\Gamma_{n \rightarrow n} = 20\%$.

We found that the aEIF model predicts up to $\Gamma_{\text{eff}} = 96\%$ of the spikes that can be predicted ($\Gamma_{\text{eff}} = \Gamma_{n \rightarrow m}/\Gamma_{n \rightarrow n}$, $m \rightarrow n$ means model compared to neuron) and on average $\Gamma_{\text{eff}} = 60\%$ (Fig. 4).

Fig. 5 shows the experimental spike trains during four repetitions with the same driving current (bottom traces) as well as the simulated spike train (top trace) for different reliability and performance cases.

5. Discussion and conclusion

We tested the aEIF model on experimental electrophysiology recordings and found a prediction of the spike
times $G_{\text{eff}}$ up to 96% (average of 60%). With the same data set, a Spike Response Model with dynamic threshold has been evaluated and the performances were $G_{\text{eff}}$ up to 75% (average 65%) [8].

We remark that the protocol used for the recordings is not the most suitable for characterizing our model: in our extraction method, we had to set the subthreshold adaptation $\alpha$ to 0. In addition, data generated purely by simulation of the aEIF model were characterized very badly with our method (average of $G = 85\%$).

A completely different protocol to extract the parameters of the aEIF model has been proposed recently by Brette and Gestner [1]. This protocol contains a series of standard electrophysiological paradigms (injection of current pulses, slow current ramps and random conductance injections). It has been tested with data generated by a detailed model and yielded excellent performances ($G = 96\%$). In addition, this protocol allows to reduce noise (averaging over several recordings), so that the subthreshold adaptation $\alpha$ could, in principal, be extracted from pyramidal cell recordings. The latter protocol is under study at the moment using a new data set recorded following the methodology proposed by Brette and Gerstner [1].

In the aEIF model, adaptation is a useful component since it allows the model to account for different driving regimes. We found as well that it is relatively easy to correctly predict the subthreshold dynamics even with a simple leaky integrator but it is difficult to find an efficient threshold criterion for spike initiation. This problem is solved by the aEIF model which includes an additional exponential term to describe early activation of voltage-gated sodium channels. This last addition allows to model

---

**Fig. 3.** Performances of the aEIF model. A. Predictions of the model (grey line) are compared to the spike train of the corresponding neuron (black line). For this graph only, the simulated trace has been shifted by 40 mV upward for reasons of visual clarity. B. Zoom on the subthreshold regime. C. Zoom on four correctly predicted spikes.

**Fig. 4.** The performance of the aEIF ($G_{m\rightarrow n}$) is plotted versus the intrinsic reliability ($G_{n\rightarrow n}$) for each data set. The diagonal yields the upper bound of the model. The average prediction is shown by the dashed line ($G_{\text{eff}} = G_{n\rightarrow n}/G_{n\rightarrow n} = 0.6$). More details on the specific cases A, B, C are shown in Fig. 5.
specific behaviors like delayed spike initiation and offers flexibility at the level of the threshold mechanism. It was recently suggested by Naundorf and colleagues that the rapid dynamics of action potential initiation in cortical neurons are outside the range of behaviors described by the classical Hodgkin–Huxley theory [12]. In the aEIF model, the exponential term allows a fast activation of the action potential. Thus, on a phenomenological level, the aEIF model could possibly account for rapid spike initiation in real neurons.

References

Fig. 5. The lower four spike trains of each graph are experimental voltage traces recorded in response to the same driving current. The top trace is the simulated spike train with this driving current. The traces shown in A have a high intrinsic reliability and high prediction, i.e. the model is good. B has high reliability but a bad prediction, i.e. the model is insufficient. In C the reliability is low and the prediction is low, but the model is good since $\Gamma_{\text{eff}}>0.65$. See Fig. 4 for the $\Gamma$ values of the different cases A, B, C.
Claudia Clopath has obtained her M.Sc. in physics from the EPFL, in April 2005. She is now a Ph.D. in the Laboratory of Computational Neuroscience at the EPFL and her current research interest is to describe neuronal activity with simple Integrate-and-Fire type models.

Renaud Jolivet obtained his Ph.D. in theoretical neuroscience at EPFL, in 2005, after studies in biophysics at the University of Lausanne (M.Sc.). He is now a postdoc in the laboratory of Prof. Pierre Magistretti at the University of Lausanne where his research is focused on neuro-astrocytic interactions in the context of brain metabolism and signal processing.

Alexander Rauch obtained his M.D., in 2003, at the University of Bern after studies in medicine at the University of Basel. His clinical experience includes surgery and neurorehabilitation. Between 1999 and 2003, he has worked as an electrophysiologist at the University of Bern focusing his research on links between cortical pyramidal neurons and simple models of neuronal activity. He is now a research assistant in the laboratory of Prof. Nikos Logothetis at the Max-Planck-Institute where his research is focused on BOLD signal and brain imaging techniques.

Hans-Rudolf Lüscher is Director of the Department of Physiology, University of Bern, Switzerland. He has a Medical Degree from the University of Zürich, Switzerland. He did his postdoctoral training with Elwood Henneman at the Department of Physiology and Biophysics, Harvard Medical School, Boston, USA. He spent extended time periods at the Division of Neuroscience, John Curtin School of Medical Research, Canberra, Australia. Hans-Rudolf Lüscher served as Dean and Vice-Dean of the Medical Faculty, University of Bern. He is a member of the Science Council of the Swiss National Science Foundation and of the Swiss Academy of Medical Sciences.

Wulfram Gerstner received his Ph.D. degree in theoretical physics from the TU Munich, Germany, in 1993, after studies in Tübingen, Berkeley, and Munich. He is a Professor and Head of Laboratory of Computational Neuroscience, EPFL, Switzerland.
Chapter 3

MODEL OF THE INDUCTION OF LONG-TERM SYNAPTIC PLASTICITY AND ITS FUNCTIONAL IMPLICATIONS

Standard models for Spike-Timing-Dependent Plasticity (STDP) take into account pair interactions of presynaptic and postsynaptic spike times (Gerstner, Kempter, van Hemmen, and Wagner 1996; Kempter, Gerstner, and van Hemmen 1999; Senn, Tsodyks, and Markram 2001; Song, Miller, and Abbott 2000; van Rossum, Bi, and Turri
giano 2000; Gütig, Aharony, Rotter, and Sompolinsky 2003a; Karmarkar and Buonomano 2002). However, a number of pairing experiments (Wang, Gerkin, Nauen, and Bi 2005; Sjöström, Turri
giano, and Nelson 2001) show that pair interactions are not sufficient to fully describe Long-Term Potentiation and Depression (LTP/LTD) (Pfister and Gerst
ner 2006). Moreover, by construction, simple spike-based models fail in voltage clamp experiments, where LTP or LTD can be induced by coincidence of presynap
ptic spike arrival and depolarization of the postsynaptic membrane (Artola, Brö
er, and Singer 1990; Ngezahayo, Schachner, and Artola 2000). The following paper presents a triplet model which takes into account the presynaptic spike times and the postsynaptic membrane potential, filtered with three different time constants. For spike induced experiments, this model can formally be reduced to the triplet rule proposed by Pfister et al. (Pfister and Gerstner 2006), and yields similar results to, for example, frequency dependent pairing experiments by Sjöström et al. (Sjöström, Turri
giano, and Nelson 2001). Moreover, it also reproduces the behavior of the ABS rule (Artola, Bröcher, and Singer 1990), i.e. no synaptic changes are observed under presynaptic stimulation when the postsynaptic potential is hyperpolarized; while small depolarization leads to LTD and strong depolarization to LTP (Fig 1.2A). Additionally, this model can describe the hybrid experiment by Sjöström et al. where low-frequency potentiation is rescued by depolarization (Sjöström, Turri
giano, and Nelson 2001). It offers testable predictions as to how other protocols may change the weights. This model therefore closes the debate whether STDP is more fundamental than voltage dependence (Lisman and Spruston 2005) since it shows that most if not all existing experimental data on STDP can be derived from a model with voltage dependence.

This paper also explores the functional consequences of this model. Due to its similarity to the well-known rate-based Bienenstock-Cooper-Munro model (Bienenstock, Cooper, and Munro 1982), the model exhibits selectivity in the
inputs, which can be seen in receptive field development scenarios. In addition, the model performs ICA-like computation. For example when presented with natural scenes the weights develop Gabor-like oriented filters. Finally, due to the frequency dependence of the model (Sjöström, Turrigiano, and Nelson 2001), a plastic network under this model exhibits a tight relation between connectivity and coding. Under rate coding the network supports a few strong bidirectional connections in a sea of weak connections as measured in visual cortex (Song, Sjöström, Reigl, Nelson, and Chklovskii 2005). On the contrary standard STDP models (Gerstner, Kempter, van Hemmen, and Wagner 1999; Kempter, Gerstner, and van Hemmen 1999; Senn, Tsodyks, and Markram 2001; Song, Miller, and Abbott 2000; van Rossum, Bi, and Turrigiano 2000; Günter, Aharonov, Rotter, and Sompolinsky 2003a) do not support stable bidirectional connections. Interestingly a network under temporal code leads, with our model, to stable unidirectional connections as seen in the barrel cortex (Lefort, Tomm, Sarria, and Petersen 2009).

Abstract

Electrophysiological connectivity patterns in cortex often show a few strong connections in a sea of weak connections. In some brain areas a large fraction of strong connections are bidirectional, in others they are mainly unidirectional. In order to explain these connectivity patterns, we use a model of Spike-Timing-Dependent Plasticity where synaptic changes depend on presynaptic spike arrival and the postsynaptic membrane potential, filtered with two different time constants. The model describes several nonlinear effects in STDP experiments, as well as the voltage dependence of plasticity under voltage clamp and classical paradigms of LTP/LTD induction. We show that in a simulated recurrent network of spiking neurons our plasticity rule leads not only to receptive field development, but also to connectivity patterns that reflect the neural code: for temporal coding paradigms strong connections are predominantly unidirectional, whereas they are bidirectional under rate coding. Thus variable connectivity patterns in the brain could reflect different coding principles across brain areas; moreover our simulations suggest that rewiring the network can be surprisingly fast.

1 Introduction

Experience-dependent changes in receptive fields [1, 2, 3] or in learned behavior [4] may occur through changes in synaptic strength. Thus, electrophysiological measurements of functional connectivity patterns in slices of
neural tissue [5, 6] or anatomical connectivity measures [7] can only present a snapshot of the momentary connectivity—which may change with the next set of stimuli. Indeed, modern imaging methods show that spine motility can lead to a rapid rewiring of the connectivity pattern [8, 9] by formation of new synapses or by strengthening or weakening of existing synapses. The question then arises whether the connectivity patterns and changes that are found in experiments can be connected to basic rules of synaptic plasticity, in particular to modern or traditional forms of Hebbian plasticity [10] such as Long-Term Potentiation and Depression [11].

Long-term potentiation LTP and depression LTD of synapses depends on the exact timing of pre- and postsynaptic action potentials [12, 13], but also on postsynaptic voltage [14, 15], and presynaptic stimulation frequency [16]. Spike-Timing-Dependent Plasticity (STDP) has attracted particular interest in recent years, since temporal coding schemes where information is contained in the exact timing of spikes rather than mean frequency could be learned by a neural system using STDP [17, 18, 19, 20, 21]. The question, however, whether STDP is more fundamental than frequency dependent plasticity or voltage dependent plasticity rules has not been resolved, despite an intense debate [22]. Moreover it is unclear how the interplay of coding and plasticity yield the functional connectivity patterns seen in experiments. In particular, the presence or absence of bidirectional connectivity between cortical pyramidal neurons seems to be contradictory across experimental preparations in visual [5] or somatosensory cortex [6].

Recent experiments have shown that STDP is strongly influenced by postsynaptic voltage before action potential firing [23], but could not answer the question whether spike timing dependence is a direct consequence of voltage dependence, or the manifestation of an independent process. In addition, STDP depends on stimulation frequency [23] suggesting an interaction between timing and frequency dependent processes — or this interaction could be the manifestation of a single process in different experimental paradigms. We show that a simple Hebbian plasticity rule that pairs presynaptic spike arrival with the postsynaptic membrane potential is sufficient to explain STDP and the dependence of plasticity upon presynaptic stimulation frequency. Moreover, the intricate interplay of voltage and spike-timing dependence seen in experiments [23] as well as the frequency dependence of STDP can be explained in our model from one single principle. In contrast of earlier attempts towards a unified description of synaptic plasticity rule that focused on detailed biophysical descriptions [24, 25], our model is a mechanistic one (phenomenological model). It does not give an explicit interpretation in terms of biophysical quantities such a Calcium concentration [24], CaMKII [25], glutamate binding, NMDA receptors etc. Rather it aims at a minimal description of the major phenomena observed in electrophysiology experiments.

The advantage of such a minimal model is that it allows us to discuss functional consequences in small [26, 27], and possibly even large [28, 29], networks. We show that in small networks of up to 10 neurons the learning rule leads to input specificity, necessary for receptive field development - similar to earlier models of STDP [17, 26] or rate-based plasticity rules [30, 31]. Going significantly beyond earlier studies we explicitly address the question of whether functional connectivity patterns of cortical pyramidal neurons measured in recent electrophysiological studies [5, 6] could be the result of plasticity during continued stimulation of neuronal model networks. We found that connectivity patterns strongly depend on the underlying coding hypothesis: With a temporal coding hypothesis, where input spikes arrive in a fixed temporal order, the recurrent network develops a connectivity
pattern with a few strong unidirectional connections. However, under a rate coding paradigm, where stimuli are stationary during a few hundred milliseconds the same network exhibits sustained and strong bidirectional connections. This is in striking contrast to standard STDP rules where bidirectional connections are impossible [26].

The mathematical simplicity of the model enables us to identify conditions under which it becomes equivalent to the well-known Bienenstock-Cooper-Munro model [30] used in classical rate-based descriptions of developmental learning; and equivalent to some earlier models of STDP [32] — and why our model is fundamentally different from classical STDP models [17, 26, 21], widely used for temporal coding.

2 Results

In order to study how connectivity patterns in cortex can emerge from an interplay of plasticity rules and coding, we need a plasticity rule that is consistent with a large body of experiments, not just a single paradigm such as STDP. Since synaptic depression and potentiation take place through different pathways [33] our model uses separate additive contributions to the plasticity rule, one for LTD and another one for LTP (see Fig. 1 and methods).

2.1 Fitting the Plasticity Model to Experimental Data

Consistent with voltage clamp [15] and stationary depolarization experiments [14] LTD is triggered in our model if presynaptic spike arrival occurs while the membrane potential of the postsynaptic neuron is slightly depolarized (above a threshold $\theta_-$) whereas LTP occurs if depolarization is big (above a second threshold $\theta_+$) (see Fig. 1). The mathematical formulation of the plasticity rule makes a distinction between the momentary voltage $u$ and the low-pass filtered voltage variables $\bar{u}_-$ or $\bar{u}_+$ which denote temporal averages of the voltage over the recent past (the symbols $\bar{u}_-$ and $\bar{u}_+$ indicate filtering of $u$ with two different time constants). Similarly, the event $x$ of presynaptic spike arrival needs to be distinguished from the trace $\bar{x}(t)$ that is left at the synapse after stimulation by neurotransmitter. Potentiation occurs only if the momentary voltage is above $\theta_+$ (this condition is fulfilled during action potential firing) AND the average voltage $\bar{u}_+$ above $\theta_-$ (this is fulfilled if there has been a depolarization in the recent past) AND the trace $\bar{x}$ left by a previous presynaptic spike event is nonzero (this condition holds if a presynaptic spike arrived a few milliseconds earlier at the synapse); these conditions for plasticity are illustrated in Fig. 1B. LTD occurs if the average voltage $\bar{u}_-$ is above rest at the moment of a presynaptic spike arrival (see Fig. 1A). The amount of LTD in our model depends on homeostatic process on a slower time scale [34]. Low-pass filtering of the voltage by the variable ($\bar{u}_-$ or $\bar{u}_+$) refers to some unidentified intracellular processes triggered by depolarization, e.g., increase in calcium concentration or second messengers messenger chains. Similarly, the biophysical nature of the trace $\bar{x}$ is irrelevant for the functionality of the model, but a good candidate process is the fraction of glutamate bound to postsynaptic receptors.

We checked the performance of the model on a simulated STDP protocol, where presynaptic spikes arrive
a few milliseconds before or after a postsynaptic spike that is triggered by a strong depolarizing current pulse. If a post-pre pairing with a timing difference of 10 milliseconds is repeated 60 times at frequencies below 35Hz, LTD occurs in our model (Fig. 2 A, B), consistent with experiments [23]. Repeated pre-post pairings (with 10 millisecond timing difference) at frequencies above 10Hz yield LTP, but pairings at 0.1Hz do not show any significant change in the model or in experiments [23]. In the model these results can be explained by the fact that at 0.1Hz repetition frequency, the low-pass filtered voltage $\bar{u}_+$ which increases abruptly during postsynaptic spiking decays back to zero before the next impulse arrives, so that LTP can not be triggered. However, since LTD in the model requires only a weak depolarization of $\bar{u}_-$ at the moment of presynaptic spike arrival, post-pre pairings give rise to depression, even at very low frequency. At repetition frequencies of 50Hz, the post-pre paradigm is nearly indistinguishable from a pre-post timing, and LTP dominates.

Since spike-timing dependence in our model is induced only indirectly via voltage dependence of the model, we wondered whether our model would also be able to account for the intricate interactions of voltage and spike timing found by Sjöström et al. [23]. If a pre-post protocol at 0.1Hz, that normally does not induce LTP, is combined with a depolarizing current pulse (lasting from 50ms before to 50ms after the postsynaptic firing event), then potentiation is observed in the experiments [23], as well as in our model (Fig. 2 C, F, I). Due to the injected current, the low-pass filtered voltage variable $\bar{u}_+$ is depolarized before the pairing. Thus at the the moment of the postsynaptic spike, the average voltage $\bar{u}_+$ is above the threshold $\theta_-$ leading to potentiation. Similarly, a pre-post protocol that normally leads to LTP can be blocked if the postsynaptic spikes are triggered on the background of a hyperpolarizing current (Fig. 2 E, H, I).

In order to study some nonlinear aspects of STDP, we simulate a protocol of burst-timing-dependent plasticity where presynaptic spikes are paired with 1, 2 or 3 postsynaptic spikes [35] (see Methods). We observe that 60 pre-post pairs at 0.1Hz do not change the synaptic weight, as discussed above. However, repeated triplets pre-post-post generate potentiation in our model because the first postsynaptic spike induces a depolarizing spike after potential so that $\bar{u}_+$ is depolarized. Adding a third postsynaptic spike to the protocol (i.e., quadruplets pre-post-post-post) does not lead to stronger LTP (Fig. 3A). Our model also describes the dependence of LTP upon the intra-burst frequency (Fig. 3B). At an intra-burst frequency of 20Hz, no LTP occurs, because the second spike in the burst comes so late that the presynaptic trace $\bar{x}$ has decayed back to zero. At higher intra-burst frequencies, the three conditions for LTP ($u(t) > \theta_+$ and $\bar{u}_+ > \theta_-$ and $\bar{x} > 0$) are fulfilled. The burst timing dependence (Fig. 3C) is qualitatively similar to that found in experiments [35], but only four of the six experimental data points are quantitatively reproduced by the model.

### 2.2 Functional implications

Connectivity patterns in a local cortical circuit have been shown to be non-random, i.e. the majority of connections are weak and the rare strong ones have a high probability of being bidirectional [5]. However, standard models of STDP do not exhibit stable bidirectional connections [36]. Intuitively, if the cell A fires before the cell B, a pre-post pairing for the 'AB' connection is formed so that the connection is strengthened. The post-pre
pairing occurring at the same time in the 'BA' connection leads to depression. Therefore it is impossible to strengthen both connections at the same time. Moreover, in order to assure long-term stability of firing rates parameters in standard STDP rules are typically chosen such that inhibition slightly dominates excitation [17] which implies that under purely random spike firing connections decrease, rather than increase. However, the non-linearity aspects of plasticity in our model change such a simple picture. If we simulate two neurons with bidirectional connections at low firing rates, the plasticity model behaves like standard STDP and only unidirectional connections emerge. However, from Fig. 3B we expect that at higher neuronal firing rates, our model could develop a stable bidirectional connection, in striking contrast to standard STDP rules [21].

Since bidirectional connections require neurons to fire at a high rate, we wondered how coding and connectivity relate to each other. We hypothesized that bidirectional connections are supported by rate-coding as opposed to temporal-coding. To test this idea we first simulated a small network of 10 all-to-all connected neurons in a simplified rate-coding scheme where each neuron fires at a fixed frequency, but the frequency varies across neurons. We find that bidirectional connections are formed only between those neurons that both fire at a high rate, but not if one or both of the neurons fire at low frequencies (Fig. 4A). In a second paradigm, the neurons in the same network are stimulated such that they are firing in a distinct order (1, 2, 3,...) mimicking an extreme form of temporal coding [37]. In that case, the weights form a loop where strong connections from 1 to 2, 2 to 3, ... develop, but no bidirectional connections (Fig. 4B). These results are in striking contrast to simulation experiment with a standard STDP rule, where connections are always unidirectional, independently of coding (Fig. 4C, D).

We wondered whether the same results would emerge in a more realistic network of excitatory and inhibitory neurons driven by feedforward input. We simulated a network of 10 excitatory neurons and 3 inhibitory neurons. Each inhibitory neuron receives input from 8 randomly selected excitatory neurons and randomly projects back to 6 excitatory neurons. In addition to the recurrent input, each excitatory neuron receives feedforward spike input from 500 presynaptic neurons \( j \) that generate stochastic Poisson input at a rate \( \nu_j \). The rates of neighboring input neurons are correlated, mimicking the presence or absence of spatially extended objects. In a rate-coding scheme, the location of the stimulus is switched every 100ms to a new random position. In case of retinal input, this would correspond to a situation where the subject fixates every 100ms on a new stationary stimulus. In a temporal-coding paradigm, the model input is shifted every 20ms to a neighboring location, mimicking movement of an object across an array of sensory receptors. For both scenarios the network is identical. Feedforward connections and lateral connections between model pyramidal neurons are plastic whereas connections to and from inhibitory neurons are fixed.

After 1000s of stimulation with the rate-coding paradigm, the excitatory neurons developed localized receptive fields and a structured pattern of synaptic connections (Fig. 5B). While the labeling of the excitatory neurons at the beginning of the experiment was randomly assigned, we can relabel the neurons after the formation of lateral connectivity patterns so that neurons with strong reciprocal connections have similar indices, reflecting the neighborhood relation of the network topology. After reordering we can clearly distinguish that three groups of neurons have been formed, characterized by similar receptive fields and strong bidirectional
connectivity within the group, and different receptive fields and no lateral connectivity between groups (Fig. 5C). If the overall amplitude of plastic changes is small (compared to that found in the experiments) the pattern of lateral connectivity is stable and shows a few strong bidirectional connections in a sea of weak lateral connectivity. Unidirectional strong connections are nearly absent. If the amplitude and rate of plasticity is more realistic and in agreement with the data of Fig. 2, then the pattern of lateral connectivity changes between one snapshot and another one 5 seconds later, but the overall pattern is stable when averaged over 100s. In each snapshot, about half of the strong connections are bidirectional (Fig. 5H).

This is in striking contrast with the temporal coding paradigm. Neurons develop receptive fields similar to those seen with the rate-coding paradigm. As expected for temporal Hebbian learning rate \cite{21} the receptive field slowly shifts over time. More importantly, amongst the lateral connections, strong reciprocal links are completely absent (Fig. 6). This suggests that temporal coding paradigms are reflected in the functional connectivity pattern by strong uni-directional connections whereas rate coding leads to strong bidirectional connections.

3 Discussion

Plasticity models over the last decades have primarily focused on questions of development of receptive fields and cortical maps \cite{30}, or memory formation \cite{38}. Because traditional plasticity rules are rate models, the relation between coding and connectivity could not be studied. Our plasticity rule is formulated on the level of postsynaptic voltage. Since action potentials present large and narrow voltage peaks, they act as singular events in a voltage rule so that in the presence of spike our rule turns automatically into spike-timing dependent rule. Indeed, for spike coding (and in the absence of significant subthreshold voltage manipulations) our plasticity rule behaves like a STDP rule where triplets of spikes with pre-post-post or post-pre-post timing evoke LTP, whereas pairs with post-pre timing evoke LTD. Moreover, for rate coding where pre- and postsynaptic neurons fire with Poisson firing statistics, our plasticity rule presents structural similarities to the model of Bienenstock, Cooper, and Munro (BCM-model, \cite{30}). Both our spiking rule and the rate-based BCM model require presynaptic activity in order to induce a change. Furthermore for our rule as well as for the simplest BCM rule (see \cite{30}), the depression terms are linear and the potentiation terms are quadratic in the postsynaptic variables (i.e., the postsynaptic potential or the postsynaptic firing rate). Beyond these qualitative similarities, an approximate quantitative relation between the BCM model and our model can be constructed under appropriate assumptions. In this case the total weight change \( \Delta w \) in our model is proportional to \( \nu_{\text{pre}} \nu_{\text{post}} (\nu_{\text{post}} - \vartheta) \) where \( \nu_{\text{pre}} \) and \( \nu_{\text{post}} \) denotes the firing rate of a pre- and postsynaptic neurons, respectively and \( \vartheta \) is a sliding threshold related to the ratio between the LTP and LTD inducing processes (see methods).

Due to its similarities to BCM, it is not surprising that our spike-based learning rule with sliding threshold is able to support independent component analysis (ICA) that has been hypothesized to underly receptive field development \cite{30,39}. In our experiments, the input consists of small patches of natural images using standard preprocessing \cite{40}. Image patches are selected randomly and presented to the neuron for \( T = 200 \text{ms} \), which
is on the order of a fixation time between saccades [41]. Pixel intensities above an average grey value are converted to spike trains of ON-cells and those below reference intensity to spikes in OFF-cells, using the relative intensity as the rate of a Poisson process. The spike trains from ON- and OFF-cells are the input to a cortical neuron. The synaptic weights undergo plasticity following our learning rule (Eq. 3). After learning, the weights exhibit a spatial structure that can be interpreted as a receptive field (Fig. 7). In contrast to the principal component analysis of the image patches (as for example implemented by Hebbian learning in linear neurons [42]), the receptive fields are localized (i.e. the region with significant weights does not stretch across the whole image patch). Development of localized receptive fields can be interpreted as a signature of ICA [40]. In contrast to most other ICA algorithms [43] our rule is biologically more plausible since it is consistent with a large body of plasticity experiments.

For a comparison of our model with experiments we have mainly focused on experiments in slices of visual cortex, but some of the results can also be related to work in hippocampus. First, as the model explicitly takes into account the postsynaptic membrane potential it can successfully reproduce the voltage dependence of LTP/LTD seen in experiments under depolarization of the postsynaptic membrane [14, 15]. Second, for classical STDP experiments such as [13, 23, 44], which have a stimulation protocol unambiguously defined in terms of pre- and postsynaptic spike times, the model gives a timing dependence reminiscent of the typical STDP function [13]. Moreover in contrast to standard STDP rules [21], more complicated effects such as the pairing frequency dependence [23] and burst-timing dependence plasticity [35] are qualitatively described. In addition the rule is expected to reproduce the triplet and quadruplet experiments in hippocampal slices [44] (data not shown), because for all STDP protocols the plasticity rule in this paper is similar to an earlier nonlinear STDP rule [32]. Deriving STDP rules from voltage dependence has been attempted before [45, 46]. However, since these earlier models use the momentary voltage [46] or its derivative [45], rather than a combination of momentary and averaged voltage as in our model, these earlier models cannot account for the broad range of nonlinear effects in STDP experiments or interaction of voltage and spike-timing. Our model shows similarities with LTP induction in the TagTriC model [47], but the TagTriC model focuses on the long-term stability of synapses, rather than spike timing dependence of the induction mechanism.

Our plasticity rule allows to explain experiments from two different laboratories by one single principle. Both the "potentiation is rescued by depolarization" [23] scenario (Fig. 2F) and that of burst-timing dependent LTP [35] (Fig. 3) show that LTP at low frequency is induced when the membrane is depolarized before the pre-post pairing. This depolarization can be due to a previous spike during a postsynaptic burst [35] or to a depolarization current. Our model is also consistent with results that LTP can be induced in distal synapses only if additional cooperative input or dendritic depolarization prevent failure of backpropagating action potentials [48]. A further unexpected result is that, with the set of parameters derived from visual cortex slice experiments, synapses fluctuate between strong and weak weights. This aspect is interesting in view of synapse mobility reported in imaging experiment [8].

There are, however, certain limitations to our plasticity rule. First, we did not address the problem of weight dependence of synaptic plasticity and simply assumed that weights can grow to a hard upper bound. Neverthe-
less, the rule can be easily changed to soft bounds \[21\] by changing the prefactors \(A_{\text{LTP}}, A_{\text{LTD}}\) accordingly \[47\].

Second, short term plasticity \[49\] could be added for a better description of the plasticity phenomena occurring especially during high frequency protocols. Third, our plasticity rule describes only induction of potentiation or depression during the early phase of LTP/LTD \[50\]. Additional mechanisms need to be implemented in the model to describe the transition from early to late LTP/LTD \[47, 51\]. Finally, in modeling voltage-clamp experiments, we assume in our model a unique voltage throughout the whole neuron. In particular the dendrite is assumed to be equipotential to the soma. Yet, experiments controlling the voltage at the soma do not guarantee an equal or even fixed voltage at the synapse with respect to the soma. An obvious and promising improvement would be to use a multi-compartment neuron model (e.g., distinct compartments for the soma and dendrites).

In the presented work we did not use a more sophisticated multi-compartment model as this would introduce a considerable number of new parameters making overfitting more likely to occur.

Our plasticity model leads to several predictions that could be tested in slice experiments. First, under the assumption of voltage clamp, our rule is linear in the presynaptic activities (see Methods). Thus the model predicts that in voltage clamp experiments the weight change is only dependent on the voltage and the number of presynaptic spikes but not on their exact timing (e.g., low frequency, tetanus, burst input should give the same result). Second, in the scenario where potentiation is rescued by depolarization, the amount of weight change should be the same whether a depolarizing current of amplitude \(B\) stops precisely when the postsynaptic spike is triggered or whether a current of slightly bigger amplitude \(B'\) stops a few milliseconds earlier. Third, multiple STDP experiments have shown that pre-post pairing (with 10 millisecond timing difference) repeated at 10Hz leads to potentiation \[23\]. In our plasticity model, LTP occurs in that case because the depolarizing spike-afterpotential of the last postsynaptic spike leads to an increase of the filtered membrane voltage just before the next postsynaptic spike.

If this interpretation is correct, a hyperpolarizing current sufficient to cancel the spike afterpotential during 40 milliseconds should block LTP (note that this is different from blocking LTP by a hyperpolarizing current a few milliseconds before the next spike \[23\]). Alternatively cutting dendrites, i.e. dendrotomy \[52\] would sharpen the spike after potential.

The influence of STDP on temporal coding has been studied in the past primarily with respect to changes in the feedforward connections \[21\]. The effect of STDP on lateral connectivity has been studied much less \[28, 29, 27\]. We have shown in this paper that, because of STDP, coding influences the network topology, because different codes give different patterns of lateral connectivity. Our results are in contrast to standard STDP rules which always suppress short loops, and in particular bidirectional connections \[36\]. Our more realistic plasticity model shows that under a rate coding paradigm bidirectional connectivity and highly connected clusters with multiple loops are not only possible, but even dominant. It is only for temporal coding, that our biologically plausible rule leads to dominant unilateral directions. Our model also predicts that for a code consisting of synchronous firing events at low frequencies synapses decrease, consistent with earlier findings \[27\]. We speculate that the differences in coding between different brain areas could lead, even if the learning rule were exactly the same, to different network topologies. Our model predicts that experiments where cells in a recurrent network are repeatedly stimulated in a fixed order would decrease the fraction of strong bidirectional connections, whereas
a stimulation pattern where clusters of neuron fire at high rate during episodes of a few hundred milliseconds would increase this fraction. In this views it is tempting to connect the low degree of bidirectional connectivity in barrel cortex [6] to the bigger importance of temporal structure in whisker input [37], compared to visual input.

Figure 1: Illustration of the model. Synaptic weights react to presynaptic events (top) and postsynaptic membrane potential (bottom) A. The synaptic weight is decreased if a presynaptic spike \( x \) (green) arrives when the low pass filtered value \( \bar{u} \) (magenta) of the membrane potential is above \( \theta^- \) (dashed horizontal line) B. The synaptic weight is increased if the membrane potential \( u \) (black) is above a threshold \( \theta^+ \) and the low pass filtered value of the membrane potential \( \bar{u} \) (blue) higher than a threshold \( \theta^- \) as well as the presynaptic low pass filter \( \bar{x} \) (orange) non zero. C. Step current injection makes the postsynaptic neuron fire at 50Hz in the absence of presynaptic stimulation (membrane potential \( u \) in black). No weight change is observed. Note the depolarizing spike-afterpotential consistent with experimental data D., reproduced from [23]. E-H. Voltage clamp experiment. A neuron receives weak presynaptic stimulation of 2Hz during 50s while the postsynaptic voltage is clamped to values between -60mV and 0mV. E-G. Schematic drawing of the trace \( \bar{x} \) (orange) of the presynaptic spike train (green) as well as the voltage (black) and the synaptic weight (blue) for the experimental conditions E. Hyperpolarization F. Slight depolarization and G. Large depolarization. H. The weight change as a function of clamped voltage using the standard set of parameters for visual cortex data (blue line, voltage paired with 25 spikes at the synapse). With a different set of parameters the model fits experimental data (red circles) in hippocampal slices [15], see methods for details.

Figure 2: A-B. Simulated STDP experiments. A. Spike-timing dependent learning window. The change of the synaptic weight is shown for different time intervals \( T \) between the presynaptic and the postsynaptic spike using 60 presynaptic/postsynaptic spike pairs at 20Hz. B. Weight change as a function of repetition frequency for 5 spike pairs at frequency \( \rho \) with a time delay of +10ms (pre-post, blue) and -10ms (post-pre, red), repeated 15 times at 0.1Hz (only 10 times for frequency of \( \rho=0.1\text{Hz} \). Weight changes are shown as a function of the frequency, dots represent the data taken from Sjöström et al. [23] and lines the plasticity model simulation. C-I. Interaction of voltage and STDP. C-E. Schematic induction protocols (green: presynaptic input, black: postsynaptic current, blue: evolution of synaptic weight). C. Low-Frequency Potentiation is rescued by depolarization [23]. Low frequency (0.1Hz) pre-post spike pairs yield LTP if a 100ms-long depolarized current is injected around the pairing. D. LTP fails in the previous scenario if an additional brief hyperpolarized pulse is applied 14-ms before postsynaptic spike so that voltage is brought to rest. E. Hyperpolarization preceding action potential prevents potentiation. Sjöström et al. [23] show that high frequency (40Hz) pairing leads to LTP. However, when a constant hyperpolarizing current is applied on top of the short pulses inducing the spikes, no weight change is measured. F. The simulated postsynaptic voltage \( u \) (black) following protocol A. is shown as well as the temporal averages \( \bar{u} \) (magenta) and \( \bar{u}^+ \) (blue). The presynaptic spike time is indicated by the green arrow. Using the model Eq. 3 this setting results in potentiation. G. Same as F., but following protocol D. No weight change is measured. H. Same as F., but following protocol E. No weight change is measured. I. Histogram summarizing the normalized synaptic weight of the simulation (bar) and the experimental data [23] (dot, blue bar=variance) 0.1Hz pairing (control 1); 0.1Hz pairing with the depolarization (protocol C.); 0.1Hz pairing with the depolarization and brief hyperpolarization (protocol D.); 40Hz pairing (control 2); 40Hz pairing with the constant hyperpolarization (protocol E.). The parameters are summarized in Table 1B.
Figure 3: Burst-timing-dependent plasticity. One presynaptic spike is paired with a burst of postsynaptic spikes. This pairing is repeated 60 times at 0.1Hz. A. Normalized weight is shown as a function of the number of postsynaptic spikes (1, 2, 3) at 50Hz. (dots: data from [35], crosses: simulation). The presynaptic spike is paired +10ms before the first postsynaptic spike (blue) or -10ms after (red). B. Normalized weight as a function of the frequency between the three postsynaptic action potentials (dot: data, line: simulation; blue: pre-post, red: post-pre). C. Normalized weight as a function of the timing between the presynaptic spike and the first postsynaptic spike of a 3-spike burst at 50Hz (dot: data, line: simulation). A hard upper bound has been set to 250% normalized weight.

Figure 4: Weight evolution in a all-to-all connected network of 10 neurons. A. Rate code: Neurons fire at different frequencies, neuron 1 at 2Hz, neuron 2 at 4Hz... neuron 10 at 20Hz. The weights (bottom) averaged over 100s show that neurons with high firing rates develop strong bidirectional connections (light blue: weak connections (under 2/3 of the maximal value); yellow: strong unidirectional connections (above 2/3 of the maximal value); brown: strong bidirectional connections). The cluster is schematically represented on top ("after"). B. Temporal code: Neurons fire successively every 20ms (neuron 1 then 20ms later neuron 2, then 3...). Connections (bottom) are unidirectional with strong connections from presynaptic neuron with index n (vertical axis) to postsynaptic neuron with index n+1, n+2 and n+3 leading to a ring-like topology (top: schematic). C. Same but with standard STDP rule [17, 26, 21]. Bidirectional connections are impossible.

Figure 5: Plasticity during rate coding. A network of 10 excitatory neurons is connected to 3 inhibitory neurons and receives feedforward inputs from 500 Poisson spike trains with a Gaussian profile of firing rates. The center of the Gaussian is shifted randomly every 100ms. A. The schematic figure shows the network before and after the plasticity experiment. B-E. Learning with small amplitudes. Model parameters are taken from table 1B (visual cortex data) except for the amplitudes $A_{LTP}$ and $A_{LTD}$ which are reduced by a factor 100. B. Mean feedforward weights (left) and recurrent excitatory weights (right) averaged over 100s. The grey level graph for the feedforward weights (left) indicates that neurons develop receptive fields that are localized in the input space. The recurrent weights (right) are classified into: light blue - weak (less than 2/3 of the maximal weight), yellow - strong (more than 2/3 of the maximal weight) unidirectional, brown - strong reciprocal connections. The diagonal is white, since self-connections do not exist in the model. C. Same as (B) but for the sake of visual clarity the index of neurons is reordered so that neurons with similar receptive fields have adjacent numbers, highlighting that neurons with similar receptive fields (e.g., neurons 1 to 4) have strong bilateral connections. D. Three snap shots of the recurrent connections taken 5s apart indicating that recurrent connections are stable. E. Histogram of reciprocal, unidirectional and weak connections in the recurrent network averaged over 100s as in (B). The total number of weight fluctuations during 100s is 79 (noted on the figure). The histogram shows an average of 10 repetitions (errorbars are the standard deviation). F-I. Rate code during learning with normal amplitudes. Same network as before but standard set of parameters (table 1B, visual cortex). F. Receptive fields are localized; G. Reordering allows to visualize that the strong bidirectional give rise to clusters of neurons. These clusters are stable when averaged over 100 seconds, but H connections can change from one time step to the next. I. The percentage of reciprocal connections is high, but because of fluctuations (fluc) more than 1000 transitions between strong unidirectional to strong bidirectional or back occur during 100 seconds.
Figure 6: Temporal coding paradigm. The setting is the same as in Fig. 5 (parameters from table 1B, visual cortex) but the input patterns are moved successively every 20ms, corresponding to a step-wise motion of the Gaussian stimulus profile across the input neurons. A. The schematic figure shows the network before and after the plasticity experiment. B. Receptive fields are localized, but in the recurrent network no reciprocal connections appear. C. Reordering of neurons shows that the network develops a ring-like structure with strong unidirectional connections from neuron 8 (vertical axis) to neuron 7 and 6 (horizontal axis); from neuron 7 to neuron 6, 5, and 4; from neuron 4 to neuron 3, 2, and 1 etc. D. Some of the strong unilateral connections appear or disappear from one time step to the next, but the ring-like network structure persists, since the lines just below the diagonal are much more populated than the line above the diagonal. E. Reciprocal connections are completely absent, but unidirectional connections fluctuate several times between 'weak' and 'strong' during 100s.

Figure 7: A small patch of 16x16 pixels is chosen from the whitened natural images benchmark [40]. The patch is selected randomly and is presented as input to 512 neurons for 200ms. The positive part of the image is used as the firing rate to generate Poisson spike trains of the 256 "ON" inputs and the negative one for the 256 "OFF" inputs. B. The weights after convergence are shown for the "ON" inputs and the "OFF" inputs rearranged on a 16x16 image. The filter is calculated by subtracting the "OFF" weights from the "ON" weights. The filter is localized and bimodal, corresponding to an oriented receptive field.

Table 1: A. Parameters for the neuron model. B. Plasticity rule parameters for the various experiments. VC stands for Visual Cortex cells (for experimental details see [23], * standard set of parameters), SC for Somatosensory Cortex cells (see [35]) and HP for Hippocampal cells (see [15]). Bold numbers indicate the free parameters fitted to experimental data. Other parameters are set in advance to values based on the literature.

6 Methods

6.1 Neuron Model

In contrast to standard models of STDP, the plasticity model presented in this paper involves the postsynaptic membrane potential $u(t)$. Hence, predicting the weight change in a given experimental paradigm requires a neuron model that describes the temporal evolution of $u(t)$. For this purpose we chose the adaptive Exponential Integrate-and-Fire (AdEx) model [53] with an additional current describing the depolarizing spike after potential [54]. The neuron model is described by a voltage equation:

$$C \frac{du}{dt} = -g_L(u - E_L) + g_L \Delta_T \exp \left( \frac{u - V_T}{\Delta_T} \right) - w_{ad} + z + I$$

where $C$ is the membrane capacitance, $g_L$ the leak conductance, $E_L$ the resting potential and $I$ the stimulating current. The exponential term describes the activation of a rapid sodium current. The parameter $\Delta_T$ is called the slope factor and $V_T$ the threshold potential [53]. A hyperpolarizing adaptation current is described by the variable $w_{ad}$ with dynamics

$$\tau_{w_{ad}} \frac{d}{dt} w_{ad} = a(u - E_L) - w_{ad},$$

where $\tau_{w_{ad}}$ is the time constant of the adaption of the neuron. Upon firing the variable $u$ is reset to a fixed value $V_{reset}$ whereas $w_{ad}$ is increased by an amount $b$. The main difference to the Izhikevich model [55] is that
the voltage is exponential rather than quadratic allowing a better fit to data [54]. The spike afterpotential of
the cells used in typical STDP experiments [23] have a long depolarizing spike after potential. We therefore
add an additional current $z$ which is set to a value $I_{sp}$ immediately after a spike occurs and decays otherwise
with a time constant $\tau_z$.

$$\tau_z \frac{d}{dt} z = -z,$$

Finally, refractoriness is shown in pyramidal cells [54] and therefore is modeled with the adaptive threshold $V_T$.
Therefore $V_T$ is set to $V_{T_{max}}$ after a spike and decays to $V_{T_{rest}}$ with a time constant $\tau_{V_T}$ as measured in [54], i.e.

$$\tau_{V_T} \frac{d}{dt} V_T = -(V_T - V_{T_{rest}}).$$

Parameters for the neuron model are taken from [53] for the AdEx, $\tau_z$ is set to 40ms in agreement with [23, 54]
and kept fixed throughout all simulations (see table 1A).

## 6.2 Plasticity Model

Since synaptic depression and potentiation take place through different pathways [33] our model exhibits separate
additive contributions to the plasticity rule, one for LTD and another one for LTP.

For the LTD part, we assume that presynaptic spike arrival at synapse $i$ induces depression of the synaptic
weight $w_i$ by an amount $-A_{LTD} [\pi_- (t) - \theta_-]_+$ that is proportional to the average postsynaptic depolarization $\bar{\pi}$. The brackets $[\cdot]_+$ indicate rectification, i.e. any value $\bar{u}_- < \theta_-$ does not lead to a change and implement experimental findings showing that postsynaptic depolarization should exceed a certain value $\theta^-$ to establish depression of the synapse [14] (see Fig. 1H). The quantity $\pi_- (t)$ is an exponential low-pass filtered version of the postsynaptic membrane potential $u(t)$ with a time constant $\tau_-:

$$\tau_- \frac{d}{dt} \pi_- (t) = -\pi_- (t) + u(t).$$

The variable $\bar{u}_-$ is an abstract variable which could, for instance, reflect the level of calcium concentration [24]
or the release of endocannabinoids [56], though such an interpretation is not necessary for our rule. Since the
presynaptic spike train is described as a series of short pulses at time $t^n_i$ where $i$ is the index of the synapse and
$n$ an index that counts the spike, $X_i(t) = \sum_n \delta(t - t^n_i)$, depression is modeled as the following update rule, see also Fig. 1:

$$\frac{d}{dt} w_i = -A_{LTD} (\bar{u}) X_i(t) [\pi_- (t) - \theta_-]_+ \quad \text{if } w_i > w_{\text{min}},$$

where $A_{LTD} (\bar{u})$ is an amplitude parameter that is under the control of homeostatic processes [34]. For slice
experiment the parameter has a fixed value extracted from experiment. For network simulations, we make it
depend on the mean depolarization $\bar{u}$ of the postsynaptic neuron, averaged over a time scale of 1 second. Eq. 1
is a simple method to implement homeostasis; other methods such as weight rescaling would also be possible [34].

For the LTP part, we assume that each presynaptic spike at the synapse increases the trace $\bar{x}_i(t)$ of some biophysical quantity, which decays exponentially with a time constant $\tau_x$ in the absence of presynaptic spikes, similar to previous work [17, 32]. The temporal evolution of $\bar{x}_i(t)$ is described by:

$$\tau_x \frac{d}{dt} \bar{x}_i(t) = -\bar{x}_i(t) + X_i(t),$$

where $X_i$ is the spike train defined above. The quantity $\bar{x}_i(t)$ could for example represent the amount of glutamate bound to postsynaptic receptors [32] or the number of NMDA receptors in an activated state. The potentiation of $w_i$ is modeled by the following expression, which is proportional to the trace $\bar{x}_i(t)$ (see also Fig. 1):

$$\frac{d}{dt} w_i^+ = +A_{LTP} \bar{x}_i(t) \left[u(t) - \theta_+\right]_+ \left[\bar{x}_i(t) - \theta_+\right]_+ \quad \text{if } w_i < w_{\text{max}}.$$  

(2)

Here, $A_{LTP}$ is a free amplitude parameter fitted to the data and $\bar{x}_i(t)$ is another low-pass filtered version of $u(t)$ similar to $\bar{x}_i(t)$ but with a shorter time constant $\tau_x$ around 10ms. Thus positive weight changes can occur if the momentary voltage $u(t)$ surpasses a threshold $\theta_+$ and, at the same time the average value $\bar{x}_i(t)$ is above $\theta_-$. The final rule used in the simulation is described by the equation

$$\frac{d}{dt} w_i = -A_{LTD} \bar{u}_i X_i(t) \left[\bar{x}_i(t) - \theta_+\right]_+ + A_{LTP} \bar{x}_i(t) \left[u(t) - \theta_+\right]_+ \left[\bar{x}_i(t) - \theta_-\right]_+,$$

(3)

combined with hard bounds $0 \leq w_i \leq w_{\text{max}}$. For network simulation, $A_{LTD}(\bar{u}) = A_{LTD} \frac{\bar{u}^2}{u_{\text{ref}}^2}$ where $u_{\text{ref}}^2$ is a reference value.

### 6.3 Parameters and Data Fitting

For the plasticity experiments in slices, we take $\bar{u} = u_{\text{ref}}$ as fixed and fit the parameters $A_{LTD}$. The total number of parameters of the plasticity model is then 7. For all data sets, except the one taken from [15], the threshold $\theta^-$ is set to the resting potential and $\theta^+$ to the firing threshold of the AdEx model, i.e. $\theta^- = -70.6$ mV and $\theta^+ = -45.3$ mV. The remaining five parameters $\tau_x$, $\tau_-$, $\tau_+$, $A_{LTD}$ and $A_{LTP}$ are fitted to each data set individually by the following procedure. We calculate the theoretically predicted weight change $\Delta w_i^{\text{th},j}$ by integrating (analytically or numerically) Eq. (3), for a given experimental protocol $j$, as a function of the free parameters. We then estimate the free parameters by minimizing the mean-square error $E$ between the theoretical calculations and the experimental data $\Delta w_i^{\text{exp},j}$:

$$E = \sum_j \left(\Delta w_i^{\text{th},j} - \Delta w_i^{\text{exp},j}\right)^2.$$
For the data set in hippocampus [15], we also fit the two parameters $\theta^-$ and $\theta^+$ since completely different preparations and cell type were used. Moreover for this data set, the time constant $\tau_x$ is taken from physiological measurements given in [13] and fixed to the values of 16ms. The parameters for the various experiments are summarized in table 1B.

6.4 Protocols and mathematical methods

**Voltage clamp experiment.** (Fig. 1H) The postsynaptic membrane potential was switched in the simulations to a constant value $u_{clamp}$ chosen from -80mV to 0mV while presynaptic fibers were stimulated with either 25 (blue line) or 100 pulses (red line) at 50Hz. Due to voltage clamping, the actual value of the voltage $u$ itself and the low-pass filtered versions $\bar{u}$ are constant and equal to $u_{clamp}$. Hence, the synaptic plasticity rule becomes

$$\frac{d}{dt} w_i = -A_{\text{LTD}} X_i(t) [u_{clamp} - \theta_-]_+ + A_{\text{LTP}} \bar{x}_i(t) [(u_{clamp} - \theta_-)(u_{clamp} - \theta_+)]_+.$$ 

**Frequency dependence experiment.** (Fig. 2B) Presynaptic spikes in the simulation were paired with postsynaptic spikes that were either advanced by +10ms or delayed by -10ms with respect to the presynaptic spike. This pairing was repeated 5 times with different frequencies ranging from 0.1 to 50Hz. These 5 pairings were repeated 15 times at 0.1Hz. However, the 5 pairing at 0.1Hz were repeated only 10 times to mimic the experimental protocol [23].

**Burst-timing-dependent plasticity.** (Fig. 3A) The presynaptic spike is paired $\Delta t = +10$ms before (or $\Delta t = -10$ms after) 1, 2 or 3 postsynaptic spikes. The frequency of the burst is 50Hz. The neuron receives 60 pairings at a frequency of 0.1Hz. Fig. 3B: The presynaptic spike is paired with a burst of 3 action potentials ($\Delta t = +10$ms and -10ms), while the burst frequency varies from 20 to 100Hz. Fig. 3C: A presynaptic spike is paired with a burst of 3 postsynaptic action potentials with burst frequency of 50Hz. The time $\Delta t$ between the presynaptic spike and the first postsynaptic action potential varies from -80 to 40 ms. For a detailed description of the experiments see [35].

**Poisson input for functional scenarios.** (Fig. 4-7) Poisson inputs are used in all the following experiments. They are generated by a stochastic process where the spike is elicited with a stochastic intensity $\nu$. 

**Relation between connectivity and coding: Toy model.** (Fig. 4) Weights of ten all-to-all connected neurons are initialized at 1, bounded between 0 and 3. Weights evolve with the voltage-based rule with homeostasis (Eq. 3) for 100s. The model is compared to a canonical pair-based STDP model written as

$$\frac{d}{dt} w_i = -A_{\text{LTD}}^{\text{pair}} X_i \bar{y} + A_{\text{LTP}}^{\text{pair}} \bar{x}_i Y,$$

where $Y$ is the postsynaptic spike train defined the same way as the presynaptic spike train $X_i$ with a filter of the postsynaptic spikes $\bar{y}$ similar to $\bar{x}_i$. The parameters are chosen $A_{\text{LTD}}^{\text{pair}} = A_{\text{LTP}}^{\text{pair}} = 1e^{-5}$ for the amplitudes and $\tau_x$ for the time constant of $\bar{x}_i$ as well as for the time constant of the postsynaptic low-pass filter $\bar{y}$. Rate code: Neuron 1 fire at 2Hz, neuron 2 at 4Hz... neuron 10 at 20Hz.
following a Poisson statistics, i.e. short current pulses are injected to make the neuron fire with Poisson statistics at this frequency. The neurons have different reference values from $u_{ref}^2 = 60$ to $600$ mV$^2$. Temporal code: Neurons fire successively every 20ms, first neuron 1 fires then 20ms later neuron 2 then... 10 then 1 etc, in a loop. The neurons have a reference value set to $u_{ref}^2 = 60$ mV$^2$.

**Rate coding in network simulation.** (Fig. 5) Five hundred presynaptic Poisson neurons with firing rates $\nu_{i}^{pre}$ ($1 \leq i \leq 500$) are connected to 10 postsynaptic excitatory neurons. The inputs rates $\nu_{i}^{pre}$ follow a Gaussian profile, i.e. $\nu_{i}^{pre} = A \cdot \exp\left(-\left(i - \mu\right)^2/(2\sigma^2)\right)$, with variance $\sigma = 10$ and amplitude $A = 30$ Hz. The center $\mu$ of the Gaussian shifts randomly every 100ms between 10 different positions equally distributed. Circular boundary conditions are assumed, i.e. neuron $i = 500$ is considered as neighbor of $i = 1$. Synaptic weights of the feedforward connections are initialized randomly (uniformly in $[0.5, 2]$) and hard bound are set to 0 and 3. The 10 excitatory neurons are all to all recurrently connected with a starting synaptic weight of 0.25 (hard bounds set to 0 and 0.75). In addition, 3 inhibitory neurons are randomly driven by 8 excitatory neurons and project on 6 excitatory neurons, also chosen randomly. Those random connections are fixed and have a weight equal to 1. The reference value is set to $u_{ref}^2 = 60$ mV$^2$ and the simulation time to 1000s. Parameters are normally chosen as in table 1B, visual cortex data, except for Fig. 5 B-E, where $A_{LTP}$ and $A_{LTD}$ where reduced by a factor 100.

**Temporal coding in network simulation.** (Fig. 6) Same setting than rate code but the patterns are presented for 20ms successively (from center position 500, to 450, to 400 etc in a circular manner). The reference value has been set to $u_{ref}^2 = 80$ mV$^2$.

**ICA-like computation - Orientation selectivity with natural images.** (Fig. 7) Ten natural images have been taken from the benchmark of Olshausen et al. [40]. A small patch of 16 by 16 pixels from any of the images is randomly chosen every 200ms. After prewhitening, the inputs for the ”ON” ("OFF") image are Poisson spike trains generated by the positive (negative) part of the patch (with respect to a reference grey value reflecting the ensemble mean) with maximum frequency of 50 Hz. The 2x16x16 inputs are connected to one postsynaptic neuron. The initial weights are set randomly between 0 and 2 and hard bounds are set between 0 and 3. The connections follow the synaptic rule (Eq. 3), where the reference value is set to $u_{ref}^2 = 50$ mV$^2$. Parameters are chosen as in table 1B (visual cortex data) but $A_{LTP}$ and $A_{LTD}$ where reduced by a factor 10. Every 20 s an extra normalization is applied to equalize the norm of the ”ON” weights to the one of the ”OFF” weights [31].

A MODEL FOR THE LATE PHASE OF LONG TERM SYNAPTIC PLASTICITY

The key element in understanding memory is the stable changes of the synapses. It is therefore essential to describe the long lasting changes which are for example measured by synaptic tagging experiments (Frey and Morris 1997). These experiments exhibit three phases leading to a maintenance of synaptic plasticity (1) the induction of long-term potentiation and depression (LTP/LTD) during the early phase of synaptic plasticity and the setting of synaptic tags, (2) a trigger process for protein synthesis, and a slow transition leading to synaptic consolidation during (3) the late phase of synaptic plasticity. In the following paper (Clopath, Ziegler, Vasilaki, Buesing, and Gerstner 2008) we present a minimal model that describes these three different phases of synaptic plasticity. The early phase of plasticity is modeled with the induction model presented in the previous paper (Clopath, Vasilaki, Buesing, and Gerstner xxxx) and leads directly to setting the tag. The synapses are considered discrete, consistent to some experimental evidence that LTP under minimal stimulation (Petersen, Malenka, Nicoll, and Hopfield 1998; O’Connor, Wittenberg, and Wang, 2005) or glutamate encaging (Bagal, Kao, Tang, and Thompson 2005) is a switch-like process. This model explains a large body of experimental data on synaptic tagging and capture, cross-tagging, and the late phases of LTP and LTD. It offers structural similarities to reinforcement learning models such as a dependence on neuromodulation.
Tag-Trigger-Consolidation: A Model of Early and Late Long-Term-Potentiation and Depression

Abstract

Changes in synaptic efficacies need to be long-lasting in order to serve as a substrate for memory. Experimentally, synaptic plasticity exhibits phases covering the induction of long-term potentiation and depression (LTP/LTD) during the early phase of synaptic plasticity, the setting of synaptic tags, a trigger process for protein synthesis, and a slow transition leading to synaptic consolidation during the late phase of synaptic plasticity. We present a mathematical model that describes these different phases of synaptic plasticity. The model explains a large body of experimental data on synaptic tagging and capture, cross-tagging, and the late phases of LTP and LTD. Moreover, the model accounts for the dependence of LTP and LTD induction on voltage and presynaptic stimulation frequency. The stabilization of potentiated synapses during the transition from early to late LTP occurs by protein synthesis dynamics that are shared by groups of synapses. The functional consequence of this shared process is that previously stabilized patterns of strong or weak synapses onto the same postsynaptic neuron are well protected against later changes induced by LTP/LTD protocols at individual synapses.

Introduction

Changes in the connection strength between neurons in response to appropriate stimulation are thought to be the physiological basis for learning and memory formation [1,2]. A minimal requirement for proper memory function is that these changes, once they are induced, persist for a long time. For several decades, experimentalists have therefore focused on Long-Term Potentiation (LTP) and Long-Term Depression (LTD) of synapses in hippocampus [3,4] and cortical areas [5,6]. LTP can be induced at groups of synapses by strong ‘tetanic’ high-frequency stimulation of the presynaptic pathway [3] while stimulation at lower frequency leads to LTD Dudek92. Both LTP and LTD can also be induced at a single synapse or a small number of synaptic contacts if presynaptic activity is paired with either a depolarization of the postsynaptic membrane [5,7] or tightly timed postsynaptic spikes [8,9].

While the induction protocol for LTP and LTD is often as short as a few seconds, the changes in synaptic efficacy persist for much longer [9]. In typical slice experiments on LTP (and similarly for LTD or Spike-Timing Dependent Plasticity (STDP)) the persistence of the change is monitored for 30 minutes to 1 hour. Accumulating evidence suggests, however, that after this early phase of LTP (E-LTP) different biochemical processes set in that are necessary for the further maintenance of potentiated synapses during the late phase of LTP (L-LTP) [10,11]. For an understanding of the transition from early to late LTP, the concept of ‘synaptic tagging and capture’ has become influential [12,13]. During induction of the early phase of LTP, each potentiated synapse sets a tag that marks it has received a specific afferent signal. A candidate molecule, involved in the tag signaling LTP induction in apical dendrites of hippocampal neurons, is the calcium-calmodulin dependent kinase II (CaMKII) [13]. Newly synthesized plasticity-related proteins are ‘captured’ by the tagged synapse and transform E-LTP into L-LTP that can be maintained over hours or days. A candidate protein involved in the maintenance of potentiated hippocampal synapses is the protein kinase Mζ (PKMζ) [11,14].

The stabilization and maintenance of potentiated synapses poses a number of theoretical challenges. First, on the level of single synapses we must require synaptic strength to remain stable, despite the fact that AMPA channels in the postsynaptic membrane are continuously exchanged and recycled [15–17]. Thus the synapse is not ‘frozen’ but part of a dynamic loop. Second, on the level of neuronal representation in cortical areas, one finds representations of input features that are stable but at the same time sufficiently plastic to adjust to new situations [18]. In the theoretical community, this paradox has been termed the stability-plasticity dilemma in unsupervised learning [19]. Third, humans keep the ability to memorize events during adulthood, but can also remember earlier episodes years back. However, continued learning of new patterns in theoretical models of associative memory networks forces the erasure or ‘overwriting’ of old ones, the so-called palimpsest property [20,21]. In the context of
Humans and animals learn by changing the strength of connections between neurons, a phenomenon called synaptic plasticity. These changes can be induced by rather short stimuli (lasting sometimes only a few seconds) but should then be stable for months or years in order to be useful for long-term memory. Experimentalists have shown that synapses undergo a sequence of steps that transforms the rapid change during the early phase of synaptic plasticity into a stable memory trace in the late phase. In this paper we introduce a model with a small number of equations that can describe the phenomena of induction of synaptic changes during the early phase of synaptic plasticity, the trigger process for protein synthesis, and the final stabilization. The model covers a broad range of experimental phenomena known as tagging experiments and makes testable predictions. The ability to model the stabilization of synapses is crucial to understand learning and memory processes in animals and humans and a necessary ingredient for any large-scale model of the brain.

Results

We study a model with a large number of synapses i onto a single postsynaptic neuron. To be specific, we think of a pyramidal neuron in the CA1 area of hippocampus. Our model combines features of traditional models for the induction of potentiation [24–26,33–36] with a simple description of tagging and synthesis of plasticity related proteins that finally lead to the maintenance of the induced changes. The section is organized as follows: We first introduce the essential components of the model step by step (‘Constructing the Model’). We then test the performance of the model with a set of stimuli typically used to induce long-term changes of synapses (‘Testing the Model’).

Constructing the Model

Our model contains three elements, Figure 1. The first one sets the tag during the induction of LTP or LTD. A tag is indicated by a value \( h = 1 \) for LTP or \( l = 1 \) for LTD. In the absence of tags we have \( h = l = 0 \). The second one describes the synthesis of plasticity related proteins. The final component describes the up-regulation of a maintenance-related process from a low value \( z = 0 \) to a high value \( z = 1 \). The dynamics of this component is intrinsically bistable and leads to a consolidation of the previously induced change at the labeled synapses upon interaction with the protein p (‘protein capture’).

The total change \( \Delta w \) of the synaptic strength reported in experiments contains contributions [13] of the early components \( l \) and \( h \) as well as the late component \( z \). Since the model describes a sequence of three steps ‘Tag-Trigger-Consolidation’ we call it in the following the TagTriC-Model (Figure 1).

Tag and Induction of LTP/LTD

Results from minimal stimulation protocols which putatively activate only a single synapse suggest that the induction of LTP is a switch-like process [7,37]. We therefore model individual synapses as discrete quantities that can switch, during the induction of LTP, from an initial ‘non-tagged state’ (N) to a ‘high state’ (H) with a transition rate \( \rho_{HT} \) that depends on the induction protocol. Similarly, induction of LTD moves the synapse from the initial non-tagged state (N) to a ‘low state’ (L) at a rate \( \rho_{LT} \). If synapse i is in the high state, the synaptic variable \( h_i \) is equal to one. If it is in the low state, another local variable \( l_i \) is set to one. These local variables \( h_i \) and \( l_i \) do not only control the weight of the synapse during E-LTP and E-LTD, but also serve as ‘tags’ for up- or down-regulation of the synapse. Tags reset to zero stochastically with a rate \( k_h \) and \( k_l \), respectively. If both tags are zero, the synapse is in the non-tagged state N. Since the synapse is either up-regulated OR down-regulated, at most one of the tags can be non-zero (Figure 1A).

The stochastic transitions from the initial state N with \( h = 0 \) and \( l = 0 \) to the down-regulated state \( l = 1 \) or an upregulated state \( h = 1 \) depend in a Hebbian manner on presynaptic activity and the state of the postsynaptic neuron. In the absence of presynaptic activity, the LTD rate \( \rho_{LT} \) vanishes. Presynaptic activity combined with a time-averaged membrane potential \( u \) above a critical value \( \delta_{LT} \) leads to the TagTriC model to a LTD transition rate \( \rho_{LT} \) proportional to \( [u(h−\delta_{LT})]^{\frac{1}{\delta_{LT}}} \). For a transition from the initial state to the high state, we require in addition that the momentary membrane potential is above a second threshold \( \delta_{LT} \). Hence the transition rate \( \rho_{HT} \) is proportional to \( [u(l−\delta_{LT})]^{\frac{1}{\delta_{LT}}} \).
Figure 1. The three components of the Tag-Trigger-Consolidation (TagTriC) model. (A) A synapse can be in the non-tagged state N, the high state H or the low state L. A synapse i in H (or L) has a tag $h_i = 1$ (or $l_i = 1$, respectively). Transitions to a tagged state occur with rates $r_H$ for potentiation and $r_L$ for depression. The tag $h_i = 1$ is indicated by a red flag in both the flow graph and the schematic drawing below. (B) Synthesis of plasticity related proteins $p$ (green squares) is triggered if the total number of set tags is larger than a critical number $N_p$. If the trigger threshold $N_p$ is not reached, the protein concentration decays back to zero. (C) The consolidation dynamics can be visualized as downward motion in a potential surface $E(z)$. The function $f(z)$ (shown to the right) is the derivative of $E$ and characterizes the dynamics $dz/dt = f(z)$. If a tag is set at the synapse ($h_i = 1$) and protein synthesis has been triggered ($\mu = 1$), the dynamics can be imagined as downward motion into the right well of the potential $E(z)$. In this case, $z = 1$ is the only fixed point of the dynamics (magenta circle). In the absence of tags ($h_i = l_i = 0$, below) the consolidation variable $z_i$ of synapse $i$ is bistable and approaches (direction of flow indicated by arrows) stable fixed points at $z_i = 0$ or $z_i = 1$ (magenta circles). The steps of synaptic tagging and capture are indicated immediately below the flow diagram. (D) The tagging rates for depression ($-2r_L$, magenta) and for potentiation $r_H$ (blue) are shown as a function of the clamped voltage under the assumption that a presynaptic spike has arrived less than 1 millisecond before. Note that for depression we plot the negative rate $-2r_L$ rather than $r_L$ to emphasize the fact that depression leads to a down-scaling of the synapse. (E) Voltage dependence of early LTP and LTD. The weight change $\Delta w / \Delta t(0)$ induced by a stimulation of 100 synapses at 2 Hz during 50 s while the postsynaptic voltage is clamped is shown as a function of voltage. The percent change $\Delta w / \Delta t$ in simulations (circles) of LTP/LTD induction experiments can be predicted from a theory (solid line) based on the difference in transition rates $\rho_H - \rho_L$. The simulation reflects the voltage dependence seen in experiments [5,39]. (F,G) Frequency dependence of early LTP and LTD. Simultaneous stimulation of 100 synapses by 3 trains (separated by 5 min) of 100 pulses at rates ranging 0.03 to 100 Hz shows LTD at low frequencies and LTP at frequencies above 30 Hz. (G) If LTP is blocked in the model, LTD (pink line) occurs up to high frequencies as in experiments [7]. Blue line: LTP with blocked of LTD.

doi:10.1371/journal.pcbi.1000248.g001
whenever these threshold conditions are satisfied; see Methods for
details.

Our assumptions regarding the transition rates essentially
summarize the qualitative voltage dependence seen in the
Artola-Brócher-Singer experiments [5]. Indeed, when 100 synap-

deses in the TagTriC model are stimulated at low frequency during
50 seconds while the membrane voltage is kept fixed at different
values (Figure 1D), the total weight change summed across all
synapses exhibits LTD at low voltage and LTP at high voltage
[38,39]. As expected, the resulting weight changes in the
simulations of Figure 1E reflect the voltage dependence of the
transition rates in Figure 1D.

Trigger for Protein Synthesis
Previously induced LTP or LTD needs to be consolidated in
order to last for more than one hour. Consolidation requires that
protein synthesis is triggered. Experimental evidence indicates that
triggering of protein synthesis needs the presence of neuromod-
ulators such as dopamine (in the apical CA1 region) or other
modulators (in other regions). In typical tagging experiments,
extracellular stimulation co-stimulates dopaminergic input leading
to a phasic dopamine signal [13,40]. In our model, induction of E-
LTP or E-LTD through appropriate stimulation protocols changes
the synaptic efficacy and sets tags at the modified synapses, both
described by the variables $h_i = 1$ or $l_i = 1$. Protein synthesis in the
model is triggered (see methods for details) if the total number of
tags $\sum (h_i + l_i)$ (which indirectly reflects the phasic dopamine signal)
reaches a threshold $N_0$ which depends on the level of background
dopamine (and other neuromodulators). More specifically, $N_0$
decreases with the concentration of background dopamine so that
the presence of dopamine facilitates the trigger process [32].

If the trigger criterion is satisfied, the concentration $p$
of synthesized plasticity related proteins approaches with rate $k_p$ a
value close to one. If the number of tags falls below the threshold
$N_0$, the protein concentration $p$ decays with a time constant $r_p$ back
to zero. Further details on the role of the trigger threshold and its
relation to neuromodulators can be found in the discussion section.

Consolidation and Late LTP
The total weight $w_i$ of a synapse $i$ depends on the present value
of the tags $h_i$ or $l_i$ as well as on its long-term value $z_i$. The slow
variable $z_i$ is a continuous variable with one or two stable states
described by a generic model of bistable switches, that could be
implemented by suitable auto-catalytic processes [16]. While the
concentration $p$ of plasticity related proteins is zero, the variable $z_i$
has two stable states at $z_i = 0$ and $z_i = 1$, respectively. If the protein
concentration takes a value of $p = 1$, one of the stable states
appears and, depending on the tag that was set, the long term-
value of the synapse can be up- or down-regulated; see methods
and Figure 1C for details.

In order to illustrate the mechanism of induction of L-LTP, let
us suppose that the synapse has been initially close to the state
$z_i = 0$. The dynamics of the synapse can be imagined as downward
motion in a 'potential' $E$. The current stable state of the synapse is
at the bottom of the left well in the potential pictured in Figure 1C.
We assume that during a subsequent LTP induction protocol the
synapse has been tagged with $h_i = 1$ and that the total number of
tags set during the LTP induction protocol surpasses the trigger
threshold $N_0$. If the protein concentration $p$ approaches one, the
potential surface is tilted so that the synapse now moves towards
the remaining minimum at $z_i = 1$. After decay of the tags, $p$ returns
to zero, and we are back to the original potential, but now with the
synapse trapped in the state $z_i = 1$. It can be maintained in this state
for a long time, until another strong tagging event occurs during
which the synapse is tagged with $h_i = 1$ as a result of LTD
induction. In this case the potential surface can be tilted towards
the left so that the only equilibrium point is at $z_i = 0$. Since
consolidation is typically studied in animals that are more than 20
days old [13], we assume that before the beginning of the experiment
30 percent of the synapses are already in the upregulated state $z_i = 1$ and the remaining 70 percent in the state $z_i = 0$; see also [7]. Because of the bistable dynamics of
consolidation, only synapses that are initially in the upregulated
state $z_i = 1$ can undergo L-LTD and only synapses that start from
$z_i = 0$ can undergo L-LTP; compare [7]. Note, however, that tags
for potentiation and depression can be set independently of the value of $z_i$. We may speculate that the variable $z_i$ is related to the
activity of PKM$\mu$ [11,14], or to the self-sustained clustering of
AMPA receptors [41], but the exact biochemical signaling chain is
irrelevant for the functional consequences of the model discussed
in the results section. In our model, the bistable dynamics of the $z_i$
variable captures the essence of synaptic persistence despite
molecular turnover [15,16,28] and mobility of AMPA receptors
[41].

Tests of the Model
The TagTriC model has been tested on a series of stimulation
protocols that reflect induction of LTP and LTD as well as the
consolidation of plasticity events.

Induction of Synaptic Changes
A typical LTP induction experiment starts with extracellular
stimulation of a bundle of presynaptic fibers (i.e., the Schaffer
collaterals leading from CA3 to CA1) that activate a large number
(typically hundreds) of presynaptic terminals. With an
extracellular probe electrode placed close to one of the
postsynaptic neurons, a change in synaptic efficacy is measured
via the amplitude (or initial slope) of the evoked postsynaptic
potential, representing the total response summed across all the
stimulated synapses. In our simulations, we mimic these
experiments by simultaneous stimulation of 100 synapses. The
state of the postsynaptic neuron is described by the adaptive
exponential integrate-and-fire model [42] and can be manipulated
by current injection.

In a preliminary set of simulation experiments done with
presynaptic stimulation alone (no manipulation of the postsynaptic
neuron), the TagTriC model exhibits LTD or LTP depending on
the frequency of the presynaptic stimulation (Figure 1F) in
agreement with experimental results [43,44]. Moreover, under the
assumption that LTP has been blocked pharmacologically ($\rho_{PT} = 0$
in the model), our model shows LTD even for high stimulation
frequencies (Figure 1G). This stems from the fact that LTD and
LTP are represented in the TagTriC model by two independent
pathways (Figure 1A) which are under control condition in
competition with each other, but show up individually if one of the
paths is blocked [43]. Together with the voltage dependence of
Figure 1E, the above simulation results indicate that our model of
LTP and LTD induction can account for a range of experiments
on excitatory synapses in the hippocampal CA1 region, in
particular, voltage and frequency dependence.

Consolidation of Synaptic Changes
In order to study whether consolidation of synaptic changes in
our model follows the time course seen in experiments, we
simulate standard experimental stimulation protocols [12,13]. A
weak tetanus consisting of a stimulation of 100 synapses at 100 Hz
for 0.2 seconds (21 pulses) leads in our model to the induction of
LTP (change by +15 percent) which decays back to baseline over
the time course of two hours (Figure 2A). Thus, after the early phase of LTP the synapses are not consolidated. A stronger stimulus consisting of stimulating the same group of hundred synapses by 100 pulses at 100 Hz (repeated 3 times every 10 minutes) yields stronger LTP that consolidates and remains elevated (weight change by 22±5 percent) for as long as the simulations are continued (more than 10 hours, only the first 5 hours are shown in Figure 2B). Thus our model exhibits a transition from early to late LTP if E-LTP is induced by the strong tetanic stimulation protocol, but not the weak one, consistent with results in experiments [12,13]. If, however, the weak tetanus at a first group of 100 synapses is given 30 minutes before or after a strong tetanus at a second group of 100 synapses, the synapses in both the weakly and strongly stimulated groups are consolidated (Figure 2C and 2D). If the weak tetanus in group one is given 120 minutes after the strong tetanus in group two, then consolidation of the synapses in the weakly stimulated group does not occur (Figure 2E). Thus our model exhibits a time course of heterosynaptic interaction between the two groups of synapses as reported in classical tagging experiments [12,13].

An advantage of a modeling approach is that we can study the dependence of the heterosynaptic interaction between the two groups of synapses upon model parameters. A critical parameter in the model is the trigger threshold $\lambda_p$ that needs to be reached in order to start protein synthesis (Figure 1B). With our standard choice of parameters, where $\lambda_p = 40$, we can plot the consolidated weight change $\Delta w(w0)$ in the weakly stimulated group (measured 10 hours after the induction) as a function of the time difference between the stimulation of the group receiving the strong tetanus and that receiving the weak tetanus. The curve in Figure 2F shows that for a time difference up to 1 hour there is significant interaction between the two groups of synapses leading to synaptic consolidation, whereas for time differences beyond 2 hours this is no longer the case. If the trigger threshold is increased to $\lambda_p = 60$ (corresponding to less available neuromodulator), then the maximal time difference that still yields L-LTP in the weakly stimulated group of synapses is reduced to about 20 minutes (Figure 2F) whereas a reduction of $\lambda_p$ yields an increased time window of interaction (data not shown). If $\lambda_p$ is reduced much further, the weak tetanus alone will be sufficient to allow a transition from the early to the late phase of LTP. We speculate that $\lambda_p$ could depend on the age of the animal as well as on the background level of dopamine or other neuromodulators so as to enable a tuning of the degree of plasticity (see discussion for details).

LTD and Cross-Tagging

We consider two experimental protocols known to induce LTD—a weak low-frequency protocol consisting of 900 pulses at 1 Hz and a strong low-frequency protocol consisting of 900 repetitions at 1 Hz of a short burst of three pulses at 20 Hz. This strong low-frequency protocol applied to 100 model synapses leads to a significant level of LTD (reduction of weights to 70±4 percent of initial value) which is consolidated 3 hours later at a level of 83±3 percent of initial value. If a group of 100 synapses is stimulated with the weak low-frequency protocol, an early phase of LTD is induced that is not consolidated but decays over the time course of 3 hours (Figure 3A and 3B). However, if the weak low-frequency stimulation occurs after another group of 100 synapses had been stimulated by the strong low-frequency protocol, then the group that has received the weak stimulation shows consolidated synapses (at 90±2 percent 5 hours after stimulus induction, Figure 3C). Moreover, consolidation of LTD (at 92±3 percent 5 hours after stimulus induction) in the group of synapses receiving the weak low-frequency protocol also occurs if it was stimulated thirty minutes after the stimulation of a second group of synapses by a strong tetanus, leading to LTP (Figure 3D). Thus, the TagTriC model exhibits cross-tagging consistent with experiments [11,32]. In our model, cross-tagging occurs because the tags for LTP and LTD ($t$, $l$, respectively) enter in a symmetric fashion into the trigger criterion for the synthesis of plasticity-related proteins (see Figure 1 and Methods).

Model Mechanism for Tagging, Cross-Tagging, and Consolidation

In order to elucidate how the model gives rise to the series of results discussed in the preceding paragraphs, we have analyzed the evolution of the model variables during and after induction of LTP (Figure 4). Critical for consolidation is the synthesis of plasticity related proteins, characterized by the variable $\phi$ in the model. Synthesis is only possible while the total number of tags $\sum_{i=1}^{N_p} z_i$ is above the protein triggering threshold $\lambda_p$. For the strong tetanic stimulus this criterion is met for about 90 minutes (shaded region in Figure 4A) leading to high levels of plasticity related proteins. After 90 minutes the concentration of proteins starts to decay back to baseline. While the level of proteins is sufficiently elevated the consolidation variable $z$ of each tagged synapse moves towards $z=1$ since this is the only stable fixed point of the dynamics (Figure 1C). This leads to a consolidation time of about 2 hours, enough to switch a large fraction of synapses into the up-regulated state $z=1$ (green line, Figure 4A). Hence the average weight of the stimulated synapses stabilizes at a value above baseline, indicating L-LTP (Figure 4A, solid line).

If, in a different experiment, 100 synapses are stimulated by the weak tetanus, the synthesis of plasticity related proteins is only possible during a few minutes (Figure 4B, red line), which is not sufficient to switch tagged synapses from $z=0$ into the upregulated state $z=1$. Hence the weights (Figure 4B, black line) decay together with the tags (Figure 4B, magenta line) back to baseline and the transition from early to late LTD does not occur. The decay of the weights is controlled by the rate $k_d$ at which tags stochastically return to zero. The evolution of the protein concentration $\phi$ and the consolidation variable $z$ after a strong tetanus that leads to 90 minutes of protein synthesis and a weaker tetanus that only leads to 40 minutes of protein synthesis has been illustrated in (Figure 5A).

The total amount of available protein that is synthesized depends in our model on the time that the total number of tags stays above the protein triggering threshold $\lambda_p$. Even though always 100 synapses are stimulated in our model, not all receive tags in each experiment; moreover because of the competition for potentiation tags ($t=1$) and depression tags ($l=1$) during induction of plasticity, different synapses can receive different tags in the same experiment. With our strong tetanus protocol, on average 70 (out of 100) synapses receive a potentiation tag and 30 a depression tag while with the weak tetanus the numbers are 30 and 10, respectively. For the depression protocols, on average 10 synapses receive a potentiation tag and 90 a depression tag under strong low-frequency stimulation, and typically zero a potentiation tag and 40 a depression tag under the weak low-frequency protocol. These numbers vary from one trial to the next so that sometimes the protein trigger threshold $\lambda_p = 40$ is reached with the weak protocols and sometimes not. The important aspect is that even if the threshold is reached for a short time, the duration of protein synthesis is not long enough to provide a sufficient protein concentration $\phi$ for consolidation of the tagged synapses; see Figure 4B and Figure 5A.
Since the concentration $p$ of plasticity related proteins is crucial for the transition from early to late LTP we wondered how a block of protein synthesis would interfere with the consolidation of weights in the TagTriC model. Application of a protein synthesis inhibitor (modeled by setting the rate $k_p$ of protein synthesis to zero) during 1 hour starting thirty minutes before a strong tetanus is given to a group of 100 synapses that would normally lead to L-LTP, induced E-LTP but prevented consolidation into L-LTP (data not shown). However, if the same simulation experiment was repeated after a second group of synapses had received a strong tetanic stimulation 35 minutes prior to the application of protein synthesis blocker, then both groups of synapses showed consolidation of weights (Figure 4D), consistent with experiments [12]. Closer inspection of the lower panel in Figure 4D shows that two components contribute to consolidation: Firstly, the concentration of plasticity related proteins (red line) that has increased because of
the first strong tetanic stimulus decreases only slowly back to baseline enabling the switching of the slow components (variable $z$, green line) even in the presence of protein synthesis blocker. Secondly, even after the end of the application of the blocker, the total number of tags that has been set by LTP induction is still above the critical value $N_p$ (shaded region in Figure 4D) so that protein synthesis can be resumed after the end of the blocking period. In summary, the detailed analysis of the TagTriC model allows to account for many aspects of tagging experiment in terms of a limited number of variables.

**Discussion**

Relation of Models to Experiments

Synaptic plasticity is based on intricate signal transduction chains involving numerous processing steps and a large number of different molecules [2,13,17]. Despite the complexity of the molecular processes, synaptic plasticity has experimentally been characterized by a small set of distinct phenomena such as short-term plasticity [44] as well as early and late phases of LTP and LTD [13].

Existing models of synaptic plasticity have focused on the description of short-term plasticity [44] and on the induction of LTP and LTD [24–26,33–36]. The question of maintenance has received much less attention and was mainly addressed in the context of bistability of the CaMKII auto-phosphorylation process [27–29], AMPA receptor aggregation [41], or four identified kinase pathways [45]. While CaMKII is necessary for induction of long-term potentiation [46], it is probably too narrow to focus modeling studies only on a single or a few kinases such as CaMKII and neglect other proteins and signaling cascades that are involved in synaptic maintenance [13]. For example, there is strong evidence that PKM* is involved in synaptic maintenance and necessary for the late phase of LTP in vitro [11] and in vivo [14]. However, the actual processes are complex and the molecules involved in setting tags may differ between different parts of the dendrite. For example PKM* is involved in setting tags during E-LTP in the basal dendrite, whereas CaMKII (or MAPK for E-LTD) plays a similar role in apical dendrites [30].

Instead of focusing on specific signaling cascades, the TagTriC model presented in this papers aims at describing the essential ingredients of any possible functional model of L-LTP and tagging. These ingredients include (i) a bistable switch (described by the dynamics of the $z$-variable) for each synapse that guarantees long-term stability in the presence of molecular turnover [16]; (ii) a global triggering signal for protein synthesis (described by the dynamics of the $p$ variable); a formalism to (iii) induce early forms of LTP and LTD and (iv) set synaptic tags. Since we aimed for the simplest possible model, we have identified the synaptic tags $h_i$ and $l_i$ for potentiation and depression with the context of bistability of the CaMKII auto-phosphorylation process [27–29], AMPA receptor aggregation [41], or four identified kinase pathways [45]. While CaMKII is necessary for induction of long-term potentiation [46], it is probably too narrow to focus modeling studies only on a single or a few kinases such as CaMKII and neglect other proteins and signaling cascades that are involved in synaptic maintenance [13]. For example, there is strong evidence that PKM* is involved in synaptic maintenance and necessary for the late phase of LTP in vitro [11] and in vivo [14]. However, the actual processes are complex and the molecules involved in setting tags may differ between different parts of the dendrite. For example PKM* is involved in setting tags during E-LTP in the basal dendrite, whereas CaMKII (or MAPK for E-LTD) plays a similar role in apical dendrites [30].

**Figure 3. The model accounts for cross-tagging between LTP and LTD.** (A) A strong low-frequency stimulus (3 pulses at 20 Hz, repeated 900 times every second) applied to a group of $N=100$ synapses induces LTD with mean weights ($w/w(0)$) stabilized at 83±3% of initial value after 5 hours (black line). (B) A weak low-frequency stimulus (1 pulse repeated 900 times at 1 Hz) induces early LTD, which is not consolidated. (C) If the weak low-frequency stimulus is applied 30 minutes after a second group of synapses has received the strong low-frequency protocol, the weights in both groups (blue, weak stimulus; black, strong stimulus) are consolidated at values below baseline. (D) Consolidation of LTD in the group receiving weak low-frequency stimulation (blue line) also happens if induction occurs 30 minutes after stimulating a second group of synapses with a strong tetanic protocol (see Figure 2) inducing LTP (black line). Downward arrows indicated the period of weak (blue arrow) or strong (black arrow) low-frequency protocols. The black upward arrows indicate strong tetanic stimulation. Lines show mean results, averaged over 10 repetitions of the simulation experiment. Error bars are standard deviation.

doi:10.1371/journal.pcbi.1000248.g003
synaptic weights during the early phase of LTP and LTD, respectively, so that points (iii) and (iv) are described by the same transition of the synapse from an initial non-tagged state to the high or low state, respectively. Variants of the model where the weight during the early phase of LTP and LTD is not directly proportional to the value of the tags are conceivable.

Even though we do not want to identify the synaptic variables $h_i$, $l_i$, $z_i$ with specific biochemical signals, a couple of candidate molecules and signaling chains should be mentioned. The setting of the tag for LTP under normal physiological conditions involves NMDA receptor activation and elevated levels of calcium which in turn trigger a signaling chain involving Calmodulin and CaMKII.

We therefore think that the $h_i$ variable (representing both the tag for LTP induction and the weight increase during the early phase of LTP) should be related to the activation of CaMKII [13,46]. The molecular interpretation of the tag $h$ for LTD is less clear [13]. In our model we have taken the tags as discrete quantities that decay stochastically, but a model with continuous tags that decrease exponentially gives qualitatively the same results (data not shown). The reason is that triggering protein synthesis in our model requires a large number of tags to be set, so that even in the stochastic model only the mean number of tags is relevant—and the mean (more precisely, its expectation value) is a continuous variable. Nevertheless, we prefer the model with discrete values over the continuous one in view of the switch-like transitions of synapses after induction of LTP and LTD [7,37]. Maintenance of enhanced synaptic weights is probably implemented by an increased number of AMPA receptors in the postsynaptic membrane. Whether the stability arises from a self-organization process of receptors [41] or from interaction with persistently activated CaMKII molecules [46] or from additional kinases such as PKMζ [11,14], is an open problem of experimental investigation. Similarly, the exact identity of many plasticity related proteins is still unknown [13]. In our model we assume that recently synthesized plasticity related proteins are accessible to all synapses onto the same postsynaptic neuron. However, a distinction between proteins synthesized in, say, basal dendrites and that synthesized in apical dendrites would be possible by

Figure 4. Dynamics of the TagTriC Model during different tagging protocols and protein synthesis blocking. The change of the total synaptic weight (top panels, black line $\Delta w = \sum_{i=1}^{N} [w_i(t) - w_i(0)]/N$) has contribution from early LTP (top panels, magenta line represents $\sum_{i=1}^{N} (h_i - z_i(0))/N$) and from late LTP (top panels, green line represents $\sum_{i=1}^{N} (\beta z_i - z_i(0))/N$). The protein variable $p$ (red line, bottom panels) grows as long as the average number of tags $\sum_{i=1}^{N} (h_i + l_i)/N$, blue line is above the protein synthesis trigger threshold ($N_p/N$, dashed horizontal line). For better visibility, the regions where the blue line is above the trigger threshold is shaded. (A) A strong tetanus ($N=100$ synapses, stimulated by 100 pulses at 100 Hz, repeated three times every ten minutes) leads to a sustained period of about 90 minutes where the number of tagged synapses is lower panel), causing an increase in the fraction of consolidated weights (green line, top panel). (B) During a weak tetanus ($N=100$ synapses, stimulated by 21 pulses at 100 Hz) the number of tags surpasses the protein triggering threshold only for a short time which does not enable switching of the $z$ variable (top panel, green line) to the up-regulated state. (C) If the weak tetanus is given 30 minutes after the strong one, the number of tags set by the strong tetanus is still above the threshold, which allows protein synthesis stabilizing both the group of 100 synapses receiving the strong tetanus (top panel) and the group of 100 synapses receiving the weak tetanus (middle panel). (D) Protein synthesis is blocked for 1 hour (indicated by black bar at bottom of panel) starting 35 minutes after a first group of 100 synapses has been stimulated by a strong tetanus. Despite protein synthesis blocking, both the first group of synapses (top panel) and a second group of 100 synapses that received a strong tetanus during the blocking period (middle panel) develop late LTP because proteins synthesized during the induction of early LTP in the first group decay only slowly (bottom panel).

doi:10.1371/journal.pcbi.1000248.g004
replacing the variable $p$ by two or more distinct variables $p_k$ with similar dynamics (but potentially different trigger thresholds $N_{p_k}$), allowing for a compartmentalization of tagging [13].

Experimental cross-tagging results clearly indicate that there are two different types of synaptic tags, one for LTP and one for LTD [13,32], which we called $k_1$ for LTP and $k_2$ for LTD, leading to three different states during tagging (Figure 1A). Since we have identified the tagging with the early phase of LTP and LTD, our model of E-LTP and E-LTD also has three different states (whereas our model of late LTP/LTD has only two states characterized by $z=0$ and $z=1$). The three-state model of early LTP/LTD presented in this paper would predict that all non-tagged synapses can undergo a transition to E-LTP or E-LTD depending on the induction protocol—whereas experiments suggest that about 70 percent of synapses show LTP but not LTD and the remaining 30 percent LTD but not LTP [7]. Moreover, only those synapses that are initially weak can be potentiated and only those that are initially strong can be depressed [7]. This aspect can be included in our model if we replace the induction rates $\rho_H$ for LTP by $\rho_H(1-z)$ and $\rho_L$ for LTD by $\rho_L z$, so LTP is only possible from a state with $z=0$ and LTD only from an initial state $z=1$ — in agreement with a two-state model of early LTP/LTD [7]. For the tagging and induction experiments presented in this paper, the results do not change significantly when we implement this extension of the induction model.

Functional Consequences and Predictions

One of the advantages of a simple phenomenological model is that it should be capable of illustrating the functional consequences of tagging and L-LTP or L-LTD in a transparent manner. What are these functional consequences?

A characteristic feature that is made transparent in our model (and which we expect to be present in any model of tagging) is that, under typical experimental conditions, the transition from early to late LTP is only possible if a sizable group of synapses have undergone E-LTP or E-LTD. Hence, while induction of E-LTP is a local Hebbian process that is likely to take place at the postsynaptic site of the synapse (e.g., the dendritic spine), the transition from the early to the late phase of LTP requires a minimum number of synapses to be activated by appropriate stimulation including co-activation of neuromodulatory input so as to trigger synthesis of plasticity-related proteins. A direct consequence of this is that synapses cannot be considered as independent. In order to predict whether a synapse memorizes an item for a long time or forgets it and re-learns some other item, it is not sufficient to consider a ‘Hebbian’ induction model, where synaptic changes depend only on the activity of pre- and postsynaptic neurons. For maintenance, it is not the synapse which decides individually, but it is the neuron as a whole (or a large functional compartment sharing the same site of synthesis of plasticity-related proteins [13,30,47]) which ‘decides’ whether it is going to store the present information, or not. Hence, classical [20,21,34] and recent [22] theoretical models which studied memory maintenance in the presence of ongoing neuronal activity on the level of single synapses need to be reconsidered, since the assumption of independent synapses does not hold (Figure 5A and 5B). In particular, our model predicts that, after an ensemble of identical neurons have received the same stimulus, some neurons learn (adapt a large fraction of their synapses to the stimulus) and others don’t (keep all their synapses unchanged). With our choice of parameters, this happens in the TagTriC model if the number of synapses that have been tagged during the induction protocol is between 55 and 70 (Figure 5B). This neuronal, rather than synaptic, decision about memorizing an input (see also [48]) is potentially attractive for prototype learning—a standard paradigm in neuronal clustering and categorization algorithms, e.g., [19]. In contrast to traditional neuronal clustering models where learned
memories need to be protected against overwriting by completely different memory items [19], a model based on tagging would have an intrinsic vigilance threshold via the trigger threshold \( N_p \). Hence it is resistant to changes at a single synapse.

In our view, the protein synthesis trigger threshold \( N_p \) is an important control parameter in the model. The results of Figure 2F show that an increase of the trigger threshold reduces the maximal delay after which a weak tetanus leads to L-LTP after a strong tetanic stimulation in a different group of synapses. With our normal value of \( N_p = 40 \) we need around 60 synapses to be initially tagged in order to retain any memory. If we decrease the trigger threshold to \( N_p = 10 \) and keep all other parameters of the model unchanged, then we need at least a group of 15 synapses tagged during the induction protocol to get any consolidation since some of the initially tagged synapses lose their tag too early to get consolidated (Figure 5B). Only for a very small trigger threshold, \( N_p = 1 \), (which could occur at high concentration of neuromodulators) synapses become (nearly) independent, since a tag at a single synapse would be sufficient to trigger the synthesis of proteins which would then become available at that synapse. Repeated stimulation of the synapse alone would then be sufficient to transform E-LTP into L-LTP.

In our opinion, the trigger threshold \( N_p \) is significantly lower in the presence of neuromodulators such as, for example, dopamine (for synapses from Schaffer collaterals onto CA1 pyramidal neurons) or noradrenaline (for synapses in the dentate gyrus). A simple model for the dependence of \( N_p \) on dopamine would be \( N_p = n_0 / (DA_{bg} + c) \) where \( n_0 \) is some arbitrary number (say \( n_0 = 1 \)), \( c \) a small number (say 0.001) and DA denotes the stationary 'background' concentration of dopamine (that is, before the start of the experiment), normalized to 0 < DA_{bg} < 1. The phasic dopamine signal caused by co-stimulation of dopaminergic input during tagging experiments is assumed to be proportional to the number of tags \( \sum_i h_i + l_i \). The trigger condition \( \sum_i h_i + l_i > N_p \) becomes then equivalent to the condition \( (\sum_i h_i + l_i) / (DA_{bg} + c) > n_0 \) which shows a trade-off between the phasic dopamine signal and the stationary background level of dopamine. In particular in the presence of a large concentration of dopamine (DA=1), single synapses can be consolidated. With the assumption that standard tagging experiments in a large group of synapses are performed at a low dopamine concentration of DA = 0.024 before stimulation, we retrieve the value of \( N_p = 40 \) used in the main part of the results section. The dependence of the trigger criterion on the number of tags \( \sum_i h_i + l_i \) takes implicitly the co-activation of neuromodulatory input during the experimental stimulation protocol into account: the larger the number of stimulated neurons and the stronger the stimulus, the higher the probability of co-activation of dopaminergic fibers. Blocking dopamine receptors amounts in the model to setting both the background and the phasic dopamine signal to zero. In this case, protein synthesis is not possible.

Our model of LTP/LTD induction does not only account for voltage and frequency dependence of LTP/LTD induction, but also for spike timing dependence. In fact, for a stimulation paradigm where postsynaptic spikes are induced by short current pulses of large amplitude either a few milliseconds before or after presynaptic spike arrival, the model of LTP/LTD induction used in the tag becomes equivalent to a simple model of spike-timing dependent plasticity [35] which can be seen as an extension of classical models of STDP [24–26]. In the case of stochastic spiking of pre- and postsynaptic neurons our model shares important features with the Bienenstock-Cooper-Munro model [33], in particular the quadratic dependence upon the postsynaptic variables. In addition, our model also accounts for the voltage dependence of the Artola-Bröcher-Singer model [38]. Thus, the model of LTP/LTD induction shares features with numerous established theoretical models and covers a large range of experimental paradigms known to induce LTP or LTD [3–6,34].

Since the subsequent steps of protein synthesis trigger and stabilization are independent of the way early phase of LTP is induced, our model predicts that tagging experiments repeated with different stimulation paradigms, but otherwise identical experimental preparation and age of animal, should give similar results as standard tagging protocols. In particular we propose to stimulate a group of synapses in hippocampal slices by 40–60 extracellular current pulses at 10 Hz while the postsynaptic neuron is receiving intracellulat current injection that triggers action potential firing either a few milliseconds before or after presynaptic spike arrival and keeps the membrane potential at a depolarized level between postsynaptic action potential firing. Our model predicts that this will induce early LTD or LTP depending on spike timing and depolarization level that is not maintained beyond 1 or 2 hours. However, if the same stimulation occurs after a second group of synapses has received a strong tetanus, then stabilization of synapses at potentiated or depressed levels should occur, similar to standard tagging and cross-tagging experiments.

In our opinion, these predictions should not depend on model details, but hold for a broad class of models that combine a mathematical description of induction of synaptic plasticity with a mechanism of consolidation.

Another finding—which is somewhat unexpected and in contrast to other conceptual models of synaptic tagging and capture [12,13,47]—is that during a strong tetanic stimulation a fraction of synapses receives tagged depression (while most, but not all, receive tags for potentiation). This is due to the fact that during induction of plasticity, transition to E-LTP and E-LTD act in parallel [7]. The prediction is that after consolidation (say 2 hours after the strong tetanic stimulation) a small fraction of synapses would show L-LTD, rather than L-LTP.

An essential ingredient of our model that allows long-term stability of consolidated synapses is the bistable dynamics of the variable \( z \). In our opinion, such bistability (or possibly multistability [49] with three or four stable states) is necessary for synaptic maintenance in the presence of molecular turn-over, as recognized in earlier theoretical work [15,16,34]. Our model therefore predicts that L-LTP and L-LTD should have bistable, switch-like properties. While there is evidence for switch-like transitions during the induction of E-LTP and E-LTD [7,37], the bistability of the late phase of synaptic plasticity has so far not been shown. A possible experiment would be to combine a minimal activation protocol (e.g., a weak tetanus) at a single synapse [7,37] with a strong to strong stimulus at a group of other synapses (e.g., tetanic stimulus varying between 30 and 100 pulses). The prediction is that the weight of the single synapse shows an all-or-none phenomenon with transition probabilities that depend on the stimulation of the group of other synapses. In particular, as the number of pulses of the tetanic stimulation is reduced (covering a continuum from strong to weak tetanic stimulation), the maintenance in the potentiated state should become less likely (averages across many experiments decrease) whereas the results of individual experiments show either full potentiation or none, which should give rise to a bimodal distribution of normalized synaptic weights.

Open Questions and Perspectives

A lot of questions remain open and need to be addressed in future studies. First, can a synapse that has been potentiated in the past and maintained after a transition to late LTP undergo a
further potentiation step [13]? In our current model this is not possible since the consolidation variable $z$ has only two stable fixed points. If we replace the function $f_{z}^{(2)}$ depicted in Figure 1 by another one with more than two stable fixed points, then the answer to the above question would be positive. Indeed, there have been suggestions that self-organization of receptors into stable sub-groups could lead to multiple stable states [49].

Second, induction of LTP or LTD is not only possible by strong extracellular stimulation of groups of synapses, but also at single synapses if presynaptic activity is paired with either a depolarization of the postsynaptic membrane [5,7] or tightly timed postsynaptic spikes as in STDP experiments [6,8]. How can it be that the change induced by STDP seems to be maintained over one hour without visible degradation? [6,7]. Are synapses in these experiments consolidated, and if so what is the concentration of neuromodulators? In the TagTriC model with the choice of parameters used in the present paper, consolidation would not be possible, since the minimum number of synapses that have undergone E-LTP or LTD is $N_p = 40$ in order to trigger protein synthesis, but, as explained above, an increased neuromodulator concentration would make consolidation possible.

Third, what is the role of NMDA receptor activation during synaptic consolidation? In our present model, protein synthesis is triggered by appropriate induction protocols, but is independent of synaptic activity during the consolidation process. However, recent experimental results suggest that protein synthesis blocker needs synaptic consolidation during the consolidation period to become effective [50], suggesting a subtle interplay between protein synthesis and synaptic activation that cannot be captured by our model.

Fourth, has each neuron a single protein synthesis unit or is protein synthesis a local process confined to each dendritic branch? In the first case, there is a single neuron-wide protein synthesis trigger threshold [12] and the neuron as a whole ‘decides’ whether early forms of synaptic potentiation and depression will be consolidated or not. This is the paradigm posited in the TagTriC model. In the alternative model of local protein synthesis [13,47], the critical unit for consolidation are local groups of synapses on the same dendritic branch. Thus, for the same number of tagged synapses, a local group of synapses on the same dendritic branch is more likely to undergo consolidation than a distributed set of tagged synapses, leading to a form of clustered plasticity [47]. The TagTriC model can be easily adapted to the case of clustered plasticity by (i) replacing the point-neuron model by a neuron model with local groups of synapses on the same dendritic branch. Thus, for the same number of tagged synapses, a local group of synapses on the same dendritic branch is more likely to undergo consolidation than a distributed set of tagged synapses, leading to a form of clustered plasticity [47]. The TagTriC model can be easily adapted to the case of clustered plasticity by (i) replacing the point-neuron model by a neuron model with local groups of synapses on the same dendritic branch. Thus, for the same number of tagged synapses, a local group of synapses on the same dendritic branch is more likely to undergo consolidation than a distributed set of tagged synapses, leading to a form of clustered plasticity [47]. The TagTriC model can be easily adapted to the case of clustered plasticity by (i) replacing the point-neuron model by a neuron model with local groups of synapses on the same dendritic branch. Thus, for the same number of tagged synapses, a local group of synapses on the same dendritic branch is more likely to undergo consolidation than a distributed set of tagged synapses, leading to a form of clustered plasticity [47].

Fifth, how can tags be reset? Experiments show that a depotentiating stimulus given 5 minutes after a weak tetanus erases the trace of E-LTP (resets the tag) whereas depotentiation 10 or 15 minutes after the strong tetanus only transiently suppresses the E-LTP, making the consolidation of the synapse by protein capture possible [51]. We have checked in additional clamp experiments (e.g., [39]) the postsynaptic voltage would be combined with a depolarization of the postsynaptic membrane (e.g., [5]) in order to induce a change of the synapse. In voltage clamp experiments (e.g., [39]) the postsynaptic voltage would be constant. However, in general the voltage is time-dependent and described by a variable $u(t)$.

In the TagTriC model, we assume that the low-pass-filtered voltage needs to be above a critical value $\sigma_{\text{LTP}}$ to make a change of the synapse possible. $\tau_{\text{lowP}}$ is the time constant of the low-pass filter and $\varepsilon \equiv 1$ ms is a short delay twice the width of a spike (see Table 1). This short delay ensures that $\sigma$ includes effects of previous presynaptic inputs and postsynaptic spikes, but not of an ongoing postsynaptic action potential.

### Methods

#### Model of Early LTP/LTD and Tagging

In our model we assume that presynaptic spike arrival needs to be combined with a depolarization of the postsynaptic membrane (e.g., [5]) in order to induce a change of the synapse. In voltage clamp experiments (e.g., [39]) the postsynaptic voltage would be constant. However, in general the voltage is time-dependent and described by a variable $u(t)$. In the TagTriC model, we assume that the low-pass-filtered voltage

$$
\sigma(t) = \frac{1}{\tau_{\text{lowP}}} \int_{0}^{t} \exp \left( -\frac{s}{\tau_{\text{lowP}}} \right) u(t-s) \, ds.
$$

needs to be above a critical value $\sigma_{\text{LTP}}$ to make a change of the synapse possible. $\tau_{\text{lowP}}$ is the time constant of the low-pass filter and $\varepsilon \equiv 1$ ms is a short delay twice the width of a spike (see Table 1). This short delay ensures that $\sigma$ includes effects of previous presynaptic inputs and postsynaptic spikes, but not of an ongoing postsynaptic action potential.

#### Table 1. Parameter values used throughout all simulations, except Figure 1E–G where $N_p = 10$ and initial percentage of $z_i = 1$ was 10%, because these simulations refer to experiments with younger animals.

Combining presynaptic spike arrival at synapse $i$ (represented by $x_i$) with a depolarization $u$ of the postsynaptic neuron above a threshold $\theta_{\text{LTD}}$ we get a rate of LTD

$$
\rho_L = A_{\text{LTD}} x_i(t) \left[ u(t) - \theta_{\text{LTD}} \right]^++
$$

where $A_{\text{LTD}}>0$ is a parameter and $[\cdot]^+$ denotes rectification, i.e., $[y]^+ = y$ if $y > 0$ and zero otherwise. Here $x_i(t) = \sum_j \delta(t - t_j^i)$ denotes the presynaptic spike train with pulses at time $t_j^i$ and $\delta$ the Dirac-delta function. Formally, $\rho_L$ describes the rate of stochastic transitions from the non-tagged state $h = 0$, $l = 0$ to the low state $l = 1$, $h = 1$, Figure 1. In simulations we work with discrete time steps of $\Delta = 1 \text{ms}$. Eq. 1 indicates that the probability $P_{l=0\rightarrow l=1}$ of a transition to the low-state during the time step $\Delta$ vanishes in the absence of presynaptic spike arrival and takes a value of

$$
P_{l=0\rightarrow l=1} = 1 - \exp(-A_{\text{LTD}}(u(t) - \theta_{\text{LTD}}) \Delta) = A_{\text{LTD}} (u(t) - \theta_{\text{LTD}})^+ \Delta$$

if a presynaptic spike arrives at the synapse $i$ during the time step $\Delta$. Note that the transition from $l = 0$ to $l = 1$ is only possible if $h = 0$ and $l$ remains zero during the transition.

Similarly, a switch from the non-tagged state $h = 0$, $l = 0$ to the high state $h = 1$ occurs at a rate $\rho_H$ which also depends on postsynaptic voltage and presynaptic spike arrival. We assume that each presynaptic spike at synapse $i$ leaves a trace $\xi_i$ that decays exponentially with time constant $\tau_x$. The exact biological nature of the trace is irrelevant, but could, for example, represent the amount of glutamate bound to the postsynaptic receptor. The value of the trace at time $t \tau$ caused by earlier spike arrivals at time $t_j^i$ is then $\xi_i(t) = \tau_x \sum \exp(-\tau_x(t-t_j^i)) \tau_x$ where the sum runs over all firing times $t_j^i < t$. With the trace $\xi_i$ we write

$$
\rho_H = A_{\text{LTP}} \xi_i(t) \left[ u(t) - \theta_{\text{LTP}} \right]^+
$$

which indicates that, in addition to the conditions for LTD induction we also require the 

$$
\text{membrane potential trajectory} u(t) \text{ to be above a second threshold } \theta_{\text{LTP}}. \text{ This threshold could change on the time scale of minutes or hours as a function of homeostatic processes. To summarize, the rate of LTP transition } \rho_{\text{LTP}} \text{ is different from } \rho_L \text{ in five aspects. First, the constant } A_{\text{LTP}} \text{ is not the same as } A_{\text{LTD}}. \text{ Second, LTP is caused by the trace } \xi_i \text{ left by presynaptic spikes, rather than the spikes themselves. This trace-formulation ensures that presynaptic spikes can interact with later postsynaptic spikes as in classical models of STDP [24–26]. Third, the time constant of the low-pass filter in } u \text{ is different; fourth, the momentary voltage needs to be above a threshold } \theta_{\text{LTP}} \text{ and fifth, the total dependence upon the postsynaptic voltage is quadratic, rather than linear. The quadratic dependence ensures that for large depolarization LTP dominates over LTD [39]. Tagged synapses with } h = 1 \text{ decay with probability } P_{h=1\rightarrow h=0} = k_p \Delta \text{ back to the non-tagged state and (analogously, but with rate } k_L \text{ for the transition } l = 1 \rightarrow l = 0)\text{.}

In the TagTriC model, the local synaptic values $h = 1$ for potentiation or $l = 1$ for depression act as tags indicating potential sites for further consolidation, but are also directly proportional to the weight of the synapse after induction of LTP or LTD. Since in minimal stimulation experiments LTD leads to a reduction of about 50% of the synaptic efficacy whereas LTD leads to an increase by up to 100 percent [7], we model the weight change during the early phase of LTP as $\Delta w = (h - \Delta) w$ where $w$ is the weight of the non-tagged synapse and $\Delta = 0.5$. The total weight change $\Delta w$ measured shortly after induction of LTP or LTD with extracellular protocols corresponds to the fraction of synapses in the high or low states, respectively, hence, if all synapses start from the non-tagged state the measured weight change is $\Delta w = \sum_i (h_i - \Delta_i) w_i / N = \langle h \rangle - \Delta z(t)$ where $N$ is the number of synapses stimulated by the protocol. The set of parameters of LTP/LTD induction and tagging is given in table 1.

**Trigger**

The triggering process is controlled by the dynamics of a variable $\rho$ which describes the amount of plasticity related proteins synthesized in the postsynaptic neuron. Protein synthesis is triggered and the variable $\rho$ increases while the concentration of dopamine exceeds a critical level $\rho_0$ [30]. If the dopamine concentration $DA$ falls below $\rho_0$, the protein concentration decays with a time constant $\tau_p$. Assuming standard first-order kinetics we have

$$
\frac{d\rho}{dt} = k_p(1 - \rho) \Theta[DA - \rho_0] - \frac{P}{\tau_p}
$$

Protein synthesis has a maximum rate $d\rho/dt$ of $k_p$ and saturates if the amount of protein approaches a value one. $\Theta[y]$ denotes the unit step function with $\Theta[y] = 1$ for $y > 0$ and zero otherwise.

Dopamine is present at a low stationary background value. In addition a phasic dopamine component is induced in standard tagging experiments in hippocampal slices, because of co-stimulation of dopaminergic inputs during extracellular stimulation of presynaptic fibers [40]. To describe the time course of the phasic dopamine component in our model, we assume that the dopamine is proportional to the total number of tags $\sum (h_i + l_i)$ induced by the stimulation protocol. The stationary background level of dopamine $DA_{bg}$ is included in the threshold $\rho_0 = N_p (DA_{bg})$ for protein synthesis. Hence Eq. 3 can be rewritten in the form

$$
\frac{d\rho}{dt} = k_p(1 - \rho) \Theta \left[ \sum_i (h_i + l_i) - N_p (DA_{bg}) \right] - \frac{P}{\tau_p}
$$

Note that we have chosen units so that the threshold for protein synthesis $N_p$ can be interpreted as the minimal number of tags necessary to stimulate protein synthesis. This interpretation is important for the discussion of the model results, in particular Figures 4 and 5.

A suitable model for dependence of the protein synthesis threshold on the background level of dopamine is $N_p (DA_{bg}) = n_0 / (DA_{bg} + n_0)$ where $n_0 = 1$ is a scaling factor, $n_0 = 0.001$ a constant and $0 \leq DA_{bg} \leq 1$ is the normalized dopamine concentration. We note that the trigger condition $[\sum (h_i + l_i) - N_p (DA_{bg})] > 0$ is then equivalent to the condition $[DA_{bg} + 0.001 \sum (h_i + l_i)] > 1$. This formulation shows that there is a trade-off between background levels and phasic dopamine. Unless stated otherwise we always use in the simulation a fixed dopamine level $DA_{bg} = 0.024$ so that $N_p = 40$. The specific model $N_p (DA_{bg})$ of the dependence upon background dopamine levels is therefore irrelevant.

We assume that the plasticity related protein $\rho$ synthesized in the postsynaptic neuron is diffused in the dendrite of the postsynaptic neuron and hence available to all the synapses under consideration. Hence, the tags $h_i$ and $l_i$ have indices, since they are synapse-specific, whereas $\rho$ in Eq. 4 does not.

**Consolidation and Late LTP**

The consolidation variable $z$ describes the late phase of LTP and follows the dynamics

$$
\tau_z \frac{d z}{d t} = f(z_i) + \gamma [DA_i (h_i - l_i)]
$$

where $f(z_i)$ is a function of $z_i$ and $\gamma$ is a constant.
The scaling factor $c$ is a function of the dopamine level $DA$. In the simulations we always assumed a fixed dopamine level and set $\gamma(DA) = 0.1$.

In the absence of plasticity related proteins ($p=0$), or if no tags are set ($hi=l=0$), the function $f_i(\hat{z}) = (1-z)(z-0.5)$ generates a bistable dynamics with stable fixed points at $z = 0$ and $z = 1$ and an unstable fixed point at $z = 0.5$ marked by the zero crossings of the function $f_i$, Figure 1C. In the presence of a finite amount of proteins $p>0$ and a non-zero tag, the location of the fixed points changes and for $p>0.47$, only one of the stable fixed points remains. The potential shown in Figure 1C is a function $E$ with $dE/dz = -f(\hat{z})$ so that $dz/dt = -dE/dz$. We note that a synapse $i$ can change its consolidated value only if both a tag ($hi=1$ or $li=1$) and protein $p>0.47$ is present—summarizing the essence of ‘synaptic tagging and capture’ [12,13].

Synaptic Weight

The synaptic weights have contributions from early and late LTP and LTD. The total synaptic weight of a synapse $i$ is $w_i = \delta_i(1hi - 2hl + f(\hat{z}))$ where $\delta_i$ is the value of a non-tagged synapse, $z = 0.5$ and $\beta = 2$ are parameters, $hi$ and $li$ are binary values indicating E-LTP and E-LTD, respectively, and $z$ is the value of the L-LTP trace of synapse $i$. Since we model slice experiments in animals older than 20 days, we assume that 30 percent of the synapses have undergone previous potentiation and have $z = 1$ while the remaining 70 percent of synapses are in the state $z = 0$ [7]. In all simulation experiments we stimulate one or several groups of $N=100$ synapses each. Assuming that no tags have been set in the recent past ($hi=li=0$), the initial value of the average weight in a group of $N$ synapses is then $\bar{w}(0) = \delta \sum_{i=1}^{N} 1 + \beta z_i / N = 1.6\delta$.

Neuron Model

For all simulations in this paper we use the adaptive exponential integrate-and-fire model [42] as a compact description of neuronal firing dynamics. Briefly, it consists of two equations. The voltage equation has an exponential and a linear term as measured in experiments [59]. The second equation describes adaptation. Although firing rate adaptation is not important for the present study, it would be relevant in the context of other stimulation paradigms. Parameters for the neuron model are as in [42] and are kept fixed for all simulations presented in this paper. The voltage threshold $V_r$ of spike initiation by a short current pulse is 25 mV above the resting potential of −70.6 mV [42]. Synaptic input is simulated as a short current pulse. The initial connection weight $\delta_0$ was adjusted so that simultaneous activation of 40 or more synapses triggers spike firing in the postsynaptic neuron. Hence the amplitude of a single EPSP is about 0.6 mV.

The adaptive exponential integrate-and-fire model is defined in continuous time. If a spike is triggered by a strong current pulse, the voltage rises within less than 0.5 millisecond to a value of 20 mV where integration is stopped. The voltage is then reset to resting level, and integration restarted after a refractory time of 1 ms. In order to enable us to perform simulations of plasticity experiments with a time step of $\Delta = 1$ ms, the voltage equation during the rising slope of the action potential was integrated once at a much higher resolution (time step 0.02 ms), so as to determine the exact contribution of each postsynaptic spike to the probability of LTP induction. Every postsynaptic spike was then treated as an event in the plasticity simulations that contributed a probability $\mathbb{P}(t)=\mathbb{P}(t_0)$ of flipping the tag from $h=0$ to $h=1$ in a time step $\Delta = 1$ ms which we can write as $\mathbb{P}(t)=\mathbb{P}(0)\exp(-\mathbb{R}t)$ with a numerical conversion factor $\mathbb{R}=A_{LTP} 5$ ms mV−1 derived by the above procedure; see Eq. 2.

Number of Consolidated Synapses

In Figure 5 we plot the number of synapses that have been consolidated as a function of the number $N_{tag}$ of initially tagged ($hi=1$) synapses. Since the number of tags decays exponentially with rate $\lambda_{hi}$ the expected duration $T^{P}_{ON}$ of protein synthesis is $T^{P}_{ON} = (1/\lambda_{PP}^i)\ln(N_{tag}/N_{p})$ where $N_{p}$ is the protein trigger threshold. While protein synthesis is ‘ON’ the variables $p$ and $z$ move along the black dashed line in Figure 5A which crosses after a time $t_1$ the separatrix (green line in Figure 5A) and at a time $t_2$ the line $z=0.5$ (vertical dashed green line). Different cases have to be distinguished. (i) $T^{P}_{ON} < t_1$, no consolidation takes place (see pink trajectory), hence $N_{tag} = 0$. (ii) $T^{P}_{ON} > t_2$, consolidation is guaranteed for all synapses that are still tagged at time $t_3$, hence $N_{tag} = N_{tag}\exp(-h_{hi})$. (iii) In the case of $t_1 < T^{P}_{ON} \leq t_2$, the time $t_{cons}$ needed to cross the vertical line $z=0.5$ is numerically calculated by integrating the equations $dp/dt = -p/\tau_p$ and $dz/dt = f(\tau_p)$ starting at $t = T^{P}_{ON}$ at the point $p(T^{P}_{ON})$, $z(T^{P}_{ON})$ on the black-dashed line (see orange line in Figure 5A for a sample trajectory). The number of consolidated synapses is then $N_{tag} = N_{tag}\exp(-h_{hi})$. The solid line in Figure 5B represents $N_{tag}$ as a function of $N_{tag}$ calculated for the cases (i)-(iii). With our standard set of parameters, we have $t_1 \approx 28$ min and $t_2 \approx 60$ min.

A TOP DOWN APPROACH TO A RULE PERFORMING INDEPENDENT COMPONENT ANALYSIS

Independent Component Analysis (ICA) is a technique able to find original source signals out of mixtures of those signals, the so-called cocktail party problem. How do we recover a voice in a cocktail party when mixed with music? There are powerful ICA algorithms that take into account either the spatial distribution of the signal ("spatial ICA") (Hyvärinen, Karhunen, and Oja 2001) or the temporal correlations of the signal ("temporal ICA") (Tong, Liu, Soon, and Huang 1991; Molgedey and Schuster 1994; Belouchrani, Abed-Meraim, Cardoso, and Moulines 1997; Ziehe and Müller 1998). Those algorithms are however difficult to interpret biologically since they are either not online or require difficult preprocessing of the data such as whitening (Hyvärinen, Karhunen, and Oja 2001). Thus the way the brain is able to solve the cocktail party problem is still unclear. In Chapter 3 however, the induction model was shown to perform spatial ICA. We were wondering if a model could solve temporal ICA and what would be the link to the induction model. In the following paper (Clopath, Longtin, and Gerstner 2008) we present a top down approach leading to a biologically plausible model performing ICA. It takes into account the temporal correlations of the signals. By decorrelating the signal mixtures at 2 different time lags, it is possible to recover the original sources. The rule is a standard rate-based Hebbian rule where the rate is taken at those two different time lags. This rule does not require any preprocessing of the data. It allows to de-mix the different sound signals of the standard ICA benchmarks (Hyvärinen, Karhunen, and Oja 2001). The link between this model and the early phase of plasticity model is explained in the "future work" section.
Abstract

Independent component analysis (ICA) is a powerful method to decouple signals. Most of the algorithms performing ICA do not consider the temporal correlations of the signal, but only higher moments of its amplitude distribution. Moreover, they require some preprocessing of the data (whitening) so as to remove second order correlations. In this paper, we are interested in understanding the neural mechanism responsible for solving ICA. We present an online learning rule that exploits delayed correlations in the input. This rule performs ICA by detecting joint variations in the firing rates of pre- and postsynaptic neurons, similar to a local rate-based Hebbian learning rule.

1 Introduction

The so-called cocktail party problem refers to a situation where several sound sources are simultaneously active, e.g. persons talking at the same time. The goal is to recover the initial sound sources from the measurement of the mixed signals. A standard method of solving the cocktail party problem is independent component analysis (ICA), which can be performed by a class of powerful algorithms. However, classical algorithms based on higher moments of the signal distribution [1] do not consider temporal correlations, i.e. data points corresponding to different time slices could be shuffled without a change in the results. But time order is important since most natural signal sources have intrinsic temporal correlations that could potentially be exploited. Therefore, some algorithms have been developed to take into account those temporal correlations, e.g. algorithms based on delayed correlations [2, 3, 4, 5] potentially combined with higher-order statistics [6], based on innovation processes [7], or complexity pursuit [8]. However, those methods are rather algorithmic and most of them are difficult to interpret biologically, e.g. they are not online or not local or require a preprocessing of the data.

Biological learning algorithms are usually implemented as an online Hebbian learning rule that triggers changes of synaptic efficacy based on the correlations between pre- and postsynaptic neurons. A Hebbian learning rule, like Oja’s learning rule [9], combined with a linear neuron model, has been shown to perform principal component analysis (PCA). Simply using a nonlinear neuron combined with Oja’s learning rule allows one to compute higher moments of the distributions which yields ICA if the signals have been preprocessed (whitening) at an earlier stage [1]. In this paper, we are...
interested in exploiting the correlation of the signals at different time delays, i.e. a generalization of the theory of Molgedey and Schuster [4]. We will show that a linear neuron model combined with a Hebbian learning rule based on the joint firing rates of the pre- and postsynaptic neurons of different time delays performs ICA by exploiting the temporal correlations of the presynaptic inputs.

2 Mathematical derivation of the learning rule

2.1 The problem

We assume statistically independent autocorrelated source signals \( s_i \) with mean \( < s_i >= 0 \) (\( <> \) means averaging over time) and correlations \( < s_i(t)s_j(t') >= K_i(|t - t'|)\delta_{ij} \). The sources \( s \) are mixed by a matrix \( C \)

\[ x = Cs, \]

where \( x \) are the mixed signals recorded by a finite number of receptors (bold notation refers to a vector). We think of the receptors as presynaptic neurons that are connected via a weight matrix \( W \) to postsynaptic neurons. We consider linear neurons [9], so that the postsynaptic signals \( y \) can be written

\[ y = Wx. \]

The aim is to find a learning rule that adjusts the appropriate weight matrix \( W \) to \( W^* \) (* denotes the value at the solution) so that the postsynaptic signals \( y \) recover the independent sources \( s \) (Fig 1), i.e. \( y = Ps \) where \( P \) is a permutation matrix with different multiplicative constants (the sources are recovered in a different order up to a multiplicative constant), which means that, neglecting \( P \),

\[ W^* = C^{-1}. \]

To solve this problem we extend the theory of Molgedey and Schuster [4] in order to derive an online biological hebbian rule.

2.2 Theory of Molgedey and Schuster and generalization

The paper of Molgedey and Schuster [4] focuses on the instantaneous correlation matrix but also the time delayed correlations \( M_{ij} = < x_i(t)x_j(t + \tau) > \) of the incoming signals. Since the correlation matrix \( M_{ij} \) is symmetric, it has up to \( n(n + 1)/2 \) independent elements. However, the unknown mixing matrix \( C \) has potentially \( n^2 \) elements (for \( n \) sources and \( n \) detectors). Therefore, we need to evaluate two delayed correlation matrices \( M \) and \( \bar{M} \) with two different time delays defined as

\[ M_{ij} = < x_i(t)x_j(t + \tau_2) > \quad \bar{M}_{ij} = < x_i(t)x_j(t + \tau_1) > \]

from equation 1, we obtain the relation \( M_{ij} = \sum_l C_{il}C_{jl}\Lambda_{ll} \) and similarly \( \bar{M}_{ij} = \sum_l C_{il}C_{jl}\bar{\Lambda}_{ll} \) where \( \Lambda_{ij} = \delta_{ij}K_i(\tau_2) \) and \( \bar{\Lambda}_{ij} = \delta_{ij}K_i(\tau_1) \) are diagonal matrices. Since \( M = CA\bar{C}^T \) and \( \bar{M} = C\bar{C}C^T \), we have

\[ (M\bar{M}^{-1})C = C(A\bar{A}^{-1}). \]
It follows that \( C \) can be found from an eigenvalue problem. Since \( C \) is the mixing matrix, a simple algorithmic inversion allows Molgedey and Schuster to recover the original sources [4].

### 2.3 Our learning rule

In order to understand the putative neural mechanism performing ICA derived from the formalism developed above, we need to find an online learning rule describing changes of the synapses as a function of pre- and postsynaptic activity. Taking the inverse of (5), we have \( C^{-1} \tilde{M} M^{-1} = \tilde{\Lambda} \Lambda^{-1} C^{-1} \). Therefore, for weights that solve the ICA problem we expect because of (3) that

\[
W^* \tilde{M} = \tilde{\Lambda} \Lambda^{-1} W^* M,
\]

which defines the weight matrix \( W^* \) at the solution.

For the sake of simplicity, consider only one linear postsynaptic neuron. The generalization to many postsynaptic neurons is straightforward (see section 4). The output signal \( y \) of the neuron can be written as \( y = w^T x \), where \( w^T \) is a row of the matrix \( W^* \). Then equation 6 can be written as

\[
w^T \tilde{M} = \lambda w^T M,
\]

where \( \lambda \) is one element of the diagonal matrix \( \tilde{\Lambda} \Lambda^{-1} \).

In order to solve this equation, we can use the following iterative update rule with update parameter \( \gamma \).

\[
\dot{w} = \gamma (w^T \tilde{M} - \lambda w^T M).
\]

The fixed point of this update rule is giving by (7), i.e. \( w = w^* \). Furthermore, multiplication of (7) with \( w \) yields \( \lambda = \frac{w^T \tilde{M} w}{w^T M w} \).

If we insert the definition of \( M \) from (2), we obtain the following rule

\[
\dot{w} = \gamma [< y(t)x(t + \tau_1) > - \lambda < y(t)x(t + \tau_2) >],
\]

with a parameter \( \lambda \) given by

\[
\lambda = \frac{< y(t)y(t + \tau_1) > - < y(t)y(t + \tau_2) >}{< y(t)y(t + \tau_1) >}.
\]

It is possible to show that \( \dot{w} \) is orthogonal to \( w \). This implies that to first order (in \( |\dot{w}/w| \)), \( w \) will keep the same norm during iterations of (9).

The rule 9 we derived is a batch-rule, i.e. it averages over all sample signals. We convert this rule into an online learning rule by taking a small learning rate \( \gamma \) and using an online estimate of \( \lambda \).

\[
\dot{w} = \gamma [y(t)x(t + \tau_1) - \frac{\lambda_1}{\lambda_2} y(t)x(t + \tau_2)]
\]

\[
\tau_\lambda \dot{\lambda}_1 = -\lambda_1 + y(t)\dot{y}(t + \tau_1)
\]

\[
\tau_\lambda \dot{\lambda}_2 = -\lambda_2 + y(t)\dot{y}(t + \tau_2).
\]

Note that the rule defined in (10) uses information on the correlated activity \( xy \) of pre- and postsynaptic neurons as well as an estimate of the autocorrelation \( < yy > \) of the postsynaptic neuron. \( \tau_\lambda \) is taken sufficiently long so as to average over a representative sample of the signals and \( |\gamma| \ll 1 \) is a small learning rate. Stability properties of updates under rule (10) are discussed in section 4.

### 3 Performances of the learning rule

A simple example of a cocktail party problem is shown in Fig 2 where two signals, a sinus and a ramp (saw-tooth signal), have been mixed. The learning rule converges to a correct set of synaptic
Figure 2: A. Two periodic source signals, a sinus (thick solid line) and a ramp (thin solid line), are mixed into the presynaptic signals (dotted lines). B. The autocorrelation functions of the two source signals are shown (the sinus in thick solid line and the ramp in thin solid line). The sources are normalized so that $\Lambda(0) = 1$ for both. C. The learning rule with $\tau_1 = 3$ and $\tau_2 = 0$ extracts the sinusoidal output signal (dashed) composed to the two input signals. In agreement with the calculation of stability, $\gamma > 0$, the output is recovering the sinus source because $\Lambda_{\text{sin}}(3) > \Lambda_{\text{ramp}}(3)$. D. The learning rule with $\tau_1 = 10$, $\tau_2 = 0$, converges to the other signal (dashed line), i.e. the ramp, because $\Lambda_{\text{ramp}}(10) > \Lambda_{\text{sin}}(10)$. Note that the signals have been rescaled since the learning rule recovers the signals up to a multiplicative factor.

weights so that the postsynaptic signal recovers correctly one of the sources. Postsynaptic neurons with different combinations of $\tau_1$ and $\tau_2$ are able to recover different signals (see the section 4 on Stability). In the simulations, we find that the convergence is fast and the performance is very accurate and stable. Here we show only a two-sources problem for the sake of visual clarity. However, the rule can easily recover several mixed sources that have different temporal characteristics.

Fig 3 shows an ICA problem with sources $s(t)$ generated by an Ornstein-Uhlenbeck process of the form $\tau_x \dot{s}_i = -s_i + \xi$, where $\xi$ is some gaussian noise. The different sources are characterized by different time constants. The learning rule is able to decouple these colored noise signals with gaussian amplitude distribution since they have different temporal correlations.

Finally, Fig 4 shows an application with nine different sounds. We used 60 postsynaptic neurons with time delays $\tau_1$ chosen uniformly in an interval [1,30ms] and $\tau_2 = 0$. Globally 52 of the 60 neurons recovered exactly 1 source (A, B) and the remaining 8 recovered mixtures of 2 sources (E). One postsynaptic neuron is recovering one of the sources depending on the source’s autocorrelation at time $\tau_1$ and $\tau_2$ (i.e. the source with the biggest autocorrelation at time $\tau_1$ since $\tau_2 = 0$ for all neurons, see section Stability). A histogram (C) shows how many postsynaptic neurons recover each source. However, as it will become clear from the stability analysis below, a few specific postsynaptic neurons tuned to time delays, where the autocorrelation functions intersect (D, at time $\tau_1 = 3$ms and $\tau_2 = 0$), cannot recover one of the sources precisely (E).
Figure 3: A. The 3 source signals (solid lines generated with the equation $\tau_s \dot{s}_i = -s_i + \xi$ with different time constants, where $\xi$ is some gaussian noise) are plotted together with the output signal (dashed). The learning rule is converging to one of the sources. B. Same as before, but only the one signal (solid) that was recovered is shown together with the neuronal output (dashed).

Figure 4: Nine different sound sources from [11] were mixed with a random matrix. 60 postsynaptic neurons tuned to different $\tau_1$ and $\tau_2$ were used in order to recover the sources, i.e. $\tau_1$ varies from 1ms to 30ms by steps of 0.5ms and $\tau_2 = 0$ for all neurons. A. One source signal (below) is recovered by one of the postsynaptic neurons (above, for clarity reason, the output is shifted upward). B. Zoom on one source (solid line) and one output (dashed line). C. Histogram of the number of postsynaptic neurons recovering each sources. D. Autocorrelation of the different sources. There are several sources with the biggest autocorrelation at time 3ms. E. The postsynaptic neuron tuned to a $\tau_1 = 3$ms and $\tau_2 = 0$ (above) is not able to recover properly one of the sources even though it still performs well except for the low amplitude parts of the signal (below).
4 Stability of the learning rule

In principle our online learning rule (10) could lead to several solutions corresponding to different fixed points of the dynamics. Fixed points will be denoted by \( w^* = e_k \), which are by construction the row vectors of the decoupling matrix \( W^* \) (see (5) and (7)). The rule (10) has two parameters, i.e. the delays \( \tau_1 \) and \( \tau_2 \) (the \( \tau_3 \) is considered fixed). We assume that in our architecture, these delays characterize different properties of the postsynaptic neuron. Neurons with different choices of \( \tau_1 \) and \( \tau_2 \) will potentially recover different signals from the same mixture. The stability analysis will show which fixed point is stable depending on the autocorrelation functions of the signals and the delays \( \tau_1 \) and \( \tau_2 \).

We analyze the stability, assuming small perturbation of the weights, i.e. \( w = e_i + \epsilon e_k \), where \{\( e_k \)\}. the basis of the matrix \( C^{-1} \), are the fixed points. We obtain the expression (see Appendix for calculation details)

\[
\dot{e} = \gamma \epsilon \frac{\Lambda_{jj}(\tau_1) \Lambda_{ii}(\tau_2) - \Lambda_{ii}(\tau_1) \Lambda_{jj}(\tau_2)}{\Lambda_{ii}(\tau_2)},
\]

where \( \Lambda(\tau)_{ij} = < s_i(t) s_j(t + \tau) > \) is the diagonal correlation matrix.

To illustrate the stability equation (11), let us take \( \tau_1 = 0 \) and assume that \( \Lambda_{ii}(0) = \Lambda_{jj}(0) \), i.e. all signals have the same zero-time-lag autocorrelation. In this case (11) reduces to \( \dot{e} = \gamma \epsilon [\Lambda_{jj}(\tau_1) - \Lambda_{ii}(\tau_1)] \). That is the solution \( e_i \) is stable if \( \Lambda_{jj}(\tau_1) < \Lambda_{ii}(\tau_1) \) for all directions \( e_j \) (with biggest autocorrelation at time \( \tau_1 \)) for \( \gamma > 0 \). If \( \gamma < 0 \), the solution \( e_i \) is stable for \( \Lambda_{jj}(\tau_1) > \Lambda_{ii}(\tau_1) \).

This stability relation is verified in the simulations. Fig 2 shows two signals with different autocorrelation functions. In this example, we chose \( \tau_1 = 0 \) and \( \Lambda(0) = I \), i.e. the signals are normalized. The learning rule is recovering the signal with the biggest autocorrelation at time \( \tau_1 \), \( \Lambda_{kk}(\tau_1) \), for a positive learning rate.

5 Comparison between Spatial ICA and Temporal ICA

One of the algorithms most used to solve ICA is FastICA [1]. It is based on an approximation of negentropy and is purely spatial, i.e. it takes into account only the amplitude distribution of the signal, but not its temporal structure. Therefore we show an example (Fig. 5), where three signals generated by Ornstein-Uhlenbeck processes have the same spatial distribution but different time constants of the autocorrelation. With a spatial algorithm data points corresponding to different time slices can be shuffled without any change in the results. Therefore, it cannot solve this example. We tested our example with FastICA downloaded from [11] and it failed to recover the original sources (Fig. 5). However, to our surprise, FastICA could for very few trial solve this problem even though the convergence was not stable. Indeed, since FastICA algorithm is an iterative online algorithm, it takes the signals in the temporal order in which they arrive. Therefore temporal correlations can in some cases be taken into account even though this is not part of the theory of FastICA.

6 Discussions and conclusions

We presented a powerful online learning rule that performs ICA by computing joint variations in the firing rates of pre- and postsynaptic neurons at different time delays. This is very similar to a standard Hebbian rule with exception of an additional factor \( \lambda \) which is an online estimate of the output correlations at different time delays. The different delay times \( \tau_1, \tau_2 \) are necessary to recover different sources. Therefore properties varying between one postsynaptic neuron and the next could lead to different time delays used in the learning rule. We could assume that the time delays are intrinsic properties of each postsynaptic neuron due to for example the distance on the dendrites where the synapse is formed [12], i.e. due to different signal propagation time. The calculation of stability shows that a postsynaptic neuron will recover the signal with the biggest autocorrelation at the considered delay time or the smallest depending of the sign of the learning rates. We assume that for biological signals autocorrelation functions cross so that it’s possible with different postsynaptic neurons to recover all the signals.
Figure 5: Two signals generated by an Ornstein-Uhlenbeck process are mixed. A. The signals have the same spatial distributions. B. The time constants of the autocorrelations are different. C. Our learning rule converges to an output (dashed line) recovering one of the signals source (solid line). D. FastICA (dashed line) doesn’t succeed to recover the sources (solid line).

The algorithm assumes centered signals. However for a complete mapping of those signals to neural rates, we have to consider positive signals. Nevertheless we can easily compute an online estimate of the mean firing rate and remove this mean from the original rates. This way the algorithm still holds taking neural rates as input.

Hyvaerinen proposed an ICA algorithm [8] based on complexity pursuit. It uses the non-gaussianity of the residuals once the part of the signals that is predictable from the temporal correlations has been removed. The update step of this algorithm has some similarities with our learning rule even though the approach is completely different since we want to exploit temporal correlations directly rather than formally removing them by a "predictor". We also do not assume pre-whitened data and are not considering nongaussianity.

Our learning rule considers smooth signals that are assumed to be rates. However, it is commonly accepted that synaptic plasticity takes into account spike trains of pre- and postsynaptic neurons looking at the precise timing of the spikes, i.e. Spike Timing Dependent Plasticity (STDP) [13, 14, 15]. Therefore a spike-based description of our algorithm is currently under study.

Appendix: Stability calculation

By construction, the row vectors \( \{ e_k, k = 1...n \} \) of \( W^* = C^{-1} \), the inverse of the mixing matrix, are solutions of the batch learning rule 9 (n is the number of sources). Assume one of these row vectors \( e_i^T \), (i.e. a fixed point of the dynamic), and consider \( w = e_i + \epsilon e_j \) a small perturbation in direction \( e_j^T \). Note that \( \{ e_k \} \) is a basis because \( det(C) \neq 0 \) (the matrix must be invertible). The rule (9) becomes:
\[ \dot{\epsilon}_i = \gamma < x(t + \tau_1) (\epsilon_i + \epsilon_j)^T x(t) > - < (\epsilon_i + \epsilon_j)^T x(t) (\epsilon_i + \epsilon_j)^T x(t + \tau_1) > < (\epsilon_i + \epsilon_j)^T x(t) x(t + \tau_2) >. \]  

We can expand the terms on the righthand side to first order in \( \epsilon \). Multiplying the stability expression by \( \epsilon_j^T \) (here we can assume that \( \epsilon_j^T \epsilon_j = 1 \) since the recovering of the sources are up to a multiplicative constant), we find:

\[
\dot{\epsilon} = \gamma \epsilon \left[ e_i^T C \Lambda(\tau_1) C^T e_j [e_j^T C \Lambda(\tau_2) C^T e_i] - [e_i^T C \Lambda(\tau_1) C^T e_i] [e_j^T C \Lambda(\tau_2) C^T e_j] \right] \\
- \epsilon \left[ 4 e_i^T C \Lambda(\tau_1) C^T e_j [e_j^T C \Lambda(\tau_2) C^T e_i] \right]
\]

where \( \Lambda(\tau)_{ij} = < s_i(t) s_j(t + \tau) > \) is the diagonal matrix.

This expression can be simplified because \( e_i^T e_i = 1 \), so that \( e_i^T C \) is the unit vector of the form \( (0,0,...,1,0,...) \) where the position of the \( \text{“}1\text{”} \) indicates the solution number \( 0 \). Therefore, we have \( e_i^T C \Lambda(\tau) C^T e_k = \Lambda(\tau)_{ik} \).

The expression of stability becomes

\[
\dot{\epsilon} = \gamma \epsilon \frac{\Lambda_{jj}(\tau_1) \Lambda_{ii}(\tau_2) - \Lambda_{ii}(\tau_1) \Lambda_{jj}(\tau_2)}{\Lambda_{ii}(\tau_2)}
\]

References

Chapter 6

CONCLUSIONS AND FUTURE WORK

6.1 SUMMARY OF THE RESULTS

The four papers presented in this thesis aim for a better understanding of synaptic plasticity. The first paper (Clopath, Jolivet, Rauch, Luescher, and Gerstner 2007) is dedicated to choose an appropriate neuron model that is compact and reproduces well experimental voltage traces of layer V pyramidal cells. The same neuron model, the adaptive Exponential Integrate and Fire model (AdEx), was shown later on to operate in different dynamical regimes and exhibit various firing patterns (Naud, Marcille, Clopath, and Gerstner 2008). The voltage time course of the neuron turns out to be important for the description of the early phase of plasticity (Clopath, Vasilaki, Buesing, and Gerstner xxxx), i.e. not only is the postsynaptic spike timing important but so is the level of depolarization of the postsynaptic neuron (Artola, Bröcher, and Singer 1990; Ngezahayo, Schacher, and Artola 2000; Sjöström, Turrigiano, and Nelson 2001). Thus the model for the early phase of plasticity presented in the second paper (Clopath, Vasilaki, Buesing, and Gerstner xxxx) combines the presynaptic spike time arrival and the postsynaptic membrane potential filtered with different time constants. It is very robust in reproducing experimental data like voltage clamp experiments (Artola, Bröcher, and Singer 1990; Ngezahayo, Schacher, and Artola 2000), frequency dependence (Sjöström, Turrigiano, and Nelson 2001), burst-timing dependent plasticity (Nevian and Sakmann 2006) and a several subtle combinations of spike-timing and voltage depolarization or hyperpolarization. Moreover, this model exhibits some important functional implications like selectivity in the input, for example receptive field development, ICA-like computation and exhibits a tight relation between coding and connectivity. Rate coding leads to few strong bidirectional connections in a sea of weak connections as measured in visual cortex (Song, Sjöström, Reigl, Nelson, and Chklovskii 2005) in contrast to temporal coding which expresses few unidirectional connections as measured in the barrel cortex (Lefort, Tomm, Sarria, and Petersen 2009). This is an interesting interpretation suggesting that different coding schemes exist in different cortical areas. Interestingly, standard STDP models (Gerstner, Kempter, van Hemmen, and Wagner 1996; Gerstner and van Hemmen 1993; Roberts and Bell 2000; Kistler and van Hemmen 2000;
Mehda, Quirk, and Wilson 2000; Song, Miller, and Abbott 2000; Legenstein, Naeger, and Maass 2005; Guyonneau, VanRullen, and Thorpe 2005) cannot sustain stable bidirectional connections (Song, Miller, and Abbott 2000). This early phase model is combined with a late-phase model of long term synaptic plasticity, the TagTriC model (Clopath, Ziegler, Vasilaki, Buesing, and Gerstner 2008) presented in the third paper. It takes into account discrete synapses for the early phase where the probabilities of transition are given by the model described in the previous paper (Clopath, Vasilaki, Buesing, and Gerstner xxxx). These discrete states also set the tags at the synapses. It is combined with a triggering process of plasticity related proteins and a consolidated phase which includes bistable states. This model reproduces a large number of synaptic tagging experiments and cross tagging. Finally, a top down approach of computing temporal ICA in a biologically plausible manner was derived in the last paper (Clopath, Longtin, and Gerstner 2008). This rate-based rule decorrelates the signal mixtures at different time points (lags) so that the original signal recovered is the one with the biggest autocorrelation at these time points. It allows different neurons, with different properties (i.e. lag) to recover different sources. The model performed greatly on standard ICA benchmarks with sound sources.

6.2 Open questions and future work

This thesis work has revealed a range of open questions and therefore offers a list of possible future work:

**Spike-based rule performing temporal ICA**

The last paper of the thesis presents a rate-based rule performing ICA (Clopath, Longtin, and Gerstner 2008). The next step is to develop a spiking version of this model. The type of encoding has to be decided but the most straightforward is to use Poisson neurons that fire with probability corresponding to the signal. Thus the presynaptic spike trains would encode the signal mixtures. Postsynaptic neurons can also be considered as Poisson neurons that fire with the probability reflecting the weighted sum of the inputs. Synaptic plasticity should converge to a set of weights so that the postsynaptic neuron encodes one of the original sources. The plasticity model can take the form of a standard STDP learning window (Markram, Lübke, Frotscher, and Sakmann 1997; Bi and Poo 1998) reflecting the correlation at two different lags in the rate-based framework. The amplitudes of this window have to vary depending on the output correlation, like the $\lambda$ term in the rate-based rule. This variable amplitudes can be interpreted for instance as homeostasis. This STDP model with homeostasis could be sufficient to perform temporal ICA. The encoding with Poisson neurons is however not exploring precise timing of the spikes. A temporal code could be considered, like the time to first spike.
Biological ICA

Humans have two ears to solve the cocktail party problem! At one given point in time they have access to two different mixtures of the original sources. However, classical ICA benchmarks contain the same number of sources as mixtures to prevent loss of information. The question remains how humans do to decouple more than two different sources? Can they recover only two sources at the same time and attention is then shifted to recover the other ones? Do they have to move slightly their head to decode different mixtures? Does the auditory preprocessing help for this problem? In fact auditory preprocessing is known to decompose the sources in different frequency bands due to the hair cells in the cochlea. Should Fourier decomposition be taken into account in this case?

Relation between spike-based rule performing temporal ICA and the model for early phase plasticity

The second paper (Clopath, Vasilaki, Buesing, and Gerstner xxxx) shows that a nonlinear rule in the postsynaptic term combined with homeostasis, i.e. BCM form, is sufficient to perform spatial ICA. It would be interesting to find out whether the nonlinearity could be shifted from the postsynaptic term to a simple nonlinear neuron or not. Moreover the link between the spiking spatial ICA model (Clopath, Vasilaki, Buesing, and Gerstner xxxx) (i.e. taking into account spatial distribution of the signal) and the spiking temporal ICA model (follow up of Clopath, Longtin, and Gerstner 2008, taking into account temporal correlations of the signal) is not yet clear. It remains an open question whether different models exist in the brain and operate with different inputs. For example visual inputs would be processed by spatial algorithms and audio inputs by temporal algorithms. On the contrary, a combined model performing temporal and spatial ICA (Müller, Philips, and Ziehe 1999; Hyvärinen 1998; Hyvärinen 2001) would be more robust to any kind of sources, like for example a movie. If that is the case, the way those two models (Clopath, Vasilaki, Buesing, and Gerstner xxxx and follow up of Clopath, Longtin, and Gerstner 2008) should be combined has to be clarified.

Extension of the model for early phase of plasticity

This model takes into account the voltage of the postsynaptic neuron which turns out the be critical for synaptic plasticity (Artola, Bröcher, and Singer 1990; Sjöström, Turrigiano, and Nelson 2001). However the proposed plasticity rule uses a neuron model with a single compartment, i.e. equal voltage at the soma and at the synapses. This is definitely not the case and a more detailed neuron model giving the voltage at the synapse would be helpful, especially describing the back propagating action potential. It would then be possible to describe quantitatively plasticity depending on dendritic location, e.g. the differ-
ence between apical plasticity when the back propagating action potential fails and basal dendrite plasticity (Sjöström and Häusser 2006). Moreover some additional non-linearities should be taken into account. For example, there seems to be a non-linearity in the number of pairing, where a small number of pairing only leads to LTP (Wittenberg and Wang 2006) and a saturation effect may occur. Finally different weight dependencies should be explored. Note that optimal models clearly predict that nonlinearities are crucial (Toyoizumi, Pfister, Aihara, and Gerstner 2005).

Interestingly, pre-post pairing at low frequency when the neuron is stimulated intracellularly does not change the weights (Sjöström, Turrigiano, and Nelson 2001) whereas extracellular stimulation leads to potentiation (Fromkne and Dan 2002). This results suggest that pre-post pairing would lead to potentiation only if previously there was some depolarization (Sjöström, Turrigiano, and Nelson 2001), high activity of the slices via extracellular stimulation (Fromkne and Dan 2002), or neuromodulation (Schultz and Dickinson 2000) (the last two could be the same since extracellular stimulation can excite dopaminergic fibers). The model should then be adjusted so that the potentiation term contains a correlation between pre-post with an additional term which could be either voltage (Clopath, Vasilaki, Buesing, and Gerstner xxxx) or neuromodulation (Schultz and Dickinson 2000), unifying triplet rule and reward-modulated learning rules. Moreover, the neuromodulation term seems to be complex and has to be tuned with additional experiments.

Finally it would be interesting to validate the model with the predictions explained in the paper (Clopath, Vasilaki, Buesing, and Gerstner xxxx).

**Combing short term plasticity with long term plasticity**

In the second paper (Clopath, Vasilaki, Buesing, and Gerstner xxxx) the model describes long term plasticity lasting 2 to 3 hours. However, synapses are also plastic at a much shorter time scale lasting hundreds of milliseconds, the so-called short-term plasticity. It would be worthwhile to combine short term (Markram and Tsodyks 1996; Abbott, Varela, Sen, and Nelson 1997) and long term plasticity models especially in protocols using high frequency spiking. The impact of short term plasticity would then be more clear and the long term model may have to be readjusted.

**Extension of the TagTriC model**

The TagTriC model has some limitations at least concerning one set of experimental data set which resets the tags (Sajikumar and Frey 2004b). This model is thus oversimplified and needs to differentiate between setting the tags and the early phase of plasticity. A more elaborate model with additional states should allow for tag resetting, possibly a hybrid model between our model and another model for synaptic tagging (Barrett, Billings, Morris, and van Rossum 2009).
Many open questions still exist concerning the late-phase of long-term plasticity. For example it is not clear what are the states of the synaptic weights 10 hours after a STDP protocol, since weights are recorded usually for 30 minutes. Do they undergo consolidation? If yes, does reducing the number of pairing prohibits maintenance? If not, is a longer STDP protocol sufficient to reach the late phase or is it necessary to pair a strong extracellular protocol in a different pathway, stimulating dopaminergic fibers? Maintenance depends on neuromodulation but how? More experiments are required using pharmacological tools.

Link between the TagTriC model and reinforcement learning models

The TagTriC model presented in the third paper (Clopath, Ziegler, Vasilaki, Buesing, and Gerstner 2008) exhibits some structural similarities to the reinforcement learning framework: (i) The selection of "definitive" memories depends in both cases on neuromodulators, such as dopamine (Schultz and Dickinson 2000). In reinforcement learning, the weights are updated in the presence of dopamine encoding prediction of reward and in the tagging experiment maintenance requires stimulation of dopaminergic fibers. (ii) The presence of a memory trace. In reinforcement learning the eligibility trace keeps a memory of the pre-post correlation and in the tagging experiment, the early phase of plasticity keeps a memory of the induction. However, the time scales for the early phase and the eligibility trace seem to be different. Thus the TagTriC model should be tested against standard reinforcement learning tasks like learning a location in a maze.

Moreover, recent experiments provide evidence for behavioral tagging (Moncada and Viola 2007), memory reconsolidation and extinction (Eisenhardt and Menzel 2007) where the time scales seem to be more consistent with the ones measured in tagging experiments (Frey and Morris 1997). The TagTriC model should be further validated with these recent experimental findings.

Functional implications of the early phase of plasticity

It is necessary to check that the functional implications of the early phase of our plasticity model (Clopath, Vasilaki, Buesing, and Gerstner xxxx) still hold when combined with the late phase model, i.e. selectivity, ICA computation, relation between connectivity and coding. Would it open up more computational possibilities? What are the consequences when applied to bigger networks?

Analytical study of a plastic recurrent network under this nonlinear model should be investigated, similarly to the case with standard STDP rule (Kempter, Gerstner, and van Hemmen 1999; Burkitt, Gilson, and van Hemmen: 2007; Gilson, Burkitt, Grayden, Thomas, and van Hemmen 2009a; Gilson, Burkitt, Grayden, Thomas, and van Hemmen 2009b).

Functional implications of the voltage dependency

The functional consequences of the early phase plasticity model (Clopath,
Vasilaki, Buesing, and Gerstner were essentially taking advantage of the nonlinearity of the model and the homeostatic properties. However, the consequence of the voltage dependence was not explored. It would be interesting to study the implications in a network with background activity that probably leads to a much higher average voltage. What are the consequences in vivo, where the voltage is closer to threshold?

**Functional implications of the TagTriC model in a large network**

What are the functional consequences of the TagTriC model in a large network? Does the network learn over a long period? In contrary, a network with multiplicative STDP shows no stable strong synapses over time (Morrison, Aertsen, and Diesmann 2007). What is the final weight distribution? Does memory consolidation increase memory capacity in a network? In fact the TagTriC model can be seen as a shallow cascade model (Fusi, Drew, and Abbott 2005) with only two levels. How good is the trade-off between a plastic network and a long lasting memory, i.e. palimpsest property (Nadal, Toulouse, Changeux, and Dehaene 1986; Amit and Fusi 1994)? However the exact construction of such a network is not straightforward: (i) Should the inhibitory plasticity in such a network be taken into account? For this, more experimental data (Gaiarsa, Caillard, and Ben-Ari 2002; Haas, Nowotny, and Abarbanel 2006) and an appropriate model is needed. (ii) Plasticity is very diverse across synapses (Caporale and Dan 2008; Sjöström, Rancz, Roth, and Hausser 2008). Should this inhomogeneity be taken into account? (iii) What would be the inputs to the network and the learning benchmarks?

**6.3 Conclusion**

The present thesis explores different types of long-term synaptic plasticity by developing models based upon simple mechanistic principles. Such models can be applied to plastic artificial networks mimicking brain areas, offering a direct interpretation of the obtained results. They reveal induction mechanisms of synaptic plasticity as well as mechanisms of its maintenance and consolidation.

The proposed models offer a good trade-off between the brain plasticity and maintenance of previous memories (known as stability-plasticity dilemma). Under different coding scheme scenarios they produce distinctive connectivity patterns that can be related to different brain areas, suggesting that the underlying reason of the experimentally observed differences may be the different encoding schemes used in the various areas, for instance rate coding in visual cortex and temporal coding in barrel cortex.

Finally these models explain how experience modifies structural properties like receptive field development and how the brain computes Independent Component Analysis when in a noisy environment such as the cocktail party problem.
In this appendix, a few extra experiments with the induction model from (Clopath, Vasilaki, Buesing, and Gerstner xxxx) is shown. These are unpublished results.

**Extended induction model fits triplet and quadruplet data**

We simulate three sets of experiments on hippocampal cultures from (Wang, Gerkin, Nauen, and Bi 2005). In the first experiment, we apply a standard pairing protocol. In the second experiment we apply the triplet protocol, i.e. a set of pre-post-pre and post-pre-post triplets with variable time distances between the spikes. In the third experiment we apply the quadruplet protocol, i.e. either a post-pre pair of spikes is followed after time T by a pre-post pair of spikes (if T positive) or a pre-post pair of spikes is followed after time -T by a post-pre pair of spikes (if T negative). For a detailed description of the protocols see (Wang, Gerkin, Nauen, and Bi 2005).

We fit the model parameters such that the data of the pairing, triplet and the quadruplet protocol are reproduced altogether with the same parameters (Fig. A.1). It turns out that for the hippocampal cultures, an additional term is necessary, i.e. a pre-post pair-term for potentiation, similar to the triplet rule from (Pfister and Gerstner 2006).

**Functional consequences of the induction model**

The induction model is used in different scenarios of rather simple feedforward networks. Selectivity is observed when a group of inputs undergoes rate modulation (Fig. A.2A) or shares spike-spike correlation (Fig. A.2B). Additionally the weights of set of common inputs exhibit spontaneous selectivity after a very long time, showing the unstable dynamics (Fig. A.2C).
Figure A.1: Weight change according to pair (A), triplet (B) and quadruplet protocols (C) following the induction model with an additional pre-post term for potentiation. A. 60 pairing at 1Hz where T is the time between the pairs (red: post-pre, blue: pre-post). B. 60 triplets at 1Hz (red:pre-post-pre, blue: post-pre-post) C. 60 quadruplet at 1Hz (red:pre-post-post-pre, blue:post-pre-pre-post). Dots are experimental data taken from (Wang, Gerkin, Nauen, and Bi 2005).
Figure A.2: A. Rate modulation. 100 presynaptic Poisson inputs are connected to one postsynaptic neuron that receives as a current the weighted sum of the inputs. The 80 last inputs fire at 10Hz. The 20 first inputs undergo a rate-modulation: a random number is chosen every 200ms between 0-10, 0-30, 0-50, 0-30, 0-10Hz for 10min each. Selectivity is observed as well as a hysteresis meaning that the selection is stable within those 10min. B. Spike-spike correlation. The 100 inputs fire at 10Hz but the 50 lasts share spike-spike correlation of c=2. Selectivity is observed. C. Spontaneous selection. The 100 inputs fire at 10Hz. Spontaneous selectivity is observed after 10hours indicating two stable points of the dynamics.
