Abstract—The problem of neural network association is to retrieve a previously memorized pattern from its noisy version using a network of neurons. An ideal neural network should include three components simultaneously: a learning algorithm, a large pattern retrieval capacity and resilience against noise. Prior works in this area usually improve one or two aspects at the cost of the third.

Our work takes a step forward in closing this gap. More specifically, we show that by forcing natural constraints on the set of learning patterns, we can drastically improve the retrieval capacity of our neural network. Moreover, we devise a learning algorithm whose role is to learn those patterns satisfying the above mentioned constraints. Finally we show that our neural network can cope with a fair amount of noise.

I. INTRODUCTION

Neural networks are famous for their ability to learn and reliably perform a required task. An important example is the case of (associative) memory where we are asked to memorize (learn) a set of given patterns. Later, corrupted versions of the memorized patterns will be shown to us and we have to return the correct memorized patterns. In essence, this problem is very similar to the one faced in communication systems where the goal is to reliably transmit and efficiently decode a set of patterns (so called codewords) over a noisy channel.

As one would naturally expect, reliability is certainly a very important issue both the neural associative memories and in communication systems. Indeed, the last three decades witnessed many reliable artificial associative neural networks. See for instance [4], [9], [10], [6], [8], [13].

However, despite common techniques and methods deployed in both fields (e.g., graphical models, iterative algorithms, etc), there has been a quantitative difference in terms of another important criterion: the efficiency. In communication systems, by using modern coding techniques it has become clear that the number of reliably transmitted codewords over a noisy channel can be made exponential in $n$, the length of the codewords. However, using current neural networks of size $n$ to memorize a set of randomly chosen patterns, the maximum number of patterns that can be reliably memorized scales linearly in $n$ [7], [9].

There are multiple reasons for the inefficiency of the storage capacity of neural networks. First, neurons can only perform simple operations. As a result, most of the techniques used in communication systems (more specifically in coding theory) for achieving exponential storage capacity are prohibitive in neural networks. Second, a large body of past work (e.g., [4], [9], [10], [6]) followed a common assumption that a neural network should be able to memorize any subset of patterns drawn randomly from the set of all possible vectors of length $n$. Although this assumption gives the network a sense of generality, it reduces its storage capacity to a great extent.

An interesting question which arises in this context is whether one can increase the storage capacity of neural networks beyond the current linear scaling and achieve results similar to coding theory. To this end, Kumar et al. [2] suggested a new formulation of the problem where only a suitable set of patterns was considered for storing. This way they could show that the performance of neural networks in terms of storage capacity increases significantly. Following the same philosophy, we will focus on memorizing a random subset of patterns of length $n$ such that the dimension of the training set is $k < n$. In other words, we are interested in memorizing a set of patterns that have a certain degree of structure and redundancy. We exploit this structure both to increase the number of patterns that can be memorized (from linear to exponential) and to increase the number of errors that can be corrected when the network is faced with corrupted inputs.

The success of [2] is mainly due to forming a bipartite network/graph (as opposed to a complete graph) whose role is to enforce the suitable constraints on the patterns, very similar to the role played by Tanner graphs in coding. More specifically, one layer is used to feed the patterns to the network (so called variable nodes in coding) and the other takes into account the inherent structure of the input patterns (so called check nodes in coding). A natural way to enforce structures on inputs is to assume that the connectivity matrix of the bipartite graph is orthogonal to all of the input patterns. However, the authors in [2] heavily rely on the fact that the bipartite graph is fully known and given, and satisfies some sparsity and expansion properties. The expansion assumption is made to ensure that the resulting set of patterns are resilient against fair amount of noise. Unfortunately, no algorithm for finding such a bipartite graph was proposed.

Our main contribution in this paper is to relax the above assumptions while achieving better error correction performance. More specifically, we first propose an iterative algorithm that can find a sparse bipartite graph that satisfies the desired set of constraints. We also provide an upper bound on the block error rate of the method that deploys this learning strategy. We then proceed to devise a multi-layer network whose performance in terms of error tolerance improves significantly upon [2] and no longer needs to be an expander.
II. Problem Formulation

In contrast to the mainstream work in neural associative memories, we focus on non-binary neurons, i.e., neurons that can assume a finite set of integer values \( S = \{0, 1, \ldots, S-1\} \) for their states (where \( S > 2 \)). A natural way to interpret the multi-level states is to think of the short-term (normalized) firing rate of a neuron as its output. Neurons can only perform simple operations. In particular, we restrict the operations at each neuron to a linear summation over the inputs, and a possibly non-linear thresholding operation. In particular, a neuron \( x \) updates its state based on the states of its neighbors \( \{s_i\}_{i=1}^n \) as follows:

1. It computes the weighted sum \( h = \sum_{i=1}^n w_i s_i \), where \( w_i \) denotes the weight of the input link from \( s_i \).
2. It updates its state as \( x = f(h) \), where \( f : \mathbb{R} \to S \) is a possibly non-linear function from the field of real numbers \( \mathbb{R} \) to \( S \).

Neural associative memory aims to memorize \( C \) patterns of length \( n \) by determining the weighted connectivity matrix of the neural network (learning phase) such that the given patterns are stable states of the network. Furthermore, the network should be able to tolerate a fair amount of noise so that it can return the correct memorized pattern in response to a corrupted query (recall phase). Among the networks with these two abilities, the one with largest \( C \) is the most desirable.

We first focus on learning the connectivity matrix of a neural graph which memorizes a set of patterns having some inherent redundancy. More specifically, we assume to have \( C \) vectors of length \( n \) with non-negative integer entries, where these patterns form a subspace of dimension \( k < n \). We would like to memorize these patterns by finding a set of non-zero vectors \( \mathbf{w}_1, \ldots, \mathbf{w}_m \in \mathbb{R}^n \) that are orthogonal to the set of given patterns. Furthermore, we are interested in rather sparse vectors. Putting the training patterns in a matrix \( X_{C \times n} \) and focusing on one such vector \( \mathbf{w} \), we can formulate the problem as:

\[
\begin{align*}
\text{min} & \quad \|X \cdot \mathbf{w}\|_2 \\
\text{subject to} & \quad \|\mathbf{w}\|_0 \leq q \quad \text{and} \quad \|\mathbf{w}\|_2^2 \geq \epsilon
\end{align*}
\]

where \( q \in \mathbb{N} \) determines the degree of sparsity and \( \epsilon \in \mathbb{R}^+ \) prevents the all-zero solution. A solution to the above problem yields a sparse bipartite graph which corresponds to the basis vectors of the null space specified by the patterns in the training set. In other words, the inherent structure of the patterns is captured in terms of \( m \) linear constraints on the entries of the patterns \( \mathbf{x}_\mu \) in the training set. It can therefore be described by Figure 1 with a connectivity matrix \( W \in \mathbb{R}^{m \times n} \) and a vector \( \mathbf{b} \in \mathbb{R}^m \) such that \( W \mathbf{x}_\mu = \mathbf{b} \) for all \( \mu = 1, \ldots, C \).

In the recall phase, the neural network is fed with noisy inputs. A possibly noisy version of an input pattern is initialized as the states of the pattern neurons \( x_1, x_2, \ldots, x_n \). Here, we assume that the noise is integer valued and additive (modulo \( S \)). In formula, we have \( y = W(x^b + z) = b + Wz \) where \( z \) is the noise added to pattern \( x^b \). Since \( b \) is known to the network, one can use \( y - b = Wz \) to eliminate the input noise \( z \). Consequently, we are searching an algorithm that can provably eliminate the effect of noise and return the correct pattern.

**Remark 1.** A solution in the learning/recall phase is acceptable only if it can be found by simple operations at neurons.

Before presenting our solution, we briefly overview the relation between the previous works and the one presented in this paper.

A. Related Works

Designing a neural network capable of learning a set of patterns and recalling them later in presence of noise has been an active topic of research for the past three decades. Inspired by the Hebbian learning rule [3], Hopfield in his seminal work [4] introduced the Hopfield network: an auto-associative neural mechanism of size \( n \) with binary state neurons in which patterns are assumed to be binary vectors of length \( n \). The capacity of a Hopfield network under vanishing block error probability was later shown to be \( O(n/ \log(n)) \) in [7].

Due to the low capacity of Hopfield networks, extension of associative memories to non-binary neural models has also been explored in the past. For instance, in [10] the authors investigated a multi-state complex-valued neural associative memories for which the estimated capacity is \( C < 0.15n \). Under the same model but using a different learning method, Muezzinoglu et al. [6] showed that the capacity can be increased to \( C = n \). However the complexity of the weight computation mechanism is prohibitive.

A line of recent work has made considerable efforts to exploit the inherent structure of the patterns in order to increase both capacity and error correction capabilities. Such methods either make use of higher order correlations of patterns or focus merely on those patterns that have some sort of redundancy. As a result, they differ from previous methods for which every possible random set of patterns was considered. Pioneering this prospect, Berrou and Gripon [13] achieved considerable improvements in the pattern retrieval capacity of Hopfield networks, by utilizing Walsh-Hadamard sequences. This improvement was made by paying the price of using a decoder based on winner-take-all approach which requires a separate neural network. Therefore, this approach increases the complexity of the overall method. Using low
correlation sequences has also been considered in [8], which results in increasing the storage capacity of Hopfield networks to \( n \) without requiring any separate decoding stage.

In contrast to the pairwise correlation of the Hopfield model [4], Peretto et al. [12] deployed higher order neural models: the state of the neurons not only depends on the state of their neighbors, but also on the correlation among them. Under this model, they showed that the storage capacity of a higher-order Hopfield network can be improved to \( C = O(n^{p-2}) \), where \( p \) is the degree of correlation considered. The main drawback of this model was again the huge computational complexity required in the learning phase. To address this difficulty while being able to capture higher-order correlations, a bipartite graph inspired from iterative coding theory was introduced in [2]. Under the assumptions that the bipartite graph is known, the authors prove that their choice of soft-thresholding function is very similar to the one selected by Donoho et al. in [1] in order to recover a sparse signal from a set of measurements. Nevertheless, many techniques we obtain the following iterative algorithm for (2) (the details are tedious and left to our technical report [16]):

**Algorithm 1 Iterative Learning**

**Input:** pattern matrix \( X \), stopping point \( p \).

**Output:** \( w \)

```plaintext
while \( \|y(t)\|_{\text{max}} > p \) do
    Compute \( g(y) \).
    Update \( w(t+1) = (1 + 2\lambda t)w(t) - 2\alpha_t X^\top y(t) \).
    Update \( \lambda_{t+1} = [\lambda_t + \gamma(t - \|w\|_2^2)] \).
    \( t \leftarrow t + 1 \).
end while
```

where \( \sigma \) is chosen appropriately. By calculating the derivative of the objective function and primal-dual optimization techniques we obtain the following iterative algorithm for (2) (the function \( g(w) = \sum_{i=1}^{n} \tanh(\sigma w_i^2) \) is the function)

\[ g(w) = \sum_{i=1}^{n} \tanh(\sigma w_i^2) \]

III. LEARNING ALGORITHM

We are interested in an iterative algorithm that is simple enough to be implemented by a network of neurons. Therefore, we first relax (1) as follows:

\[
\min ||X \cdot w||_2 - \lambda(||w||_2^2 - \epsilon) + \gamma(g(w) - q'). \tag{2}
\]

In the above problem, we have approximated the constraint \( ||w||_0 \leq q \) with \( g(w) \leq q' \) since \( \|\cdot\|_0 \) is not a well-behaved function. The function \( g(w) \) is chosen such that it favors sparsity. For instance one can pick \( g(w) \) to be \( ||\cdot||_1 \), which leads to \( \ell_1 \)-norm minimizations. In this paper, we consider

learning linear constraints by a neural network is hardly a new topic as one can learn a matrix orthogonal to a set of patterns in the training set (i.e., \( Wx^\mu = 0 \)) using simple neural learning rules (we refer the interested readers to [3] and [11]). However, to the best of our knowledge, finding such a matrix subject to the sparsity constraints has not been investigated before. This problem can also be regarded as an instance of compressed sensing [15]. Nevertheless, many decoders proposed in this area are very complicated and cannot be implemented by a neural network using simple neuron operations. Some exceptions are [11] and [14] from which we derive our learning algorithm.

Remark 2. the above choice of soft-thresholding function is very similar to the one selected by Donoho et al. in [1] in order to recover a sparse signal from a set of measurements. The authors prove that their choice of soft-threshold function results in optimal sparsity-undersampling trade-off.

The next theorem derives the necessary conditions on \( \alpha_t \), \( \lambda_t \) and \( \theta_t \) such that Algorithm 1 converges to a sparse solution.

**Theorem 1.** If \( \theta_t \to 0 \) as \( t \to \infty \) and if \( \lambda_t \) is bounded above by \( a_{\min}/(a_{\max} - a_{\min}) \), then there is a proper choice of \( \alpha_t \) in
Now we feed each sub-pattern to a neural network which is a variant of the "bit-flipping" method proposed in [2], to correct the errors. Note that if the states of the pattern neurons $x_i$ correspond to a pattern from $X$ (i.e., the noise-free case), then for all $i = 1, \ldots, m$ we have $y_i = 0$. The quantity $g_j$ can be interpreted as feedback to pattern neuron $x_j$ from the constraint neurons. Hence, the sign of $g_j$ provides an indication of the sign of the noise that affects $x_j$, and $|g_j|$ indicates the confidence level in the decision regarding the sign of the noise.

**Theorem 2.** Algorithm 2 can correct a single error in the input pattern with high probability if $\varphi$ is chosen large enough.

For the proof, we refer the interested readers to our technical report [16]

Given that each local network is able to correct one pattern, $L$ such networks can correct $L$ input errors if they are separated such that only one error appears in the input of each local network. Otherwise, there would be a probability that the network could not handle the errors. In that case, we feed the overall pattern of length $n$ to the second layer with the connectivity matrix $W_g$, which enforces $m_g$ global constraints. And since the probability of correcting two erroneous nodes increases with the input size, we expect to have a better error correction probability in the second layer. Therefore, using this simple scheme we expect to gain a lot in correcting errors in the patterns. In the next section, we provide simulation results which confirm our expectations and show that the block error rate can be improved by a factor of 100 in some cases.

**A. Some remarks**

First of all, one should note that the above method only works if there is some redundancy at the global level as well. If the set of weight matrices $W_1, \ldots, W_L$ define completely separate sub-spaces in the $n/L$-dimensional space, then for sure we gain nothing using this method.

Secondly, the number of constraints for the second layer affects the gain one obtains in the error performance. Intuitively, if the number of global constraints is large, we are enforcing more constraints so we expect obtaining a better error performance. We can think of determining the number even adaptively, i.e. if the error performance that we are getting is unacceptable, we can look deeper in patterns to identify their internal structure by searching for more constraints. This would be a subject of our future research.

**V. SIMULATION RESULTS**

We have simulated the proposed learning algorithm in the multi-level architecture to investigate the block error rate of the suggested approach and the gain we obtain in error rates by adding a second level. We constructed 4 local networks, each with $n/4$ pattern and $m$ constraint nodes.

---

**Algorithm 2** Error Correction

1. for $t = 1 \rightarrow t_{max}$ do
2.  Forward iteration: Calculate the weighted sum $h_i = \sum_{j=1}^{n} W_{ij} x_j$, for each neuron $y_i$ and set:
3.    $y_i = \left\{ \begin{array}{ll} 1, & h_i < b_i \\ 0, & h_i = b_i \\ -1, & \text{otherwise} \end{array} \right.$
4.  Backward iteration: Each neuron $x_j$ computes $g_j = \sum_{i=1}^{m} W_{ij} y_i / \sum_{i=1}^{m} |W_{ij}|$
5.  Update the state of each pattern neuron $j$ according to $x_j = x_j + \text{sgn}(g_j)$ only if $|g_j| > \varphi$.
6. end for

**Sketch of the proof:** Let $E(t) = \|y(t)\|_{max}$. We would like to show that $E(t + 1) < E(t)$ for all iterations $t$. We can write $w(t + 1) = w(t) - \chi(w(t); \theta_t)$ where $w(t)$ denotes $(1 + 2\lambda_t)w(t) - 2\alpha_t \frac{x^T \cdot y}{\|x\|^2}$. We can then show that $E(t + 1) \leq \|x \cdot w(t)\|_{max} + \theta_t$. By expanding $x \cdot w(t)$ we will obtain $E(t + 1) \leq \|w(t)\|_{max} E(t) + \theta_t$ where $D(t) = (1 + 2\lambda_t)I_{C \times C} - 2\alpha_t \frac{x x^T}{\|x\|^2}$. Hence we need $\theta_t \rightarrow 0$ as $t \rightarrow \infty$ and ensuring $\|D(t)\|_{max} < 1$. The latter condition is satisfied if $\lambda_t \leq a_{min} / (a_{max} - a_{min})$. For the detailed proof, we refer the interested readers to our technical report [16].

---

**IV. MULTI-LEVEL NETWORK ARCHITECTURE**

In order to have error correction capabilities we propose a new network structure (see Figure 2). To make the description clear and simple we only concentrate on a two-level neural network. However, the generalization of this idea is trivial and left to the reader.

The idea behind this new architecture is that we divide the input pattern of size $n$ into $L$ sub-patterns of length $n/L$. Now we feed each sub-pattern to a neural network which enforces $m$ constraint\(^7\) on the sub-pattern in order to correct the input errors. The local networks in the first level and the global network in the second level use Algorithm 2, which is a variant of the "bit-flipping" method proposed in [2], to correct the errors.
A. Learning Phase

We generated a sample data set of $C = 10000$ patterns of length $n$ where each block of $n/4$ belonged to a subspace of dimension $k < n/4$. Note that $C$ can be an exponential number in $n$. However, we selected $C = 10000$ as an example to show the performance of the algorithm because even for small values of $k$, and exponential number in $k$ will become too large to handle numerically. The result of the learning algorithm is four different local connectivity matrices $W_1, \ldots, W_4$ as well as a global weight matrix $W$. The number of local constraints was $m = n/4 - k$ and the number of global constraints was $m_g = n - k_t$, where $k_t$ is dimension of the subspace for overall pattern. The learning steps are done until $99\%$ of the patterns in the training set converged.

Table V-A shows the average number of iterations executed before convergence is reached for different constraint nodes at the local and global level. It also gives the average sparsity ratio for the columns of matrix $W$. The sparsity ratio is defined as $\rho = \kappa/n$, where $\kappa$ is the number of non-zero elements. From the figure one notices that as $n$ increases, the vectors become sparser.

B. Recall Phase

For the recall phase, in each trial we pick a pattern randomly from the training set, corrupt a given number of its symbols with $\pm 1$ noise and use the suggested algorithm to correct the errors. As mentioned earlier, the errors are corrected first at the local and then the global level. When finished, we compare the output of the first and the second level with the original (uncorrputed) pattern $x$. A pattern error is declared if the output does not match at each stage.

Figure 3 illustrates the pattern error rates $n = 400$ with two different values of $k_t = 100$ and $k_t = 200$. The results are also compared to that of the bit-flipping algorithm in [2] to show the improved performance of the proposed algorithm. As one can see, having a larger number of constraints at the global level, i.e. having a smaller $k_t$, will result in better pattern error rates at the end of the second stage. Furthermore, note that since we stop the learning after $99\%$ of the patterns had learned, it is natural to see some recall errors even for 1 initial erroneous node.

Table V-B shows the gain we obtain by adding an additional second level to the network architecture. The gain is calculated as the ratio between the pattern error rate at the output of the first layer and the pattern error rate at the output of the second layer.
