To the three women: my mum, my mum-inlaw and my daughter

I have not failed. I've just found 10000 ways that won't work. - Thomas Edison

Abstract

The development of atomic force microscopy (AFM) has enabled a major breakthrough in the study of individual biological objects, such as nucleic acids, proteins and protein complexes. More recently the use of AFM to investigate eukaryotic cells has been explored. In one approach, the AFM probe can be used as a needle that delivers material into a single living cell while the AFM microscope controls precisely the interactions between the probe and the biological sample. The work presented here was dedicated to the development of a microinjection system for single cells based on atomic force microscopy. Demonstration experiments of liquid delivery into cells were also performed in order to characterize the system, its potential and its limits. As the injection of liquid into a cell requires the insertion of the tip into a cell, a detailed study of AFM probe-cell interactions was carried out.

In the introduction microinjection into adherent cells, its applications and limitations are described. The main limitation of this method is lack of control over the cell penetration. Since atomic force microscope (AFM) offers this possibility, a novel microinjection tool for liquid delivery into single adherent cells based on the AFM is proposed in this work.

A case study examines the specifications of an AFM-based microinjection system, such as control of delivered volume and control of AFM-probe cell interactions. Given the specifications, a detail design of the system is proposed with an AFM probe with microfluidic channels (NADIS) as a core component.

In next two chapters, the fabrication and characterization of the system is presented including the flow of liquids through the NADIS probes. Some limitations of the system are discussed together with possible approaches to improvement.

Further, an in depth analysis of cell indentation is undertaken. Aspects such as determination of tip insertion and factors influencing the probability of cell membrane penetration by an AFM tip are discussed. Cell membrane rupture with an AFM probe is described with a simple mechanical model. Biophysical analysis of the tip insertion is presented followed by development of a five parameter analysis of force-separation curves. In addition the effect of tip penetration on cell viability is addressed.

Finally, the AFM-based microinjection system is used to deliver liquids into individual adherent cells. Microinjection into the cytoplasm, but not into the nucleus is demonstrated. The experiments study possible system leakage, clogging of the tip opening with cell residues and injection parameters. Finally the probe-cell interactions during the injections are analysed.

Keywords: microinjection, atomic force microscopy, Nanoscale Dispensing Probes, adherent cells

Résumé

Le développement de la microscopie à force atomique (AFM pour atomic force microscope) a permis une avancée majeure dans l'étude d'entités biologiques individuelles, telles que les acides nucléiques ou les protéines et leurs complexes. Plus récemment, des études ont exploré l'aptitude des techniques AFM à analyser des cellules eucaryotes. Dans une des approches, la sonde de l'AFM est utilisée comme aiguille permettant de délivrer une substance à l'intérieur d'une cellule individuelle vivante, l'interaction entre la sonde et la cellule étant contrôlée de manière précise par l'AFM.

Le travail présenté ici est consacré au développement d'un système de micro-injection pour des cellules individuelles, basé sur le principe de l'AFM. Des expériences démontrant la libération de substances à l'intérieur de cellules ont été réalisées dans le but de caractériser le système, ainsi que son potentiel et ses limites. L'injection intracellulaire nécessitant une pénétration de la sonde AFM dans la cellule, une étude approfondie de l'interaction sonde-cellule a été effectuée.

L'introduction décrit la méthode de la microinjection dans des cellules, les applications et les limites. La limitation principale de cette méthode est l'absence de contrôle sur la pénétration de la cellule. Puisque la microscopie à force atomique (AFM) offre cette possibilité elle a été proposée comme alternative. Pour cela un nouvel outil de microinjection pour la libération de substances à l'intérieur de cellules individuelles basé sur l'AFM est développé dans le cadre de cette thèse.

Une étude de cas examine les spécifications d'un système de micro-injection basé sur un AFM, telles que le contrôle du volume délivré et le contrôle de l'interaction sonde-cellule. Une conception détaillée d'un système tenant compte des spécifications est présentée, dont la composante principale est une sonde AFM pourvue de canaux microfluidiques (sonde NADIS). Les deux chapitres suivants décrivent la fabrication et la caractérisation du système, y compris du flux de liquide passant par la sonde NADIS. Quelques limitations du système sont discutées conjointement avec les améliorations possibles.

Ensuite, une analyse approfondie de l'indentation cellulaire est entreprise. Des aspects tels que la détermination de l'insertion de la sonde et des facteurs influençant la probabilité d'une pénétration de la membrane cellulaire sont discutés. La rupture de la membrane cellulaire par la sonde AFM est décrite à l'aide d'un modèle mécanique simple. Une analyse biophysique de l'insertion de la pointe est présentée, ainsi qu'une analyse des courbes force-séparation à l'aide de cinq paramètres. De plus, l'effet de la pénétration de la sonde sur la viabilité des cellules est abordé.

Enfin, le système de micro-injection basé sur un AFM est utilisé pour libérer des substances dans des cellules adhérentes individuelles. La micro-injection dans le cytoplasme, mais non pas dans le noyau, est démontrée. Les expériences analysent les fuites possibles dans le système, l'obstruction de l'ouverture située à la pointe de la sonde par des résidus cellulaires et les paramètres de micro-injection. Enfin, les interactions sonde-cellule durant la micro-injection sont analysées.

Mots-clés : microinjection, microscopie à force atomique, Nanoscale Dispensing Probes, cellules adhérentes

1 Introduction

1.1 Microinjection into single adherent cells

Microinjection is a method in which a fine tipped needle is inserted inside a cell to deliver a clearly defined amount of a substance. The substance is injected into the desired sub-cellular, cellular, or intercellular compartment upon a pressure pulse. Once the substance is injected the needle is removed from the cell. The movement of the needle during the entire process is controlled by micromanipulators and visually observed with a specialized microscope. The substance can be delivered into suspended and adherent cells. The suspended cells grow loosely in the medium. To inject liquid into a single suspended cell, the cell has to be held by a capillary on one side so the needle can penetrate the cell and inject the substance into it from the other side (Figure 1.1 a)). The adherent cells grow on the bottom of a culture dish. The microinjection needle is penetrating a single adherent cell from above to deliver the substance (Figure 1.1 b)).

Figure 1.1: Microinjection a) into a suspended cell (source: cctrdev.uams.edu) and b) into an adherent cell (source: www.visualphotos.com)

1.2 Components of a microinjection system

Every microinjection system consists of a standard set of components [1, 2]: a micropipette needle used to penetrate the cell and deliver the substances into it; a micromanipulator used

Chapter 1. Introduction

for precise positioning of the micropipette needle; an inverted microscope equipped with phase-contrast for visualization of target cells and coordination of positioning and a vibration isolation tabletop to decrease vibrations of the fine tipped needle. The micropipette needles are fabricated from glass capillary tubing with micropipette pullers. The most common material of glass capillary tubing is borosilicate glass due its excellent strength¹. A fabricated micropipette needle consists of four parts: the tip, the shank, the shoulder, and the shaft. The shape of the needle and size of its opening depends on the pulling parameters. Standard inner diameter of a needle opening varies from 0.2 μm to 0.5 μm . It is more common for a standard user to fabricate its own needles than to buy it. Therefore on the market numerous types of micropipette pullers are available, for example David Kopf Instruments, MicroData Instrument or Energy Beam Sciences. There are also direct producers of micropipette needles, for example Eppendorf. Figure 1.2 shows examples of Eppendorf micropipette needles. Figure 1.2a) shows the entire micropipette needle held by a microloader, Figure 1.2b) shows a SEM image of the needle tip of the type Femtotip® and creffig:1-2c) shows a SEM image of the needle tip of the type Femtotip® II.

Figure 1.2: a) image of an Eppendorf micropipette needle held by a microloader; SEM images of needle tips: b) the Femtotip®, and c) the Femtotip® II.

The micromanipulator controls the movement of the micropipette needle in 3 ways: horizontal (x- and y-axis), vertical (z-axis) and tilt angle (t). For microinjection of adherent cells the micropipette needle is held at an angle of 30°-60° to the microscope stage for cell penetration. There are standard micromanipulators available on the market produced by Eppendorf, Narishige, Leiz, etc., and there are also research groups which have developed their own micromanipulators, like the MANiPEN [3, 4] and “Steady Hand” micromanipulator [5]. Figure 1.3 shows the MANiPEN micromanipulator.

Another crucial element is the microinjector. The microinjector is used to apply a pressure pulse to the micropipette needle for substance ejection from its tip. There is a wide range of analog and digital pressure microinjectors, where the ejected substance volume depends on pressure, time, fluid viscosity and size of the tip opening. The microinjectors can deliver volumes smaller than 10 nanoliters. There exist also positive-displacement and syringe-type injectors on the market. However, their precision allows only to deliver volumes larger than tens of nanoliters due to the thermal expansion of their components.

The inverted microscope is required to visualize the cells and coordinate the cell-needle positioning. The inverted microscope arrangement provides enough space for the micromanipu-

Figure 1.3: MANiPEN micromanipulator [3].

lator with the micropipette needle. Since the cells are optically transparent, the microscope has to be equipped with phase contrast, or differential interface contrast (DIC). The microscope can be additionally equipped with a mercury lamp to combine the microinjection with fluorescent observations. Figure 1.4 shows an example of a microinjection system.

The vibration isolation tabletop is required to assure vibration-free conditions during the microinjection. The tabletops are commercially available products.

1.3 Applications

Microinjection into single adherent cells plays an important role in research field like drug discovery [6–9] toxicology [10–13] and biology [14–17]. In drug discovery microinjection is used to study and produce recombinant human and animal cell lines. In toxicology injection of foreign substances (nanoparticles [10] or molecules [11–13]) into cells is used to study toxicity mechanisms. In biology the microinjection is used to study human cancer cells [18–20], transport between nucleus and cytoplasm [21], to deliver RNA [22–25], proteins, peptides and cDNAs [26]. Microinjection is also used for stem cell biology [17, 27, 28]. In most of these research fields microinjection into adherent cells dominates comparing with the injection into suspended cells.

1.4 Limitations of the microinjection systems for adherent cells

The microinjection technique allows to target specific cells in order to deliver any type of material. However, this technique has two main disadvantages. It has been reported that the

Figure 1.4: A microinjection system for injection into adherent cells: the Olympus microscope with Eppendorf InjectMan NI 2 micromanipulator and FemtoJet microinjector. (source: www.biocompare.com)

success penetration rate of a cell with a micropipette needle can be as high as 100% [14, 29, 30], however the efficiency of successful substance delivery rate is not higher than 50%[4]. As an explanation two main reasons were given: clogging of the needle tip and lack of control of the needle-cell interactions. Since an atomic force microscope (AFM) allows to precisely control the interactions between a cell and an AFM probe it has been proposed to develop novel techniques for the delivery of substances into single adherent cells.

1.5 AFM-based delivery systems into single adherent cells

The development of atomic force microscopy (AFM) has been a major breakthrough in the study of single biological objects, such as DNA [31, 32], bacteria [33, 34] and, in particular, eukaryotic cells [35–37]. The main components of the AFM are a microfabricated probe with a thin cantilever and a sharp tip on its end, a piezoelectric scanner and a system to measure the interactions between the tip and the sample. The interactions are measured via deflection of the cantilever due to attractive or repulsive forces acting on the tip. The cantilever deflection is monitored by reflection of a laser beam from the cantilever to the photodiode. Figure 1.5 shows a basic schematic of an AFM microscope, placed on an inverted microscope with an adherent cell as a sample.

When an AFM tip is brought into contact with a cell membrane, it can be scanned across the cell surface to investigate the topography and structure of the cell [38, 39], or it can be pressed into the cell, deforming it, and revealing the mechanical properties of the cell [40]. Pressing on the cell with a high force can result in a cell penetration [41, 42].

1.5. AFM-based delivery systems into single adherent cells

Figure 1.5: Schematic of a typical AFM set up for cell biology. (source: Roduit, C. "AFM figures" 2010, www.freesbi.ch, Creative Commons Attribution)

The possibility of controlled cell penetration being offered by the AFM has invited researchers to explore this technique as a tool to deliver substances. The AFM also offers possibility of more precise positioning of the tip in x-, y- and z-axis than the micromanipulator used in standard microinjection systems. Also since the cell penetration with the AFM tip can be better controlled less cell damage is expected to occur. Figure 1.6 shows comparison between the micropipette needle and a standard AFM probe. Figure 1.6a) shows the penetration of a primary neuronal cells using a micropipette needle [2], and Figure 1.6b) shows the penetration of an HEK293 cell membrane using a standard AFM probe.

Figure 1.6: Optical images of a) a micropipette needle penetrating primary neuronal cells 2; and b) a standard AFM probe penetrating HEK293 cell.

When in December 2003 the research group of professor Atsushi Ikai has shown that an AFM tip can be inserted into a living cell to extract mRNA [43] it became clear that the AFM tip can

be used as a tool for operations on single living adherent cells. One year later the group of professor Jun Miyake has demonstrated first molecular delivery system using an AFM [44]. From then, many research groups have shown successful delivery of molecules into single living cell [38, 45–49].

1.6 Delivery of biomolecules with AFM probes

The molecular delivery system using AFM developed by the group of professor Miyake [44] consisted of a standard AFM microscope and a nanoneedle fabricated by the group. The nanoneedle was a standard AFM probe with a pyramidal tip etched to a shape of a fine long column (Figure 1.7a). The AFM probe was further chemically treated to immobilize fluorescent biomolecules on the surface of the nanoneedle. The nanoneedle was used to penetrate single human cells. Confocal analysis of the cells has shown fluorescent signals, which proofed the successfully delivery of the biomolecules.

Figure 1.7: a) shows an SEM image of a nanoneedle; b) confocal image showing a nanoneedle (emitting green fluorescence) inserted inside a cell nucleus (the cell is emitting red fluorescence).

Further the same group has shown that the nanoneedle can penetrate not only the cell but also its nucleus⁵⁰ (Figure 1.7b)) and demonstrated highly efficient DNA delivery in human cells [45, 50]. Recently, the nanoneedle was used to monitor drug effects in a single breast cancer cell [51]. The nanoneedle was covered with an adsorbed responsive vector and delivered into the cell. The responsiveness of the cell was evaluated using lipofection.

Cuerrier et al. [49] have demonstrated delivery of molecules into single human cells using AFM probes decorated with plasmid DNA encoding for the fluorescent protein EGFP. This result is interesting as it is demonstrating cell transfection using standard AFM probes with pyramidal tips. Later on delivery of biomolecules into cells with standard AFM probes was demonstrated by Ikai [38].

Delivery into single cells using AFM microscope was also demonstrated using a carbon nanotube attached to an AFM tip. The carbon nanotube was functionalized with quantum dots and inserted into a human cell line [52].

Several groups began to work on AFM systems allowing to deliver not only molecules, but also liquids inside the cells [46, 47, 53]. Delivery of liquids into single cells is technologically more challenging than delivery of 'dry' molecules that are attached to the AFM tip chemically or by adhesion forces. Liquids, however, cannot be attach to the tip and require more sophisticated carriers. In order to deliver liquids into cells AFM probes with integrated microfluidic systems are being developed.

1.7 AFM probes with microfluidic systems

To deliver liquids inside single living cells attached to a culture dish and filled with culture cell medium AFM probes have to have embedded microfluidic system. Such a system has to have a built in reservoir and channels connected to the tip. In the literature, probes have been already demonstrated: NanoFountain Probe [48, 53], NADIS Probe [47, 54, 55], and Bioprobe [46].

The NanoFountain Probe is a probe with microfluidic channels and a "high volcano-like dispensing tip integrated at the free end of the cantilever, which has an annular aperture around a core AFM tip" [56]. The tip aperture is connected to the microchannels. Figure 1.8a) shows a schematic drawing of the NanoFountain Pen and Figure 1.8b) shows a SEM image of the tip.

Figure 1.8: a) shows a schematic of a NanoFountain Probe; b) shows a an SEM image of the dispensing tip; c) shows schematic of nanodiamonds delivery into a single cell with the NanoFountain Probe.

The NanoFountain Probe was used to demonstrate delivery of functionalized nanodiamonds into single cells [53]. Figure 1.8c) shows a schematic drawing of the delivery. The sharp tip is used to penetrate the cell membrane and to guide the nanoparticles into the cell.

The NADIS Probes, where NADIS stands for Nanoscale Dispensing, are AFM probes with microfluidic channels connected to a tip. The tip has an aperture next to its apex for liquid delivery. The sharp apex is used to penetrate the cell membrane and to insert the tip inside the cell. Injection of liquid into single cells was demonstrated with these probes [47]. The injection was obtained via hydrostatic pressure. Figure 1.9 shows SEM images of the NADIS probe. Figure 1.9a) shows an image of the cantilever with a tip, Figure 1.9b) shows cross-section image of the cantilever to shows the fluidic channels, Figure 1.9c) shows an AFM tip with an opening for liquid delivery (side view), and Figure 1.9d) shows a detailed top view of the tip apex and the tip opening positioned next to the apex.

Figure 1.9: SEM images of a) NADIS cantilever with a tip; b) cross-section of the cantilever with the microfluidic channels; c) a NADIS tip with an opening positioned next to the tip apex; d) top detailed view on the tip apex and the opening.

The Bioprobe is an AFM probe with microfluidic channels connected to a pyramidal tip with embedded hollow needle. It was reported in 2011 as a tool for operations on single living cells, however up to now only penetrations of a cell membrane with the probe were demonstrated [46]. Figure 1.10 a)–c) show schematics of the probe design and its fabrication process. Figure 1.10 d) shows a SEM image of the fabricated tip with a sharp needle.

Figure 1.10: a)–c) show schematic of the probe design and its fabrication process, d) shows an SEM image of the fabricated tip with embedded needle with a detail view on the tip [46].

Although liquid delivery into cells with most of these probes has been demonstrated, none of these technologies are ready yet to challenge the position of standard microinjection using micropipette needles. The AFM probes with integrated microfluidics are the core component for liquid delivery into single cells. However, in order to control not only the cell penetration, but also liquid delivery into cells, further development is required.

1.8 Thesis objectives

The main objective of this thesis is to develop an AFM-based microinjection system for liquid delivery into single adherent cells. The development will be based on the NADIS probe with integrated microfluidic channels and a hollow tip.

In order to deliver liquid into a cell via the AFM tip, it is crucial to understand the complex tip–cell interactions. These interactions will be studied via ‘force spectroscopy’.

Also the invasiveness of the tip insertion will be studied to verify possible cell damage. Finally, the AFM–based microinjection system will be used to demonstrate intracellular injection.

2 Materials and methods

In this chapter materials and experimental methods are detailed.

2.1 Fabrication of the apertures

Fabrication of the tip apertures in NADIS probes was performed using focused ion beam milling (FIB).

FIB was used in a wide range of applications such as imaging [57] and deposition [58] but its main application is localized milling of material with high precision [59, 60]. To create apertures in the AFM tips, precise control of the volume of the material being removed at precise location was required; hence the FIB milling was the method of choice.

The FIB milling was carried out with an FEI Nova 600 NanoLab - DualBeam system. The DualBeam system consists of electron and gallium ion beams. The electron beam plays the role of the SEM and allows image sampling with ultra-high resolution. The DualBeam system allows one to operate the two beams at the same time. When the sample is being milled with the ion beam, the process can be observed in real time with the SEM. The process takes place in a high-vacuum environment. The critical point of making the system work correctly is to set the sample to the eucentric point. The eucentric point is where the coincidence of the beams with the stage tilt axis occurs. At this point, the place of interest on the sample remains in focus and very little image displacement occurs, independently of how the sample is tilted or rotated. To position the place of interest at the eucentric point, the working distance of the electron beam (the eucentric height) has to be found. The milling process is the most efficient when the ion beam is perpendicular to the place of interest-the angle of the incidence $\theta = 0^\circ$ (the angle of the incidence is the angle between the surface normal of the AFM chip and the ion beam). In this configuration the system with the sample is ready to work. Figure 2.1 illustrates the configuration for the NADIS chip inside the FIB system. The tip apex was placed in the eucentric point. Figure 2.1 b) shows a micrograph of the tip seen with the ion beam and Figure 2.1 c) shows a micrograph of the tip seen at the same time with the electron beam.

Figure 2.1: Configuration of the system and the sample, the tip apex was placed in eucentric point and the sample was tilted to 52° where the ion beam is perpendicular to the AFM tip a). Micrographs on the right show how the tip in this configuration is seen by b) the ion beam and c) the electron beam.

2.1.1 Interaction of the ion beam with the matter (specifications)

When the Ga^+ ion beam hits the sample surface the interaction of the ions with the matter can be chemical and physical in nature. The physical interactions are the result of a kinetic momentum transfer of incident ions to a target substrate leading to a sputtering deposition. A large momentum transfer triggers a collision cascade resulting in a removal of atoms situated close to the surface. The kinetic energy transfer causes photon emission, which is responsible for heating effects, and releases electrons. These secondary electrons are the ones used for imaging. In addition to material removal side effects such as implantation, swelling and re-deposition of sputtered material also occurs.

Important process parameters are ion energy, current and voltage, beam diameter, angle of incidence and dwell time. In general the ion energy lies in the range from 10 to 100 keV where sputtering takes place. A large removal rate can be obtained using a large current with, consequently, a large beam diameter. Smaller beam diameters are used for imaging and larger apertures are used for faster milling. Recommended current values for milling submicron holes are 30 or 50 pA [61] and the acceleration voltage is 30 kV [61]. During the milling of the sample the beam moves from one beam pixel to another. The distance between the beam pixels is called the beam overlap. In order to ensure a uniform exposure of the milled area to the ions, the beam overlap is usually set to 50%. The dwell time is the time the beam spends on a single pixel of the milled pattern. In the context of re-deposition the dwell time is a crucial parameter for advanced structure quality. Longer dwell times lead to a deeper milling

2.2. Development of parylene C mask for KOH etching

but at the same time cause larger re-deposition, thus its value depends on the compromise between these two effects. A dwell time of 500 ns has been chosen to mill the tip apertures, since shorter dwell time does not improve the quality and the FIB system becomes unstable at dwell times shorter than approximately 200 ns. The angle of the incidence (θ) has an influence on a sputtering yield of the ion beam and roughly increases with $1/\cos(\theta)$ [62]. Milling of the tip apertures occurred always at 0° .

2.2 Development of parylene C mask for KOH etching

2.2.1 Substrates

To study adhesion properties of parylene C, the following substrates were used: 4 inch silicon wafers (Silitronix France), silicon wafers with 250 nm thermally grown silicon dioxide and silicon wafers coated with silicon dioxide and additional LPCVD deposited 100 nm nitride. After the cleaning process 1 wafer per substrate type was diced to $1\text{ cm} \times 1\text{ cm}$ samples.

For testing parylene C mask on 3D structures Pyrex wafers with microfluidic channels were anodically bonded to structured silicon wafers with inlets. The microfluidic channels were $10\text{ }\mu\text{m}$ and $20\text{ }\mu\text{m}$ wide and $1.2\text{ }\mu\text{m}$ high. The length of the channels varied from $1.1\text{ }\mu\text{m}$ to $1.6\text{ }\mu\text{m}$. The inlets were etched through the entire thickness of the silicon wafer by KOH etching.

2.2.2 Substrate cleaning¹

The wafers were immersed 10 minutes in a solution of H_2SO_4 (96 %, 120°C) followed by 1 minute in a BHF solution (1:7, 23°C) and 10 minutes in a HNO_3 solution 70 %, 116°C). Finally the samples were rinsed in DI water and dried in spin rinse dryer (SRD).

2.2.3 Chemical adhesion promotion

To promote adhesion of parylene C to the substrates -methacryl-oxy-propyl-trimethoxy-silane, also known as the Silquest A-174® silane (ABCR GmbH&Co, Germany) was used. Silane deposition was studied in liquid and gas phase. The samples silanized in the liquid phase were left for 5 min in a solution of silane A-174 and water (ratio 1:10 ml). For the gas phase silanization, the samples were placed in a custom made parallel plate vacuum chamber and pumped down to a base pressure of 8×10^{-3} mbar. The surface activation was done using air plasma (0.3 mbar, 50 watts during 15 minutes). The chamber was then returned to the base pressure before closing the pump valve and introducing the silane A-174 up to a pressure of 2×10^{-2} mbar. Finally, the silane was left to condense on the samples for 60 minutes. Static and dynamic contact angle measurements were used to optimize the deposition parameters. The contact angle of water was measured at $(100 \pm 8)^\circ$ for the gas silanization and $(115 \pm 6)^\circ$

¹The substrate cleaning was done by group of Dr Philippe Niedermann at CSEM SA (Switzerland)

for the liquid phase silanization on all substrates. The cleaning procedure consisting of a sonication for 10 min in hexane and rinsing with Milli®-Q water had no effect on the contact angle.

2.2.4 Parylene deposition ²

The Parylene deposition took place in a COMELEC model 1010 deposition chamber using the conventional LPCVD process. 10 grams of dichloro[2.2]-paracyclophane dimer (Galxyl C purchased from Galentis Srl, Italy) yielded layers of 5 microns ($\pm 10\%$) of Parylene C on the samples. It was verified and confirmed on dummy samples using a Dektak profilometer.

2.3 Thermal treatment

Samples dedicated to test influence of thermal treatment on parylene adhesion were placed in an oven, under a nitrogen atmosphere at atmospheric pressure. The oven was heated $10\text{ }^{\circ}\text{C min}^{-1}$ from room temperature up to $350\text{ }^{\circ}\text{C}$. This temperature was kept for 2h before cooling down the oven at a rate of $5\text{ }^{\circ}\text{C min}^{-1}$ down to room temperature.

2.3.1 Potassium Hydroxide (KOH) Exposure ³

The samples were immersed in a 40 % solution of KOH (Potassium hydroxide) at $60\text{ }^{\circ}\text{C}$ for 5 or 25 hours. The etching rate was approximately $16\text{ }\mu\text{m h}^{-1}$ on a 110 orientated Si wafer.

2.3.2 Scratch test

The adhesion of the Parylene layers was assessed using a scratch test equipment REVETEST® from CSM Instruments S.A (Switzerland), controlled by the proprietary Scratch software. The measurement principle consists in a stylus with a diamond tip of spherical shape and diameter of $200\text{ }\mu\text{m}$ that is put in contact with a surface. An increasing load is applied on the stylus as it is dragged across the sample. The instrument measures the acoustic signal made by the stylus scratching the layer. A layer breaking is characterized by a large noise that indicates the rupture load. A visual inspection kit enables to check the accuracy of the information recorded by the acoustic signal and it enables to visualize the shape of the imprint left by the stylus. Even though this kind of instrument is normally used to characterize the adhesion of hard thin films on a softer substrate, it enabled to compare the adhesion of the treated and non-treated Parylene layer on our samples. Prior to the measurements, the samples were fixed with in a substrate holder with acrylate glue. The measurement length was set to 5 mm with a load of 30 N cm^{-1} . The measurements were recorded using the proprietary software and 3

²The parylene deposition, thermal treatment and scratch test were done by group of Prof. Herber Keppner at HE-ARC (Switzerland)

³The KOH exposure was done by Dr Fabio Jutzi and Dr Dara Bayat from EPFL (Switzerland)

pictures (start of the imprint, rupture point and end point) were taken for each sample.

2.3.3 XRD measurements ⁴

The XRD measurements were used to understand the influence of carried different treatment conditions on crystalline properties of the parylene. The X-Ray Diffraction data were measured in reflection mode on a X'pert pro PAN'alytical diffractometer (MRD) using $CuK\alpha$ radiation. The data was collected first in the $\omega/2\theta$ mode and secondly in the range 2θ ($\omega = 1^\circ$ range of 5° to 40° (step size 0.02° , $1s/step$). The crystallite size were calculated using the Scherrer equation and the contribution of the peak width from the instrument was taken into account (Si sample was used).

2.3.4 The AFM imaging

The AFM measurements were performed in tapping mode on a 3100 Dimension microscope (Digital Instruments, Santa Barbara, CA). Silicon tips (Tap 150-AL-G from Budget Sensors, USA) with a radius less than 10 nm, spring constant of 5 N m^{-1} and resonance frequency of 150 kHz were used. The samples were cleaned with N_2 nitrogen gun directly before the measurements.

2.4 Instrumentation

2.4.1 Atomic force microscope (AFM)

The AFM based microinjection system was built based on a Nanowizard® II BioAFM (JPK Instruments, Germany) mounted on an Axiovert 200 inverted optical microscope (Carl Zeiss, Germany). Figure 2.2 shows pictures of the setup. Additionally a CellHesion® module (JPK Instruments, Germany) was used to extend the travel range of the AFM microscope in the z-axis to $100\ \mu\text{m}$. The module has a precise sample lift mechanism integrated into the AFM stage. To the setup a fully compatible Petri dish heater was used (PetriDish Heater, JPK Instruments, Germany) to maintain the cells at the temperature of 37°C .

2.4.2 Pressure generator

To apply pressure pulses into the NADIS probes PM 8000 Programable 8-Channel Pressure Injector (MicroData Instrument, Inc., USA) was used. It is a standard device used in microinjection.

⁴The XRD measurements were done by group of Dr Antonia Neels, CSEM SA (Switzerland)

Figure 2.2: Picture of a) the setup: the Nanowizard® II BioAFM and Cell Hesion® module mounted on the Axiovert 200 inverted optical microscope; b) the stand alone Nanowizard® II BioAFM and Cell Hesion® module; c) the PetriDish heater.

2.4.3 Flow measurements system

To experimentally determine the hydraulic resistance of the AFM-based microinjection system a measurement system was designed, where for a given applied pressure ΔP the flow of liquid Q through the NADIS probe was assessed. The system consisted of an optically transparent glass tube connected at one end to the pressure generator and on the other hand to the NADIS probe. Knowing that the flow of liquid being ejected through the opening in the NADIS probe is the same as the liquid flow in the glass tube, the flow through the tube was measured.

Knowing that for a given applied pressure ΔP , the liquid in the tube of a known radius a has been displaced for a length ΔL in the time Δt , the liquid flow through the opening in the NADIS probe was calculated as:

$$Q = \frac{\pi a^2 \Delta L}{\Delta t} \quad (2.1)$$

where, $\pi a^2 \Delta L$ is a volume of liquid ejected through the opening in the NADIS probe.

Figure 2.3: Optical images of a tube filled with liquid (marked as black) taken at a) time t_1 and b) time t_2 for a given applied pressure. The liquid displacement ΔL over time Δt was measured with a reference grid.

2.5 Substrates for biological experiments

For biological experiments three types of substrates were used: Petri Dish made of polystyrene (35mm), glass coated with fibronectin and glass patterned with PLL-g-PEG/fibronectin. The last two types were commercially available CYTOOchipTM samples (CYTOO SA, France). The CYTOOchipTM is a $2\mu\text{m} \times 2\mu\text{m}$ $170\mu\text{m}$ thick gridded coverslip with micropattern arrays and a large area homogeneously covered with fibronectin. The micropattern of the fibronectin had a disc shape of a diameter of $45\mu\text{m}$; the pitch between the discs was $130\mu\text{m}$. The entire surrounding surface was PLL-g-PEG, a surface chemistry which discourages cell spreading.

A single CYTOOchipTM was divided into 4 samples. Samples containing homogeneously covered with fibronectin area were used as glass coated with fibronectin substrates and samples

containing the micropattern arrays were used as glass patterned with PLL-g-PEG/fibronectin substrates.

2.6 Cell culture⁵

The human osteosarcoma cell line (SaOs-2) was obtained from American Type Culture Collection (Manassas, VA, USA) and maintained in culture in McCoy's 5A medium supplemented with 10% heat-inactivated standardized foetal bovine serum (Biochrom AG, Germany), 1% L-glutamine and 50 mL⁻¹ of penicillin, 50 µg mL⁻¹ of streptomycin at 37 °C in humidified 5% CO₂ atmosphere.

2.6.1 Cell seeding on Petri dish substrates

A cell suspension of 105 SaOs-2 cells was seeded on Petri dishes and cultured for 24 hours on complete medium. Experiments with the samples were performed in regular medium supplemented with 25 mmol HEPES.

2.6.2 Cell seeding on CYTOOchip™

The CYTOOchip™ was attached to the bottom of the petri dish. 120,000 cells were added to the top of the CYTOOchip™ and left to settle under the laminar flow hood for 10 minutes before transferring to a 37 °C incubator for 40 minutes. The CYTOOchip™ was then rinsed with PBS three times to remove any unattached cells and then left in the incubator for 3 hours before using.

A 25mM EDTA in cell culture media solution was used for experiments with EDTA.

2.6.3 Cell staining

Cells have been fixed with 4% formaldehyde after 3 hours of culture. Then incubated in PBS-glycine 0.1 M to permeabilize the cell membrane, and in blocking buffer to block nonspecific sites. Alexa Fluor 488 Phalloidin (Molecular probes) was used to label F-actin while DAPI (4',6-diamidino-2-phenylindole) was used to label the cell nuclei.

2.6.4 Confocal analysis

All confocal measurements were done with Leica Confocal Microscope (Leica Microsystems, Germany). Measurements of cell height, nucleus height and nucleus-membrane distances were done as follows: from the top of the cell we take a stack of images in z-direction, step

⁵The cell culture was prepared by Ms. Marta Giazson, Ms. Nadège Matthey and Mr. Sher Ahmed from CSEM SA (Switzerland)

500 nm. The entire cell thickness has been calculated on the basis of the number of sections necessary to image completely the cell. The distance sub-membrane nucleus has been calculated by analysing the number of sections with actin before to have the nucleus appearing. The nucleus height was calculated making the sum of the sections where DAPI signal was present.

2.6.5 Cell death analysis

To measure cell survival rate a LIVE/DEAD kit (Sigma Aldrich) was used. The LIVE/DEAD kit contained two components. The first component is Calcein-AM. This is a highly lipophilic and cell membrane permeable. Although CAM is not a fluorescent molecule, when it enters viable cells it emits a strong green fluorescent signal. The second component is propidium iodide. This is a nuclear stain which cannot pass through viable cell membranes. It passed through the dead cell's membranes and intercalates with the DNA in the nucleus to emit a strong red fluorescence. After applying the kit to the cells, the cells were viewed by confocal microscopy.

2.6.6 Cell fixation

Cell fixation was used to investigate cells spread on substrates coated with Parylene. Samples were rinsed with PBS. The cell fixation was done in a solution of 2.5% glutaraldehyde in 0.2 M cacodylate buffer, pH 7.4, overnight. Afterwards, the cells were dehydrated in a series of ethanol/water mixtures: 20%, 30%, 40%, 50%, 60%, 70%, 80%, 90%, 100%, ethanol (5 min each), followed by air drying. Once the samples were ready, the substrates were coated with 20 nm Au layer and investigated with a XL-30 ESEM (Royal Philips, Netherlands) scanning electron microscope.

2.7 AFM probes

For the force spectroscopy experiments two types of AFM probes were used. The first type was commercially available silicon probes (Tap150-G, Budget Sensors, Bulgaria) with a pyramidal tip shape and tip radius of approximately 10 nm. The probes were 125 μm long with a nominal spring constant of 5 N m^{-1} . Before every experiment each cantilever was calibrated using cantilever-on-cantilever method. The final working spring constant of cantilevers was in the range of 3 N m^{-1} to 7 N m^{-1} .

The second type of probe was fabricated and developed at CSEM SA, Switzerland Nanoscale Dispensing (NADIS) probes. The NADIS probes contain a microfluidic system and are a core component of the AFM-based microinjection system. Chapter 4 is dedicated to its design and microfabrication process and Chapter 5 describes its characterization.

2.8 Data processing and statistical analysis

2.8.1 Analysis of force-distance curves

Data analysis was carried out using Image Processing software (JPK Instruments, Germany). For every single cell 1 force distance–curve was obtained. The force–distance curves were first transformed into force vs. tip–sample separation curves and analysed in terms of the indentation depth (D), the penetration depth ($D1$), the penetration force ($F1$), the force drop (Fd) and the membrane slip (d). The mean of these values together with the sample standard deviation was then taken to be characteristic of each condition.

2.8.2 Statistical analysis

The obtained data was analysed with the Microsoft Excel with Data Analysis Tool. Two types of statistical analysis were used: ANOVA and T–test. The ANOVA (Single Factor) test was used to compare four population means (populations of cells spread on glass coated with fibronectin and cells spread on glass patterned with PLL-g-PEG/fibronectin, with and without EDTA). The Sheffé test was further used to find which of the samples means are different. For any other statistical analysis two–sample T-test was used.

For all statistical tests, a $p < 0.05$ was considered significant.

3 Concept study

3.1 Introduction: Delivery of liquids into a living body

In order to inject a liquid into a living organism, the outer membrane must have an opening through which the liquid can enter the organism. For this reason, it is necessary to puncture a hole in the membrane while minimizing the damage inflicted on the organism such that the desired amount of liquid which can be tolerated by the organism can be transferred. Liquid delivery by this manner requires a specific tool in which several parameters must be considered (Figure 3.1):

1. The size of the tool must be appropriate for the size of the organism.
2. Interactions between the tool and the organism must be controlled during formation of the opening, delivery of liquid and post-delivery to minimize invasiveness.
3. The tool must control the amount of delivered liquid within the range determined by the organism

Figure 3.1: Schematic of liquid delivery into a living organism.

Our ecosystem consists of trillions of soft living organisms. The most common are cells. Manipulation and understanding of their functionality requires the development of a wide variety of experimental methods. Delivery of liquids is one such method; however, developing a tool for the delivery of liquids into all types of cells is very challenging. There is a large variety of different cell types (Figure 3.2) which can be divided into two subdomains: prokaryotic and eukaryotic cells. Each of these is further divided into subcategories and those are again divided into smaller and smaller groups. This case study investigates a tool to deliver liquids into animal cells, in particular mammalian cells, a group that belongs to a category of animal cells in the eukaryotic domain.

Figure 3.2: Diversity of cell types.

3.2 Design of a liquid delivery system into single mammalian cells

Most mammalian cells are adherent cells, cultured typically at a temperature of 37°C in a gas mixture of 5% carbon dioxide (CO_2) and 95% air. The size of a single cell depends on several parameters and varies from tens to hundreds of micrometers [63]. The height does not usually exceed 10 micrometers [64]. Delivery of liquids into adherent cells demands a tool that is smaller than a single cell, can be accurately positioned above it and precisely controlled in order to insert the tool into the cell [65]. A tool that matches these criteria already exists and is well known. It is a probe attached to a chip mounted on an AFM microscope. The probe consists of a cantilever with a sharp tip. This tool has been already used to investigate cell properties and to deliver molecules to cells (outlined previously in Chapter 1). However, a standard AFM cantilever with a tip cannot accommodate liquid in order to inject it inside the cell. For this reason, a new type of AFM probe must be considered; the type that has a fluidic system enclosed inside the cantilever and the tip, all connected to the body of the chip – a Nanoscale Dispensing (NADIS) probe. Figure 3.3 presents a schematic of the NADIS concept. Inside the AFM cantilever, there is a channel connected to a hollow tip. The tip has an opening next to the tip apex through which the liquid can be transferred to the cell. Control of the interaction between the tip and the cell are measured by the AFM microscope by means of attractive and repulsive forces between the tip and the cell [42].

3.2. Design of a liquid delivery system into single mammalian cells

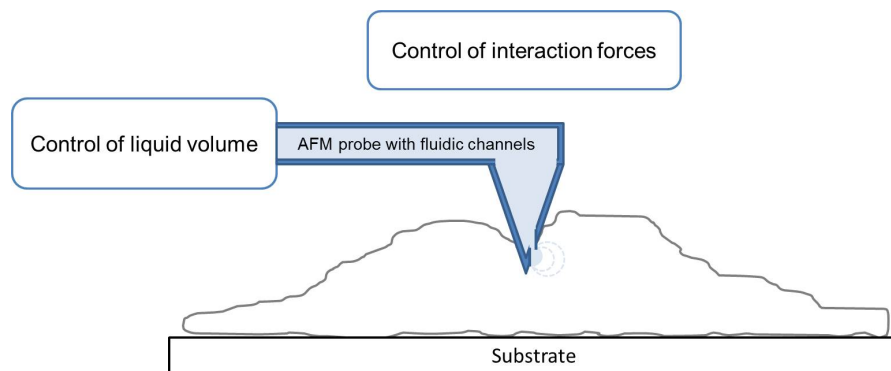

Figure 3.3: Schematic of an AFM based system for liquid delivery into adherent cell. The system consists of an AFM probe with integrated fluidic channel. The probe uses its sharp tip to penetrate the cell membrane. An external system is precisely monitoring the interaction forces between the tip and the cell to assure low invasiveness of the penetration step. Once the tip is inserted into the cell the liquid is delivered through the opening located next to the tip apex. The amount of delivered liquid is controlled by external controller.

The NADIS concept fulfils the first two criteria introduced at the beginning of this chapter: the size of the tool and the interaction control between the tool and the cell. However, the last criterion, precise control of the delivered quantity of liquid, must still be considered.

3.2.1 Amount of liquid delivered into a single cell

To solve the problem of the precise quantity control it is first necessary to ask the question: what quantity of liquid can be delivered to a single cell?

In theory it is possible to calculate the amount if the size of the cell is known. However, the cell is an elastic [35] living body that will respond to the delivered volume of liquid. Thus, there are two main parameters that need to be taken into consideration: variation in the cell volume, and variation in viscoelastic properties of the cell. Within the same cell type it is impossible to find two identical single cells in terms of volume and morphology. The volume of adherent cells is calculated as follows. The cells are detached from the surface causing them to take on a spherical form. By measuring the diameters of the cells in this state, the volume can be calculated based on the formula for the volume of a sphere. The diameter of mammalian cells varies from 10 to 20 μm [2], resulting in a volume variation between 500 to 4000 femtoliters. This shows that the amount of volume supported by the cell can vary up to 8 times.

Cells viscoelastic properties vary as much as their volume. Their viscoelastic properties allow the cell to deform and change shape. Delivery of liquid in to a cell can cause cell deformation. This deformation will depend on the quantity of injected liquid. It is very difficult to predict how much the cell can be deformed without causing damage or even death. In addition, the viscosity of the cell cytoplasm and organelles can impede the delivery of the liquid [66]. This impediment will vary from one cell to another and will influence the quantity of liquid that

Chapter 3. Concept study

can be delivered to each cell.

Taking into account these parameters, it is correct to assume that the delivered volume should be in the range of femtoliters. However, it is very difficult to theoretically determine this quantitative range. For this reason, it would be preferable if the amount of delivered volume could be determined experimentally.

There is very little information in the literature concerning the measurement of liquid volume delivered to a single cell. Minashek et al. [66] investigated the volume range used during standard microinjection, by injecting a fluorescent TRITC-labeled bovine serum albumin (TRITC-BSA) into adherent 3T3 mammalian cells (obtained from Swiss mouse embryo tissue). After the injections, the fluorescent intensities of the cells were measured with scanning fluorometry. Reported results showed extremely high variations in the delivered liquid quantities to single cells. The liquid amount varied from 1 to 10% of the cell volume.

For the purpose of this thesis, this result was assumed to be true for all types of adherent mammalian cell. This assumption combined with theoretical calculations of the cell volume allows one to calculate the amount of liquid that can be delivered into a cell (Table 3.1). The amount varies from 5 to 400 femto liters.

Table 3.1: Calculations of liquid amount that can be delivered into a single cell. Calculations are based on the results presented by Minashek et al.

Cell diameter [μm]	Cell volume [fL]	Maximal volume of liquid that can be delivered	
		1% of cell volume [fL]	10% of cell volume [fL]
10	500	5	50
20	4000	40	400

Knowing what range of volumes is required and permits an investigation of how to deliver said amounts.

3.2.2 Control of liquid delivery

Delivery of a defined volume into a cell can be performed by controlling the flow of the liquid through the fluidic channel enclosed inside the AFM probe. There are two main methods that can be used to generate a flow inside the channel: application of a pressure differential and application of an external electric field. In the first case, an external pressure is applied to the channel creating a pressure gradient. This pressure gradient causes movement of the liquid through pressure driven flow. In the second case, an electric field is applied to the channel causing movement of the ionized liquid through electroosmotic flow.

However, the electroosmotic flow is limited to polar liquids and is sensitive to contamination of channel surface [67], ionic strength and pH [68]. In addition, fabrication of the AFM probes with fluidic channels and integrated electrodes is technologically more challenging than

3.3. Detailed design of the AFM – based microinjection system

simply fabricating probes with channels and connecting them to a pressure generator. Based on these factors, pressure driven flow was chosen.

The final concept of the cell injection system is based on an AFM probe with a microfluidic channel connected to a pressure generator, where interaction forces between the tip and the cell are controlled by the AFM microscope. When the tip is inserted into the cell, the generator applies a pressure and the liquid is injected. The injected volume is controlled by the value of the applied pressure and the time of the injection (the time of the pressure pulse). Based on this concept, a detailed design of the system and its specifications can be established.

3.3 Detailed design of the AFM – based microinjection system

A detailed design must take all experimental aspects of the AFM-based liquid delivery system into consideration:

1. the AFM tip must access the cell from the top;
2. the AFM tip must be mounted on an AFM holder that will be placed inside the AFM microscope;
3. the fluidic channel inside the AFM probe must be connected to the pressure pulse generator via the AFM holder;
4. the cell must be kept in a cell medium in a controlled atmosphere (temperature and pH); and
5. finding the cell and placing the AFM probe above it can be done only with a phase contrast optical microscope.

Based on these aspects, a detailed design of the system is presented. Figure 3.4 illustrates a schematic of the system.

The AFM probe with the AFM holder is mounted on the AFM microscope. The inlet of the probe channel is connected to an outlet of the holder channel. The holder channel is further connected to the pressure generator via elastic tubing. The probe with its holder is placed inside the Petri dish. The Petri dish is a standard dish made of optically transparent material. The adherent cells are located inside on the bottom surface. The cells are kept in a liquid medium in a controlled temperature. This is done by placing the Petri dish inside a heated support. The cells and the probe are visualized with the inverted phase contrast microscope through the opening in the Petri dish heater.

With this system, delivery of the liquid into the cell can be performed as follows. The probe is placed above the target cell and the AFM microscope is used to insert the tip (with precision) inside the cell in force spectroscopy mode. When penetration of the cell is detected via the

Figure 3.4: Schematic of an AFM-based microinjection system. The system consists of an AFM probe with closed fluidic channel. The fluidic channel is connected via the AFM holder to a pressure pulse generator. The AFM holder with the probe is mounted inside the AFM microscope. The microscope is placed on top of the Petri Dish holder. The Petri Dish contains cell medium and adherent cells. The AFM probe and part of the holder are immersed in the medium. The Petri Dish holder contains a heater that keeps the Petri Dish at required temperature. The cells are observed from the bottom with optical phase contrast microscope through an opening in the Petri Dish heater.

force distance curve, the pressure generator applies a pulse and the liquid is ejected through the aperture in the tip and into the cell. After the liquid is injected, the probe is retracted from the cell to its initial position.

Once the detailed design of the system is completed, it is necessary to investigate fabrication of specific elements. The main elements of the system are:

1. the AFM microscope;
2. the AFM holder with fluidic channels;
3. the AFM probe with fluidic channels – NADIS probe;
4. the pressure pulse generator;
5. the Petri dish heater; and
6. the inverted phase contrast microscope.

Fabrication of an AFM holder with fluidic channels as well as the NADIS probe with an embedded fluidic system require technological development whereas the rest of the elements are commercially available products. An AFM microscope for cell biology with integrated inverted optical microscope and Petri dish heater has existed on the market for more than 10

years [67]. The pressure pulse generator, known as a microinjector is used for liquid injection into cells using glass capillaries (outlined previously in Chapter 1). Taking into consideration these products, fabrication of the AFM-based injection system needs to be focused on the AFM probe with fluidic channel and the compatible AFM holder. In order to fabricate these elements, it is necessary to define the specifications of the system.

3.4 Specifications of the system

The AFM probe containing fluidic channels will have the main influence on the system specifications.

3.4.1 Characteristics of the AFM probe

There are two main parameters that determine the properties of the AFM probe: the cantilever stiffness and its resonance frequency. The stiffness of a cantilever is defined by the spring constant. Assuming that the cantilever beam has a rectangular cross-section, the spring constant c_k can be calculated as follows:

$$c_k = \frac{4EI}{L^3} \quad (3.1)$$

where E is the Young's modulus, I is the moment of inertia and L the cantilever length. For a probe with fluidic channel, the moment of inertia will be different than a standard probe (Figure 3.5). Assuming that the channel has rectangular cross-section, the spring constant can be calculated according to Equation (3.2).

Figure 3.5: Schematic of rectangular cross-sectional view of a) standard probe and b) probe with integrated channel.

$$c_k = \frac{4EI}{L^3} \equiv \frac{EWH^3}{3L^3} \quad (3.2)$$

$$c_k = \frac{4EI}{L^3} \equiv \frac{E}{3L^3}HW^3 - hw^3 \quad (3.3)$$

where E is the Young's modulus, W and H are the width and the height of the cantilever, and w and h are the width and the height of the channel. Based on this equation, the spring constant strongly depends on cantilever length and the relation between the widths and heights of the

Chapter 3. Concept study

cantilever and the channel.

It has been shown that cell indentations with an AFM probe should be performed with a very flexible cantilever (preferably in the range of 10^{-2} N m^{-1}). Thus, geometrical parameters of a cantilever should be adapted to fulfill this requirement. Standard flexible cantilevers have a length in the range of several hundreds of micrometers, the width varies from 10 to 40 micrometers and the height can be as small as 600 nm. The same range of values for length and width can be adopted when designing cantilevers containing fluidic channels. The cantilever height, however, has to be larger due to the presence of the channel. The cantilever height will depend on the channel height and thickness of the cantilever wall. As the height of the channel will have the most influence on the flow of liquid through the cantilever, it is preferable to keep it relatively large. Thus, the channel height and the cantilever height must be adjusted to provide a compromise between cantilever stiffness and liquid flow through the channel. Figure 3.6 shows an example of the spring constant dependency on cantilever length L when the width W and wall thickness $\Delta/2$ are constant and the cantilever height H is changing.

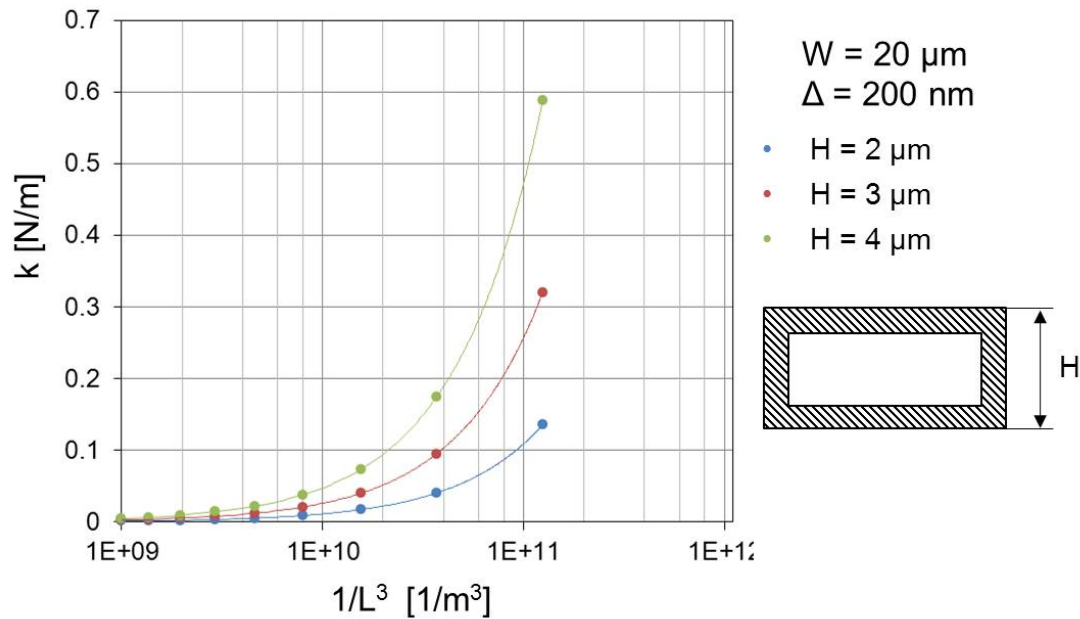

Figure 3.6: Spring constant dependency on the length of a cantilever with defined width and wall thickness $\Delta/2$ for three cantilever heights (and three channel heights consequently).

It can be seen that for the same cantilever length the cantilever stiffness increases when the cantilever height increases (the height of the channel increases).

Once the geometrical values of the cantilever are chosen, it is necessary to determine the influence of the size of the channel embedded in the cantilever on its spring constant. Figure 3.7 shows dependency of the cantilever spring constant on its wall thickness.

In order to obtain soft cantilevers with rectangular channels, the following requirements

Figure 3.7: Spring constant dependency on the length for a cantilever with defined width and height. The height and width of the channel embedded inside the cantilever changes accordingly to the thickness of the cantilever wall defined as $\Delta/2$ parameter.

should be fulfilled: the cantilever should be long, have a small height and its walls should be thin. However, the longer the cantilever and the smaller its height, the higher is the hydraulic resistance of the cantilever channel. Equation (3.4) shows the influence of the cantilever length L , height h and width w of its channel, and wall thickness Δ on the cantilever stiffness, and Equation (3.5) shows the influence of the cantilever length L , and height h and width w of the cantilever channel on its hydraulic resistance R_{hydrop} .

$$\frac{1}{k} \sim \frac{L}{w\Delta h^3} \quad (3.4) \quad R_{hydrop} \sim \frac{Lh^3}{w} \quad (3.5)$$

Therefore, in the final design of the AFM probe, a compromise must be found between the cantilever stiffness and hydraulic resistance of the cantilever channel.

3.4.2 Characteristics of the pressure driven flow in the system

Pressure driven flow through a channel with an arbitrary cross-section is described by the Hagen–Poiseuille law, where the flow changes linearly with the pressure drop:

$$Q = \frac{1}{R_{hyd}} \Delta p \quad (3.6)$$

Chapter 3. Concept study

where Q is the flow, R_{hyd} is a proportionality factor known as hydraulic resistance and Δp is the pressure drop. The hydraulic resistance depends on the geometrical parameters of the channel and viscosity of the flowing liquid.

The investigated AFM-based fluidic system consists of a flexible tubing connected via the channel of the AFM holder to the fluidics of the AFM probe. The fluidic channel inside the probe is further connected to an opening in the tip. Knowing that the cross-section of the channel is rectangular and assuming that the flexible tubing and the AFM holder channels have circular cross-sections, the hydraulic resistance for each fluidic element can be calculated as follows [69] (the presence of fluidic connectors and the tip is neglected):

$$R_{hyd\,cir} = \frac{8}{\pi} \eta L \frac{1}{a^4} \quad (3.7)$$

$$R_{hyd\,rec} = \frac{1}{h^3 w} \cdot \frac{12\eta L}{1 - 0.63h/w} \quad (3.8)$$

where, η is the liquid viscosity, L , h and w or a are channel length, height and width or the radius respectively.

The hydraulic resistance of the entire fluidic system is defined by the sum of hydraulic resistance of the individual elements [70]:

$$R_{hyd} = \sum_i R_{hyd\,i} \quad (3.9)$$

Figure 3.8 presents schematic of the simplified fluidic system. Simple models can be used with this approach to determine values for the geometrical parameters of the fluidic system based on calculated values of the hydraulic resistance.

Figure 3.8: Schematics of a simplified fluidic system of the AFM-based microinjection system. On the left is the detailed view of the cantilever channel connected to the tip opening.

The geometrical values of the system are discussed in Table 3.2.

Based on the given description, the hydraulic resistance of the system can be calculated as a function of liquid viscosity $R_h(\eta)$ Table 3.3. The result shows that the hydraulic resistance of the system is entirely dominated by the AFM probe, thus the hydraulic resistance of the other

3.4. Specifications of the system

Table 3.2: Size description of the fluidic components.

Fluidic component	Description
Flexible tube	As the tube connects the AFM holder with the external pressure generator, the length of the tube will be in range from 50 to 100 centimeters , and the tube radius will be in range of 100 to 200 micrometers .
AFM holder channel	The channel size will depend on the size of the holder; the length will be in millimeters range (5 to 10) , while the channel radius will be in range of 50 to 100 micrometers .
AFM probe channel	The channel length will depend on the length of the cantilever and the length of the channel enclosed in the AFM chip, thus the total channel length will be in millimeters range (1 mm to 2 mm) . The width will be in range of few tens of micrometers (10 μm to 20 μm) , the height smaller than few micrometers (2 μm to 4 μm) .
Tip opening	The opening radius will be in tens to hundreds of nanometers (50 to 150 nm) , due to the volume that has to be delivered into cells. The thickness of the tip wall will be in range of 100 nm to 200 nm .

elements can be neglected.

Table 3.3: Calculated range of values of the hydraulic resistance for each fluidic component and the entire system, given the minimum and maximum size of the system.

System elements	Flexible Tube	Holder channel	Probe channel	Tip opening	Complete system
	L: 50-100cm R: 100-200μm	L: 5-10mm R: 50-100μm	L: 1-2mm R: 50-100μm	L: 100-200nm R: 50-150nm	
Hydraulic resistance $R_s(\eta)$ [1/m ³]	$\eta \cdot (10^{15} - 10^{16})$	$\eta \cdot (10^{14} - 10^{15})$	$\eta \cdot (10^{19} - 10^{20})$	$\eta \cdot (10^{21} - 10^{22})$	$\eta \cdot (10^{21} - 10^{22})$

The calculated hydraulic resistance is expressed as a function of viscosity of the liquid that will be injected into the cells. The injected liquids have to be isotonic (have the same osmotic pressure as the cell) to prevent the cell from bursting. Examples of such liquids are: any cell medium, phosphate buffered saline (PBS) or Hank's Balanced Salt Solution (HBSS). These liquids are aqueous solutions containing salt constituents, hence it can be assumed that their viscosity is similar to the viscosity of water [71] ($\eta = 6.92 \times 10^{-4}$ Pa s at 37 °C[70]). Taking into consideration the liquid viscosity, the total hydraulic resistance of the system will be in the

range of:

$$R_{hyd\,tot} \sim 10^{18} \frac{\text{Pa s}}{\text{m}^3} - 10^{19} \frac{\text{Pa s}}{\text{m}^3} \quad (3.10)$$

for the minimum and maximum size of the system, respectively. Knowing these values, further analysis of the system parameters is possible. For example, the time required to completely fill the system with liquid, the flow of liquid as a function of applied pressure and finally, the volume precision that can be ejected from the tip opening.

3.4.3 Control of volume injected to single cell

In the Section 3.2.1, the range of volumes that can be delivered into single cell was calculated to be from 5 fL to 400 fL. Assuming that the flow of liquid in the system is constant in time and depends linearly on the applied pressure, the length of a pressure pulse for cell injection can be calculated (Table 3.4).

Table 3.4: Values of the pressure pulses applied to the fluidic system for cell injection.

Applied pressure Δp [Pa]	Flow Q [$\text{m}^3 \text{s}^{-1}$]	Ejected volume V [m^3]	Length of the pressure pulse $t = V/Q$ [s]
10^1	10^{-16}	10^{-18}	10^{-2}
10^2	10^{-15}	10^{-18}	10^{-3}

Based on these results, the specifications of the pressure generator can be defined. The generator must be able to produce short pressure pulses on the order of milliseconds and the minimum operating pressure must be in the Pascal range.

3.5 Summary

Design of the AFM-based microinjection system is based on a concept of injecting liquid to cells using an AFM probe with integrated fluidic system – the NADIS probe. The probe has an enclosed fluidic channel connected on one side to a reservoir in the AFM chip, and on the other side to a hollow tip with an aperture. Delivery of liquids through the tip aperture is controlled by the pressure generator, and the tip – cell interactions are controlled by the AFM – microscope. Conceptually, only the NADIS probe and the AFM probe holder with fluidic channels require development whereas the rest of the components are commercially available.

The system is designed in a way to control the volume of the injected liquid via the injection parameters (height of the applied pressure and length of the pressure pulse). To estimate hydraulic resistance of the system a simple model was designed based on the assumptions that the flow of liquid in the system is a steady-state flow described by the Poiseuille law. Based on the estimated values of the hydraulic resistance, theoretical values of the injection parameters

were proposed.

The conceptual description of the AFM based microinjection system presented here is an introduction to a detailed design and fabrication of the NADIS probe and the AFM probe holder and is used as a guide when choosing elements that are commercially available.

4 Design and fabrication of the NADIS probes for a microinjection system

Creating an AFM – based microinjection system starts with the fabrication of the NADIS probes. Originally, the NADIS probes were developed for controlled deposition of droplets on substrates using capillary forces. Initially, the probe had simply a hollow pyramidal tip with an aperture at the tip apex. Later on, a more sophisticated design with a fluidic system embedded inside the probe was developed – the closed NADIS probes. These probes gave a solid foundation to create the AFM–based microinjection system. However, the design of the chip was not suitable for connection to the external fluidics components of the system. Additionally, the design of the probes made it difficult to obtain a controlled liquid delivery. The scope of this thesis was to modify the design of the closed NADIS probes, improve their fabrication process flow and fabricate tip apertures in a way that enabled the tip to penetrate the cell membrane. The first part of this chapter will give a detailed description of the design and the fabrication of the closed NADIS probes. Based on this, the second part of the chapter will give a comparative description introducing the modifications to the design and fabrication process. In addition to this, a new process step was developed and this will be detailed here. The improved fabrication process was done on the wafer scale by the experts at CSEM SA. At the end of the process the wafers were characterized in the scope of this work. To complete the fabrication of the NADIS probes the tip apertures were fabricated. This fabrication step is an important part of this work and thus a large part of this chapter will detail this step. In the final sections, the difficulties and the limitations of the fabrication method will be described in general.

4.1 Introduction

4.1.1 Closed NADIS probes

The closed NADIS probes were developed at CSEM SA. A microfluidic system was embedded inside the chip holder and the cantilever. The chip had an inlet called a ‘reservoir’ connected to the fluidic channels. The fluidic channels protruded from the chip enclosed inside the cantilever. The free end of the cantilever had a tip connected to the channel. A small aperture

Chapter 4. Design and fabrication of the NADIS probes for a microinjection system

was located at the tip apex for liquid deposition (Figure 4.1). Two types of microfluidic system were designed. The type I design contained one fluidic channel connected to an inlet reservoir on one side and the tip on the other (Figure 4.2a)). The type II design had two fluidic channels, each connected on one end to its own reservoir and on the other end to a common tip (Figure 4.2b)).

Figure 4.1: a) Schematic of the NADIS probe. The fluidic system inside the probe is filled with liquid. The free end of the cantilever has a hollow pyramidal tip with a nanometer-scaled aperture at the tip apex. b) Liquid transfer occurs when the tip is brought in contact with a substrate. Due to the capillary forces liquid is transferred from the tip aperture to the surface.

Figure 4.2: Schematic of a) the Type I design, the fluidic system has one inlet reservoir with a channel connected to the tip with an aperture. b) The Type II design has two reservoirs and two fluidic channels connected to the tip.

4.1.2 Fabrication Process

The process flow was designed based on the pre-fabrication of two (100) silicon wafers (Wafer 1 and Wafer 2) and further fabrication of the two wafers bonded together in a thermal fusion bonding process. Figure 4.3 shows the fabrication flow-chart of the principle process steps.

Pre – structuring of Wafer 1:

1a) First, the wafer is thermally oxidized to form silicon dioxide (SiO_2). Next, the top side of the wafer is coated with patterned photoresist. The wafer is then etched by reactive ion etching (RIE) to remove the unprotected SiO_2 . After which the wafer is etched with potassium hydroxide (KOH) and a pyramid is formed in the areas where the SiO_2 was removed. In the next step the wafer is etched in buffered hydrofluoric acid solution (BHF) to remove the rest of the SiO_2 . Finally, the wafer is thermally oxidized to create uniformly thick SiO_2 film.

1b) First, a low –stress LPCVD silicon nitride (Si_xN_y) is deposited. Next, the top side of the wafer is coated with patterned resist and etched by RIE to remove the unprotected Si_xN_y layer.

Figure 4.3: Graphical representation of the main steps of pre-structuring Wafer 1 and Wafer 2 and final processing of the sandwiched wafers.

In this way the silicon nitride probe tip is fabricated.

1c) The bottom side of the wafer is coated with resist, patterned and etched by RIE to remove unprotected Si_xN_y layer. Next, the wafer is etched in BHF to remove the rest of the SiO_2 .

1d) Final step of the pre- structuring of the wafer starts from coating the top side of the wafer with a resist and etching fluidic channels. Once, the channels are etched by RIE the wafer is ready to be bonded with Wafer 2.

Pre-structuring of Wafer 2:

2a) First, the wafer is thermally oxidized to form SiO_2 and a low-stress LPCVD Si_xN_y is deposited. In the next step, the top side of the wafer is coated with patterned resist and etched by RIE. Then the wafer is etched in BHF solution to remove the remainder of the SiO_2 layer. Finally, the wafer is exposed to KOH and is etched through to form the future reservoirs.

Thermal fusion bonding and further structuring:

a) The Wafer 1 and 2 are cleaned and prepared for the bonding process. The top side of Wafer 1 is brought in contact with bottom side of Wafer 2 and thermal fusion bonded. The wafer

Chapter 4. Design and fabrication of the NADIS probes for a microinjection system

sandwich is further thermally oxidized to obtain 1.2 microns of silicon dioxide.

b) The top side of the wafer sandwich is coated with patterned resist and etched by RIE to remove the unprotected SiO_2 .

c) In the last process step the sandwich is etched by KOH solution in order to remove the unprotected silicon and create chips with free standing cantilevers. After the etching step the wafers is rinsed and dried.

4.1.3 Design of the NADIS probes

The geometry of the NADIS probes was determined by the geometry of the fluidic system and by the constraints of the process flow. For reason of compatibility the AFM chip was designed to be similar to commercially available chips. The chips had a rectangular geometry with a width (W) of $1400\ \mu\text{m}$, length (L) of $3800\ \mu\text{m}$ and height (H) of $450\ \mu\text{m}$. A single chip has 4 reservoirs and 2 or 4 probes. Figure 4.4 shows schematic drawings of the chips including the geometrical parameters. Around each chip a thin rim (V-groove) was designed to ease the removal of the chip from the wafer. The Type A chip with only 2 probes had one probe on each side (Figure 4.4a)), the Type B chip with 4 probes had two probes per side (Figure 4.4b)).

Figure 4.4: Schematic of a) Type A chip with marked geometrical parameters. The values are as follows: $W = 1400\ \mu\text{m}$; $L = 3800\ \mu\text{m}$; $a = 64\ \mu\text{m}$; $b = 582\ \mu\text{m}$; $c = 278\ \mu\text{m}$; $d = 298\ \mu\text{m}$. Around the chip is a thin rim called the V-groove. It was designed (dotted line) to easily remove the chip from the wafer. The chip has one cantilever on each side. Each cantilever has two fluidic channels connected to their own reservoirs. b) The Type B chip has two cantilevers per side. On one side one of the cantilevers has two channels connected to two reservoirs. One of the two reservoirs is shared with the second cantilever with a single channel. On the other side of the chip there are two cantilevers, each having two fluidic channels connected to the same pair of reservoirs.

4.1.3.1 Design of the AFM probe and fluidic channels

An AFM probe consisted of a cantilever and a tip. The design of the cantilever is extremely important as it defines the stiffness of the probe. The NADIS cantilevers had fluidic channels embedded inside their beams. Figure 4.5a) presents a single beam cantilever and Figure 4.5b)-d) show a double beam cantilever with two fluidic channels, each embedded inside one of the beams.

Figure 4.5: Schematic of a single beam cantilever a); parallel double beam cantilever b); oblique parallel beam cantilever c) and V-shape cantilever d). Figure e) shows cross-sectional view of the cantilever beam with fluidic channel. Figure f) presents cross-sectional view of the cantilever connected to the reservoir.

Four probe types were designed, one type of the single beam straight cantilever (Figure 4.5a), and three types of the two beam cantilever: the parallel cantilever (Figure 4.5b), the oblique parallel cantilever (Figure 4.5c) and the V-shape cantilever (Figure 4.5d).

Figure 4.5e) shows a cross-sectional view of a single beam. The width (w_1) and the height (h_1) of the beam were determined by the width (w_2) and the height (h_2) of the fluidic channel and the thickness of silicon oxide created by thermal oxidation. The width was controlled by the etching mask while the height was determined by the etch time in step 1d). The free length of the cantilever (Figure 4.5f)) was defined as the sum of: A - the distance from the free end of the cantilever to the apex of the tip; B - the designed length, which is the distance from the apex to the V-groove; C - the distance from the V-groove to the fixed end of the cantilever. The distances A and B were determined by the design of the photolithographic masks, whereas the distance C depended on the etching time (etching done in the microfabrication step c)). Three cantilever free lengths were investigated: short, medium and long. Table 4.1 contains the values of the free length for each of the three types.

Table 4.1: Values of the free length of the cantilevers.

Cantilever length	Length of the distances			Free length of the cantilever [μm]
	A [μm]	B [μm]	C [μm]	
short	15	50	50-100	115-215
medium	15	300	50-100	365-465
long	15	500	50-100	565-765

4.1.4 Fabrication Results

Figure 4.6 presents optical micrographs of the fabricated probes. The short cantilevers (single straight probe and the double straight probe) had a released free length in the range from 120 μm to 250 μm . The medium and long cantilevers (the parallel oblique and the V-shaped) had a released free length in the range from 350 μm to 450 μm and 500 μm to 700 μm respectively.

Figure 4.6: Optical micrographs of a single beam a); parallel double beam b) oblique double beam c) and V-shape d) cantilever.

The size of the tip, a square based pyramid, was approximately 11 μm . The radius of the tip apex varied from 25 nm to 50 nm. Two main problems were encountered during the fabrication process: breakage of the cantilevers and contamination of the fluidic channels.

Breakage of the cantilevers occurred during the drying process, when part of the liquid was trapped between the free standing cantilevers and the surface of the wafer. Cantilevers longer than 300 μm were bent towards the wafer due to the capillary forces. The bending effect resulted in the cantilever deflection of about 50 μm and caused the probe to snap. Comparison between the double beam oblique and the V-shaped cantilevers showed that the first type is less prone to breakage.

The contamination of the fluidic channels occurred during the last processing step, when the wafer sandwich was exposed to the KOH etch bath. During this step the KOH could enter inside the fluidic channels and stay inside. After the KOH etch the wafer sandwich was immersed in 5% hydrochloric acid (HCl) to neutralize the KOH residues. During this step the HCl also entered the fluidic channels and reacted with KOH to create potassium chloride (KCl). In the last step the sandwich was rinsed in water to remove the residues. However, the rinsing was ineffective. After drying, some of the fluidic channels were blocked with KCl salt and could not be used. Figure 4.7a) presents an optical micrograph of a cantilever with single channel without residues. Figure 4.7b) shows a double beam cantilever with one channel blocked by the KCl salt. This cantilever could not be used for liquid deposition.

Figure 4.7: Optical micrograph of double beam cantilever with a) clean channel; b) one channel contaminated with KCl residues (marked with arrows).

4.1.5 Metallization of the AFM probes

Metallization of the AFM probes was required for two reasons: firstly, for the detection system of the AFM microscope and secondly for the fabrication of the tip aperture. The AFM microscope used in the experiments measures the deflection of the cantilever by detecting the reflection of an IR laser from the cantilever. However, the closed NADIS probes are made of silicon dioxide which is transparent for infrared light [72]. For this reason, they need to have a reflective coating.

The fabrication of the tip aperture is done with focused, gallium (Ga^+) ion beam (FIB) milling. Since the NADIS probe is made of nonconductive materials (silicon dioxide cantilever and a silicon nitride tip) charging effects occur during milling: during the interaction of the ion beam with the substrate a large number of electrons leaves the sample surface and a net positive charge builds up. This charge causes movement of the sample during the milling process. A conductive, metal coating of the probes prevents charging effects.

The probes were coated with thermally evaporated gold, which gives excellent (98 % to 99 %) reflectivity throughout the infrared [73]. A thin layer of chromium was used as an intermediate layer. The thickness of chromium was approximately 11 nm and that of gold 45 nm to 50 nm. The probes were coated from the front side (where the tip is) for milling and from the back to enhance reflectivity. Unfortunately, the gold was rapidly removed by FIB imaging being necessary to adjust the ion beam and tip position for milling. To avoid these effects the AFM tips were protected with an additional sputtered carbon layer.

4.1.6 Fabrication of the tip aperture

The complete fabrication of the NADIS probe ends when the tip has an aperture. Figure 4.8 shows schematic drawing of the NADIS probe with aperture. The aperture was located at the tip apex to use the capillary forces to transfer the liquid from the tip.

Fabrication of the aperture was performed on a single chip level using focused ion beam milling. The FIB milling was carried out with an FEI Nova 600 NanoLab-DualBeam system. A single AFM chip was removed from a wafer, metalized and placed on a holder (Figure 4.9a). AFM chips were fixed with conductive tape so the tip pointed upwards. The holder was

Figure 4.8: a) A cross sectional view of the NADIS probe with an aperture located at the tip apex. The deposition of the molecules occurs via the aperture. The top view b) and the side view c) of the NADIS tip with an opening.

mounted on the FIB stage and tilted to 52° so that the ion beam was perpendicular to the base of the tip. In this configuration apertures were milled from the top of the pyramid. Two types of apertures were fabricated: a square one (Figure 4.9b) and c)), with a size of $1\ \mu\text{m} \times 1\ \mu\text{m}$ and circular one (Figure 4.9d) and e)) with a diameter from 100 nm to 500 nm.

Figure 4.9: a) Schematic of the FIB holder fabricated to mill NADIS apertures. SEM micrographs of the square shape aperture, b) view from the top and c) the side. SEM micrographs of the circular shape aperture, d) view from the top and e) the side.

4.1.7 Summary

The fabrication process of the closed NADIS probes consisted of two main steps: microfabrication on a wafer scale of the silicon AFM chip with a silicon oxide cantilever and silicon nitride tip, and fabrication of tip apertures on a single chip level using FIB techniques. Two main problems were encountered during the fabrication process – breakage of the cantilevers and contamination of the fluidic channels with KCl.

4.2 Design and fabrication of NADIS probes for the cell microinjection system

The closed NADIS probes with integrated microfluidic channels gave a solid foundation on which to develop NADIS probes for microinjection. This part of the chapter concerns the work that was done in the scope of the thesis and describes the modifications and innovations introduced to the design and fabrication of the NADIS probes. Modifications to the chip and

4.2. Design and fabrication of NADIS probes for the cell microinjection system

cantilever design, the process flow and the tip aperture were carried out in order to:

- facilitate connection to an external fluidic system;
- reduce breaking and blocking of the cantilevers during fabrication;
- facilitate cell penetration and injection by the AFM tip

4.2.1 Design of the AFM chip

Several modifications were made to the design of the closed NADIS chips. In order to create a good watertight connection between the NADIS chip and the AFM holder, a chip with a large contact area was designed. This was done by increasing the size of the chip and reducing the number of reservoirs from 4 to 2. The on-chip fluidics system was also simplified by reducing the number of cantilevers per chip to a maximum of two. In previous designs two fluidic channels, each belonging to a different probe, were connected to the same reservoir. This meant that a pressure pulse on one reservoir would result in ejection of liquid from both cantilevers. In the new design each probe had its own reservoir. Two different types of chips were designed. The type A chip had two single beam cantilevers (Figure 4.10a)) and the type B (Figure 4.10c)) had one double beam cantilever. Figure 4.10 shows schematic drawings of the resulting NADIS chip with their geometrical parameters.

The design of the AFM probes was based on the previous NADIS design and the results of its fabrication process. The results revealed that the oblique shape of the cantilevers is easier to release. In the present design three types of probes were proposed: single beam straight cantilever (Figure 4.11a)), single beam oblique cantilever (Figure 4.11b)) and double beam oblique cantilever (Figure 4.11c)).

Figure 4.11d) shows a cross-section of the cantilever beam. As in the previous design the width (w_1) and the height (h_1) of the beam were determined by the width (w_2) and the height (h_2) of the fluidic channel and the thickness of the SiO_2 layer. The width was controlled by the etch mask and the height was determined by the etch time of the entire wafer and was uniform for all the designs. Table 4.2 contains the height and width values for the different cantilever designs.

Table 4.2: The widths and heights of channels and beam depending on the design

Type of the probe	width of the channel w_2 [μm]	width of the probe w_1 [μm]	height of the channel h_2 [μm]	height of the channel h_1 [μm]
Single beam straight	18.2	20.6	1.4	3.8
Single beam oblique	18.2	20.6	1.4	3.8
Double beam oblique	8.2	10.6	1.4	3.8

Figure 4.10: Schematics of a) the Type A chip with marked geometrical parameters. The values of the parameters are as follows: $W = 2300\mu\text{m}$; $L = 3800\mu\text{m}$; $a = 709\mu\text{m}$; $b = 582\mu\text{m}$; $c = 718\mu\text{m}$. Around the chip a thin rim called the V-groove was designed (dotted line) to easily remove the chip from the wafer. The chip has one cantilever on each side. Each cantilever has a single fluidic channel connected to its own reservoir. Figure b) shows a cross-section of the type A probe. The type B chip c) has one double beam cantilever. The cantilever has two channels, each connected to independent reservoirs.

The free length of the cantilever (Figure 4.11e) was defined according to the previous design as the sum of: A - the distance from the free end of the cantilever to the apex of the tip; B - the designed length, which is the distance from the apex to the V-groove; C - the distance from the V-groove to the fixed end of the cantilever (C). The distances A and B were determined by the design of the photolithographic masks, whereas distance C depended on the etch time of the KOH release step.

The free length of the cantilever was determined by the desired spring constant. The desired value of the spring constant was calculated to be in the range between 0.3 N m^{-1} to 3 N m^{-1} , due the height of the cantilever channel. To fabricate probes with a low spring constant values (below 1 N m^{-1} the free length of the cantilevers has to be in the range of a few hundreds of micrometres. However, fabrication results for the closed NADIS probes showed that cantilevers longer than $300\mu\text{m}$ are difficult to obtain. Given this limitation three types of the free length were proposed: short (from $115\mu\text{m}$ to $215\mu\text{m}$; $k = 14.8\text{ N m}^{-1}$ to 2.1 N m^{-1} respectively), medium (from $215\mu\text{m}$ to $315\mu\text{m}$; $k = 2.1\text{ N m}^{-1}$ to 0.66 N m^{-1}) and long (from $365\mu\text{m}$ to $465\mu\text{m}$; $k = 0.42\text{ N m}^{-1}$ to 0.2 N m^{-1}). Table 4.3 contains details of the free length parameters for each type.

4.2. Design and fabrication of NADIS probes for the cell microinjection system

Figure 4.11: Schematic of a) the single beam straight cantilever; b) the single beam oblique cantilever; c) double beam oblique cantilever. Figure d) shows a cross-sectional view of the cantilever beam with fluidic channel. Figure e) presents the cross-section of the cantilever connected to the reservoir.

Table 4.3: Detailed summary of the free length for different cantilever design

Type of the probe	Type	A [μm]	B [μm]	C [μm]
Single beam straight	short	15	50	50-150
Single beam oblique	medium	15	150	50-150
Single beam oblique	long	15	300	50-150
Double beam oblique	medium	15	150	50-150

4.2.2 Modification of the process flow

The microfabrication process was adapted from the fabrication of the closed NADIS probes. Two modifications were introduced to the process. The first modification concerned the drying of the wafers after the final KOH etching step. The standard drying was replaced with a critical point drying step. This step was out of the scope of this thesis and therefore will not be described here in detail. The modification was introduced to eliminate the breakage of the cantilevers with a free length longer than 300 μm . The breakage problem arose from the capillary forces between the cantilevers released in KOH and remaining liquid on the wafer. The issue was overcome by keeping the devices constantly in the liquid and using the supercritical point drying technique: after release in KOH the wafers were quickly transferred to the water bath which was then gradually replaced by ethanol; once in ethanol the wafer were placed in supercritical drying machines for a controlled liquid removal. High pressure and sufficiently high temperature of supercritical point dryers allow devices to bypass the liquid-gas boundary i.e. to go from liquid phase to gas phase through so called supercritical fluid where capillary forces are not so strong. The second modification was dedicated to solve the problem of blockage of the cantilevers due to KCl residues inside fluidic channels. To solve the problem of KCl residues two methods were developed in parallel: an extensive rinsing of the wafer under vacuum after the final release step (not in the scope of this thesis) and a 3D parylene mask to prevent entry of the etch liquid into the fluidics channels during the KOH processes. The second method was developed in the frame of the thesis and will be

Chapter 4. Design and fabrication of the NADIS probes for a microinjection system

described in detail in the next section. Even though both process worked well, for the final microfabrication process the extensive rinsing method was chosen as it involved less change to the process flow.

4.2.3 3D parylene mask for KOH etching of NADIS probes

Poly-(p-xylylene) polymers, also known as Parylenes have been used in microfabrication processes as a sacrificial layer or mask [74]. To solve the problem of KCl residues in the fabrication process, experiments were conducted to develop a protective coating against KOH using Parylene C. The goal was to develop a mask that can prevent the KOH from entering into the fluidic channels of the probes, and after the etching step can be easily removed. This would involve additional steps in the microfabrication process. Figure 4.12 shows the process-flow chart with the additional steps.

Figure 4.12: Graphical representation of the main steps of pre-structuring Wafer 1 and Wafer 2 and final processing of the sandwiched wafers.

The pre – structuring of Wafer 1 and Wafer 2 did not require any modifications.

4.2. Design and fabrication of NADIS probes for the cell microinjection system

Thermal fusion bonding and further structuring of the wafer sandwich (wafer 1+2):

- a) The Wafer 1 and 2 are cleaned and prepared for the bonding process. The top side of Wafer 1 is brought in contact with bottom side of Wafer 2 and thermal fusion bonded. The wafer sandwich is then thermally oxidized.
- b) The top side of the wafer sandwich is coated with resist, patterned and etched by RIE to remove the unprotected SiO_2 . The bottom part is coated with Parylene C to close the channel inlets.
- c) The sandwich is etched by KOH solution to remove the unprotected silicon and create chips with free standing cantilevers.
- d) The Parylene C is removed by RIE and thermal treatment from the wafer and capillaries.

The concept of using Parylene C mask had one major shortcoming: Parylene C adheres poorly to surfaces and delaminates when exposed to liquid environments [74–78]. Many attempts have been made to improve its adhesion [75, 77–82] however none of them seemed sufficient to prevent delamination.

In order to use the Parylene C as a KOH mask in the NADIS microfabrication process it was first necessary to improve the polymer adhesion to silicon, silicon nitride and silicon dioxide substrates. Methods to improve Parylene C adhesion to these substrates were studied to develop a technique that provides the best adhesion between the parylene and the substrates.

During the wet etching step, wafers with NADIS probes are immersed in a KOH bath for 25h. In the first 20h the wafers are kept in chucks to protect the backside of the wafers from etching and at the same time from KOH filling the fluidic channels of the probes. The last 5h is continued without the chuck, resulting in KCl residues in the fluidic channels. In order to make the 3D parylene mask successful, the polymer has to well adhere to the wafers during the KOH etch step for a minimum of 5h.

4.2.3.1 Parylene adhesion study¹

For the present study, the use of a silane as an adhesion promoter was investigated separately and in combination with a thermal treatment (recrystallization) of Parylene C layer on native silicon wafers, and on silicon wafers coated with silicon dioxide and silicon nitride films. Table 4.4 shows a summary of tested conditions.

Adhesion promotion of parylene C with pre-silanization was tested with 3-methacryl-oxypropyl-trimethoxy-silane, also known as Silquest A-174®. Its molecules form a covalent bond with hydroxyl groups on the silicon-based surface on one side and with the paraxylylene radicals on the other side. The pre-silanization was a vacuum deposition process preceded

¹“Optimizing Parylene – C for MEMS processes.” Jérôme Charmet, Joanna Bitterli, Olha Sereda, Martha Liley, Philippe Renaud, Herbert Keppner; submitted to JMEMS.

Table 4.4: Parylene C adhesion study: summary of tested conditions.

Tested conditions
1 no adhesion promotion – a reference method
2 Pre-silanization of substrates to promote parylene C adhesion
3 Post-thermal treatment (recrystallization) of parylene C deposited on the substrates
4 Combination of pre-silanization of substrates and recrystallization of parylene film

by surface activation of the substrates with air plasma. Post-thermal treatment of parylene C films was done in an oven at 350°C for 2h, under a nitrogen atmosphere at atmospheric pressure.

The samples were further exposed to 5 and 25h of KOH to test the adhesion properties of parylene. Exposed to KOH samples together with control samples were further characterized with following methods: optical characterization, XRD measurements, AFM characterization and scratch test.

Parylene on wafers prepared according to condition 1 (no adhesion promotion) and 2 (pre-silanization only) has completely delaminated from the substrates. The samples treated according to condition 3 (recrystallization) were stable after 5 hours in KOH irrespective of the substrate, but the samples exposed to KOH for 25h were dependent on the substrate material. The silicon dioxide sample showed minor delamination (up to 3 mm) in a few areas around the rim, while a more widespread delamination could be observed on the silicon sample. The layer on the silicon nitride was completely delaminated. The samples treated according to condition 4, combining both the silanization and the thermal treatment, have shown an overall improvement for the 25 hours exposure for both the silicon and silicon dioxide substrates. In the latter case, no delamination was observed. This observation can be explained by the fact that there is a higher density of Si-OH surface bonds on that surface and hence a higher density of silane molecules. This seems to be confirmed as the layer on the silicon nitride substrate once again was completely delaminated.

The XRD measurements² were used to understand the influence of the different treatment conditions (see Table 4.4) on crystalline properties of the parylene.

It is well known that the parylene polymer phase consists of crystalline and amorphous domains (in semi-crystalline polymers) [83]. XRD diffraction patterns of the parylene films show a broad peak at about 13.8° (d-spacing= 6.41 Å) in 2θ for both condition 1 (non-treated) and condition 2 (pre-silanization). This peak corresponds to the (020) diffraction plane of the monoclinic unit cell with dimensions: $a = 5.96\text{Å}$, $b = 12.69\text{Å}$, $c = 6.66\text{Å}$, $\beta = 135.2^\circ$ [84]. The typical crystallite sizes, calculated using the Scherrer equation, were 8 nm for generic Parylene grown on each substrate and did not change with the silanization (condition 2). After annealing (condition 4) the (020) reflection shifts to 14.09° in 2θ resulting in a larger crystallites

²Work performed by Dr. Olha Sereda from the XRD group, CSEM, Switzerland.

4.2. Design and fabrication of NADIS probes for the cell microinjection system

with smaller inter-planar d-spacing (6.28 Å) yielding a smaller full width half max (FWHM). The crystallite size increased to 40 nm, 47 nm and 45 nm for the silicon, silicon oxide and silicon nitride substrates respectively. The thermal treatment outcomes with more pronounced amorphous part (Figure 4.13) as expected when heating Parylene C above its melting point, regardless of the cooling rate [83]. The samples treated according to condition 4 and immersed in KOH for 5 hours, show a neat diffractogram with the complete disappearance of the amorphous part. It is indeed known that a solvent can swell the Parylene layer and increase the mobility of polymer chains which, as a consequence, can lead to a higher crystallinity of the Parylene.

Figure 4.13: Diffraction patterns (under $2\omega/\theta$ geometry) of Parylene films on a silicon nitride substrate for condition 1 (black curve), condition 2 (red curve), condition 4 (green curve) and condition 4 after 5 hours in KOH (blue curve).

The above evidences show that KOH swells the recrystallized Parylene layer and changes its morphology. One expects such swelling to be even more pronounced on a non-recrystallized, less dense, Parylene layer. This swelling could induce additional stress at the interface which probably plays a role in the delamination of the layer. The recrystallization evidences pointed by the XRD were also investigated with optical and AFM microscopes. Figure 4.14 shows optical and AFM micrographs of Parylene layer before and after thermal treatment. The non-treated Parylene film has a smooth surface with a roughness of approximately 10nm (measured on a $10\mu\text{m} \times 10\mu\text{m}$ area). The recrystallization induces changes in morphology of the Parylene. The treated polymer films consist of large domains that can be easily detected with optical microscope. Size of a domain varies from $20\mu\text{m}$ to $500\mu\text{m}$. Detailed imaging of a single domain with an AFM shows fiber like structures. The length of the fibers varies from 200 to more than 1000nm. The diameter of the fibers varies from 30 nm to 40 nm. AFM

Chapter 4. Design and fabrication of the NADIS probes for a microinjection system

measurements of the Parylene films after exposure to 5h KOH showed no change in the morphology of the Parylene surface. However exposure to the 25h KOH had influence on the thickness of the fibers. The fiber diameter decreases to less than 30 nm. Those results corroborate the XRD measurements.

Figure 4.14: Images showing non treated (condition 1) and recrystallized (condition 3) Parylene layers on the left (images a, c and e) and right column (images b, d and f) respectively. Images a) and b) show an optical image. Images c) and d) are AFM images on a $100\ \mu\text{m} \times 100\ \mu\text{m}$ scan area and images e) and f) are AFM images on a $1\ \mu\text{m} \times 1\ \mu\text{m}$ scan area. The images reveal that the recrystallization changes the morphology of the polymer. The AFM images reveal a fiber like structure that cluster into domains whose size vary between $20\ \mu\text{m}$ to $500\ \mu\text{m}$ (AFM and optical microscopy).

The scratch tests³ were used to compare the adhesion of our layers. Figure 4.15 shows the average rupture load values for each sample. The rupture load corresponds to the load at the time of the film rupture (when the acoustic signal reaches an abrupt peak). The scratch tests were used to compare the adhesion of our layers. As mentioned in Section 2.3.2, those values should not be regarded as absolute as the scratch test method is designed for measuring the adhesion of a hard coating on a softer substrate. They give however comparative information between the different samples and conditions. The rupture load values are comparable on each substrate for identical conditions. However, one can clearly see that the thermal

³Work was done by group of Prof Herbert Keppner, HE-ARC, Switzerland

4.2. Design and fabrication of NADIS probes for the cell microinjection system

treatment (condition 3 and 4) leads to a higher rupture load of the Parylene layer on all substrates. It seems also that the KOH treatment, be it 5 or 25 hours, do not change the rupture load significantly.

Figure 4.15: Graphs showing the rupture load for samples treated according to conditions 1-4 and on samples treated according to condition 4 after 5 or 25 hours KOH exposure. The height of the bar represents the average value of the rupture load and the error bars represent the maximum and minimum values measured (taken on 3 or 4 samples).

The images of the indentation give also invaluable information about the various treatments and complement the information obtained by the rupture load. From those pictures, we can define two distinct parameters that give information about a) the mechanical properties of the layer (i.e. internal cohesion forces) and b) the adhesion between Parylene and the substrate (i.e. interfacial adhesion forces). Figure 4.16 shows the beginning and the end of the indentation for a Si_3N_4 substrate treated according to all 4 conditions. The silanization increases the interfacial adhesion force (i.e. the adhesion between the layer and the substrate). It can be seen by the smaller delamination area of Figure 4.16b) (condition 2), compared to Figure 4.16a) (condition 1) while the thermal treatment increases both the internal cohesion forces (i.e. the internal forces of the layer due to a higher crystallinity) and the interfacial adhesion force. On Figure 4.16c) one cannot see delamination outside of the indentation area whereas it is the case for condition 1 (Figure 4.16a)) Therefore, comparatively, the adhesion has improved with the thermal treatment. In addition, unlike condition 2 (Figure 4.16b)) where the silanisation has improved the adhesion also, the Parylene layer is not torn apart, but ripples at the end of the indentation. This confirms that the mechanical properties of the layer were improved by the treatment. The combination of the silanization with the thermal treatment improves both the interfacial and internal cohesion forces as can be seen on Figure 4.16d).

Based on the XRD measurement, AFM characterization and scratch test, it can be concluded that the thermal treatment is the main factor preventing the delamination of the Parylene

Figure 4.16: Images of the position of the rupture load (top) and the end (bottom) of the imprints after a scratch test measurement on a Si_3N_4 sample. a) shows the imprints for condition 1, b) condition 2, c) condition 3 and c) conditions 4.

layer exposed to KOH. The thermal treatment enables to densify the layer so as to prevent the KOH from penetrating through the layer for at least 5 hours. However for longer exposure time, as suggested by the XRD and AFM data, the morphology of the film changes which indicates a swelling and a penetration of KOH through the layer. The combination of the thermal treatment with the silanization (condition 4) improves the adhesion of the layer and delays the delamination. As a result parylene treated according to condition 4 can be used as a mask for KOH etching.

4.2.3.2 Testing of the 3D mask

The final test was dedicated to prevent KOH from entering into microfluidic channels during 5h of wet etching. Figure 4.17 shows an example of a channel at different process steps. Figure 4.17a) shows channel after Parylene deposition and treatment according to condition 4. The detailed view of the inlet shows that Parylene has entered and blocked the entrance. Figure 4.17b) shows a channel after 5h hours in KOH. It can be seen that the Parylene has prevented the KOH from entering inside the channel. Analysis of all the tested channels showed that 96% of them were still protected from the KOH.

After the KOH etching and analysis of the channel an assessment was made to remove the Parylene from the sample. Since Parylene is extremely resistant to most chemicals, an O_2

4.2. Design and fabrication of NADIS probes for the cell microinjection system

Figure 4.17: Optical images and details (inset) of a microfluidics channel (height $1.2 \mu\text{m}$) seen through the transparent Pyrex slide. Image a) shows a channel after Parylene deposition and recrystallization. We can clearly see that Parylene has entered approximately $200 \mu\text{m}$ into the channel and is still here, unaffected after 5 hours KOH exposure (image b).

plasma was used to etch the mask. However, improved properties of the Parylene mask made it harder to remove the polymer with an O_2 plasma during 90 minutes at 500 W and base pressure of 0.7 mbar. Figure 4.18a) shows inlet of the channel with small residues. Additional exposure to O_2 plasma for 150 minutes has not enabled the complete removal of Parylene residues in the channels. To remove the residues a thermal oxidation was used. It has been shown [85] that thermal oxidation of Parylene leads to chain scission. Therefore a thermal treatment at 700°C during 2 hours (in an air atmosphere) was performed. This treatment enabled to remove all residues from inside the channel as can be seen in Figure 4.18b). The probable chain scission of Parylene by thermal oxidation has probably lead to formation of CO_2 or other volatile chains that escaped from the channels.

Figure 4.18: Images showing residues after first attempt to remove the Parylene mask with and Oxygen plasma treatment (a). Image b) shows the same channel after a heat treatment that has removed all the residues.

Presented results of the KOH etching of channels protected with Parylene allow to conclude

that Parylene treated according to condition 4 can be used as a 3D mask to effectively block the entrance of a microchannels. It has been also shown that it is possible to remove the Parylene afterwards without affecting the microchannels.

4.2.4 Microfabrication results

Once the final microfabrication process was completed, the NADIS probes were characterized with optical and scanning electron microscopes. Figure 4.19 shows optical micrographs of the single and double beam probes. The 'short' cantilevers (Figure 4.19a)) had a free length in the range from 120 μm to 140 μm . The 'medium', single beam cantilevers (Figure 4.19b)) had a free length in the range from 150 μm to 180 μm , whereas free length of the 'medium' double beam cantilevers varied from 220 μm to 320 μm . The difference in the release length is due to the geometry of the design. The 'long' cantilevers (Figure 4.19c)) had a free length from 350 μm to 400 μm . Modification of the fabrication process with critical point drying decreased the cantilever breakage. However, detailed investigations of the long cantilevers with SEM revealed small cracks which could cause leakage during the microinjection experiments, and therefore it was decided not to use them. The extensive rinsing used to eliminate the amount of KCl residues reduced the number of probes with blocked channels. In total, the modifications of the microfabrication process decreased the number of broken cantilevers to 8% and the probes with blocked channels to 5%.

Figure 4.19: Optical micrograph of a) the short, single beam straight cantilever; b) the medium, single beam oblique cantilever; c) the long, single beam oblique cantilever; d) the medium, double beam cantilever.

Figure 4.20 shows SEM micrographs of a NADIS probe. The shape of the tip, the square based pyramid (Figure 4.20a)) was determined by the KOH etching of the (100) silicon wafer. The height of the tip was approximately 11 μm . The radius of the tip apex varied from 25 nm to 50 nm. The cross-sectional view of the tip (Figure 4.20b)) shows its hollow core that is connected to the fluidic channel.

Figure 4.20c) and d) show cross sectional views of a single and double beam cantilever respec-

4.2. Design and fabrication of NADIS probes for the cell microinjection system

Figure 4.20: SEM micrograph presenting a) top view of the free end of the cantilever with the tip; b) the cross sectional view of the hollow tip connected to the channel; c) the cross sectional view of the single beam cantilever; d) the cross sectional view of the double beam cantilever.

tively. The width of the single beam cantilever was $20.6\ \mu\text{m}$; the width of the fluidic channels was $18.2\ \mu\text{m}$. The double beam cantilever had a beam width of $10.6\ \mu\text{m}$ and a channel width of $8.2\ \mu\text{m}$ respectively. The values of the beam and the channel width were varied between 5 % to 10 % across the wafer for both types of probes due to inhomogeneous thermal oxidation. The height of the probe and the channel depended strongly on the RIE etching process step. The etching was uneven and therefore resulted in many different heights across the wafer. The expected height of the channel and the beam was $1.4\ \mu\text{m}$ and $3.8\ \mu\text{m}$ respectively. The fabricated height of the channel varied from $2\ \mu\text{m}$ to $3.2\ \mu\text{m}$ and the beam height varied from $4.4\ \mu\text{m}$ to $5.6\ \mu\text{m}$.

4.2.5 Metallization of the AFM probes

Initially, the probes were coated with subsequent layers of chromium, gold and carbon. However, the coating required several process steps and therefore was not very practical. To simplify the metallization process the probes were coated with platinum. Platinum thin films on glass are known to have good reflectance⁸⁷ and in our case did not require chromium to promote adhesion. Deposition was made in a simple sputtering process, which was shorter than gold evaporation. The platinum thickness was approximately $47\ \text{nm}$, similar to the gold thickness. Platinum has higher density than gold - $21\ 450\ \text{kg m}^{-3}$, while gold's density

Chapter 4. Design and fabrication of the NADIS probes for a microinjection system

is 19300 kg m^{-3} . This makes the platinum more resistant during imaging with the ion beam and during the milling process; hence the protective carbon layer was no longer needed. A comparison of the two metallization processes is presented in Table 4.5. Figure 4.21 shows SEM micrographs of AFM tips coated with gold and platinum after the milling process. The surface of the tip coated with platinum is rougher than the tip coated with gold due to the larger platinum grains.

Table 4.5: A comparison of two metallization processes.

	Gold (Au)	Platinum (Pt)
Coating method	thermal evaporation	sputtering
Adhesion promotion layer	Chromium (Cr)	-
Film protective layer	Carbon (C) - sputtered	-
Thickness	45 nm Au + 5 nm Cr	47 nm Pt
Reflectance	excellent	good

4.2.6 Fabrication of the tip aperture

The closed NADIS tips described in Section 4.1.1 had a simple circular and square aperture located at the tip apex for the deposition of liquid on a surface by capillarity. Three further tip apertures were developed for single cell manipulation: a needle-like aperture (Figure 4.22b)) and two flat apertures, square shaped (Figure 4.22c)) and titled trapezoidal (Figure 4.22d)) apertures.

A needle-like aperture was produced for cell injection. The ellipsoidal opening was located next to the tip apex in order to retain a sharp tip to break the cell membrane. In this situation the role of the apex would be to penetrate the cell membrane and help the insertion of the

4.2. Design and fabrication of NADIS probes for the cell microinjection system

tip into the cell. Once the tip is inserted a biomaterial can be delivered into the cell via the aperture.

Flat apertures were also developed for labelling the cell membrane and other surfaces. Here the goal was to avoid sharp points that might damage the membrane and to bring the aperture into very close contact with the membrane to minimise leakage of liquid and label into the surrounding environment. The first aperture that was produced was a square aperture. This fulfils the criteria of removing sharp points from the tip. However, because of the 10° angle of the AFM cantilever from the horizontal it does not bring the aperture into perfectly close contact with a flat surface. For this reason, a tilted trapezoid aperture was designed and fabricated. This aperture compensates the 10° tilt caused by the AFM holder (since the tip was milled at -10° in reference to the tip base). In this case the tip could be brought in contact with a sample and deposit material only at the restricted, by the geometry of the tip aperture, contact area with the sample.

Figure 4.22: Schematic drawings of a NADIS tip with a) a circular aperture at the tip apex, brought in contact with the cell membrane to deposit biomolecules; b) a needle-like aperture located next to the apex, to use the sharp tip to penetrate the cell membrane and deliver molecules into the cell; c) a flat square shaped aperture to label the cell membrane d) a tilted trapezoidal aperture, which allows a perfectly flat contact with the membrane.

4.2.6.1 Milling the apertures

A standard FIB holder was used to mill the aperture tip with an ion beam perpendicular to the base of the pyramidal tip. This configuration allowed the milling of the tip from the top and it could create circular and needle like apertures. However, the holder could not be used to position the AFM tip so as to mill the pyramid from the side as was required to fabricate flat apertures (both square and trapezoidal). To fabricate these apertures a new FIB holder was developed (Figure 4.23a).

The new FIB holder had one face tilted at 45°. The AFM chips were fixed to the face of the holder with the tips pointing upwards. By using the different rotation and tilting angles

Figure 4.23: Schematic drawings of the new FIB holder. The AFM chips are fixed to the inclined face of the holder (the tips pointed upwards) to mill the apertures with the ion beam tilted at different angles with respect to the base of the tip a). Configuration of the tip vs. the ion beam to fabricate: the needle-like aperture b); the flat square shaped aperture c); and the tilted trapezoidal aperture d).

of the FIB stage the pyramidal tips were milled when the ion beam was 1) perpendicular (Figure 4.23b)), 2) parallel (Figure 4.23c)) or 3) tilted at -10° with respect to the base of the tip (Figure 4.23d)).

The process parameters used to mill the apertures were adapted from the fabrication of closed NADIS probes. The angle of incidence depended on the type of aperture. Table 4.6 gives a summary of the process parameters used for fabrication of the tip openings.

4.2.6.2 Results

When the beam was perpendicular to the base of the tip, the tip was milled from the top and circular and needle like apertures were created (Figure 4.24a-d)). By milling the tip apex with a parallel ion beam the tip apex could be removed, creating a flat square shaped aperture

4.2. Design and fabrication of NADIS probes for the cell microinjection system

Table 4.6: A comparison of two metallization processes.

Parameter	Value
Ion beam current	$I = 30 \text{ pA}$
Acceleration voltage	$U = 30 \text{ kV}$
Dwell time	$t = 500 \text{ ns}$
Beam Overlap	50 %
Angle of incidence	$\Theta = 0^\circ$ when milling circular openings $\Theta = 35^\circ$ when milling flat square openings $\Theta = 45^\circ$ when milling tilted trapezoidal openings $\Theta = 55^\circ$ when milling needle-like openings

(Figure 4 e)-h)). When the ion beam was tilted -10° relative to the base of the tip the tip apex was developed by an oblique plane and a tilted trapezoid shaped aperture was created (Figure 4 f)-l)).

Different sizes of the apertures were fabricated. Typically the circular opening was 200 nm in diameter; the needle-like opening usually had a 200 nm long semi-minor axis; and 600 nm long semi-major axis, the flat square-shaped aperture was 500 nm \times 500 nm in size; the tilted trapezoidal aperture had long and short bases 500 nm and 300 nm in length respectively, and the legs were 400 nm long.

Fabrication of the needle like aperture revealed problem of uneven tip sharpness. Figure 4.25 shows SEM micrographs of two tip apexes with different radii after the metalization step. Figure 4.25a) shows an AFM tip with an approximate tip radius of 75 nm and Figure 4.25b) presents a tip with an approximate tip radius of 100 nm.

4.2.7 Discussion

The fabrication of the NADIS probes for microinjection into living cells was based on the fabrication process of the 2nd generation NADIS probes. Two main modifications were introduced to the fabrication process: The extensive rinsing of the wafer under the vacuum after the KOH etching step significantly decreased the contamination problem, such that it now affected just 5% of the cantilevers. The second modification introduced a critical point drying step to prevent the long cantilevers from breakage. Unfortunately, the long cantilevers still had cracks and could not be used. The origin of these cracks is not yet fully understood.

Fabrication of the needle like aperture revealed two fabrication problems. The first problem was the uneven sharpness of the tip apex presented in. The fabrication process of the first design of the NADIS probes had the same uneven tip sharpness, but since the tip apexes were removed to create a circular opening, the problem did not exist. However in the present fabrication of the NADIS probes, the aperture is located next to the tip apex, in order to use the apex to break the membrane of the living cell. An uneven sharpness of the tip apex will cause

Figure 4.24: Schematics of the tip-ion beam configuration. The ion beam (i.b.) is perpendicular to the base of the tip a). SEM micrographs b-c) show the NADIS tip with the needle-like aperture from the side and d) from the top. Figure e) shows changed configuration for milling the flat square shaped apertures. The ion beam is parallel to the base of the pyramidal tip so the tip apex is removed from the side. SEM micrographs shows f) the NADIS tip with the aperture seen from the side, g) a closer look at the flat apex and h) top view of the aperture. Figure i) shows configuration for milling with the beam tilted to -10° in reference to the base of the tip. In this case the beam removed the apex creating an oblique plane with a trapezoidal aperture j-l).

discrepancies during the cell membrane penetration. The radius of the tip apex varies from 25 nm to 50 nm after the fabrication of the wafer. After the metalization step, when the tip is coated with 47 nm thick platinum the final values of the radius varies from 75 nm to 100 nm.

The second important problem was encountered during the FIB milling process. In the first part of this fabrication step the ion beam is adjusted (focus and astigmatism) and the milling pattern is positioned next to the apex. This whole procedure is manual and its accuracy depends on user experience. Due to the inaccuracy in the beam adjustment the length of the semi-minor axis of the ellipsoidal opening varies from 190 nm to 250 nm. This can cause a variation in the amount of delivered material into the cell. The position of the milling pattern is even more critical. The milling pattern has to be positioned close to the tip apex, so when the apex penetrates the cell membrane a part of the tip with the opening can be inserted into the cell (Figure 4.26b)). When the aperture is too far away from the apex (Figure 4.26a)) it might not fit inside the cell. However, if the milling pattern is positioned too close to the apex (Figure 4.26c)), the apex might be partially destroyed by the ion beam and the tip might not be

Figure 4.25: SEM micrograph presents a) a tip apex with 75 nm radius; b) a tip apex with 100 nm radius.

sharp enough to penetrate the cell.

Figure 4.26: SEM micrograph of a tip with a) the aperture positioned too far away from the apex; b) positioned correctly; c) positioned too close and the apex was destroyed by the ion beam milling..

4.3 Summary

The fabrication of the NADIS probes for microinjection into living cells was based on the fabrication process of the second design of the NADIS probes. Several modifications of the NADIS chip and the cantilever design were introduced. The width of the chip was increased and the number of reservoirs was reduced in order to ensure good closed channel between the chip and the fluidic system of the AFM holder. The cantilevers had single or double beams and three lengths: short (from 120 μm to 140 μm), medium (single beam: 150 μm to 180 μm ; double beam: 220 μm to 320 μm) and long (350 μm to 400 μm). Two main modifications introduced to the microfabrication process allowed to successfully fabricate single and double beam probes with cantilever length up to 320 μm .

The fabrication of the NADIS chips with the cantilevers was on the wafer scale, whereas the fabrication of the tip apertures was on a single chip level. Three new types of tip apertures were proposed: the needle like tip designed for delivery of molecules inside the living cells; the square shaped aperture and the titled trapezoid shaped aperture for labeling the cell

Chapter 4. Design and fabrication of the NADIS probes for a microinjection system

membrane and other surfaces. The fabrication of the last two apertures was possible due to the design and fabrication of a new FIB probe holder, which allows milling of the tips from different sides.

5 AFM – based microinjection system: assembly and characterization

This chapter discusses the assembly of the system, the spring constant of the NADIS probes, filling of the system with liquid, liquid expulsion and flow of fluids through the system. The system specifications are extensively discussed. Finally, based on the specifications, injection parameters are determined.

5.1 Assembling of the system components

The AFM-based microinjection system was built based on the NADIS probe, AFM probe holder with fluidic channels and four commercially available components: the NanoWizard® AFM microscope, the inverted microscope Axiovert 200, the JPK PetriDishHeater and the pressure pulse generator – PM8000 Injector (details of these products are outlined in the Section 2.4.1). Figure 5.1 presents the complete system. The NADIS probe is first placed on the AFM probe holder and mounted on the AFM microscope. The microscope is then placed on the top of the inverted phase contrast microscope such that the NADIS probe is located inside a Petri dish held by the Petri dish heater. The Petri dish heater has an opening in the middle which is used for optical access by the inverted microscope to visualize the cells and control the position of the NADIS probe inside the Petri dish.

The development and fabrication of the NADIS probe was extensively described in the previous chapter. To mount the probe on the AFM microscope and connect its fluidic channels to the microinjector, an AFM holder with fluidic channels was developed. The geometry of the holder is based on the geometry of a standard AFM holder used for the given AFM microscope. Since the NADIS probe consists of single or double channels, the AFM probe holder was designed to incorporate two fluidic channels. The outlets of the channels are on the top of the holder, where the NADIS probe is to be placed, and the inlets are positioned at the side of holder. Connectors were mounted to the inlets so that flexible tubes could be connected to the holder channels (Figure 5.2).

For the NADIS probe with a single channel, only one channel of the AFM holder is used. To

Figure 5.1: a) Shows entire system where the AFM microscope is placed on the top of the inverted phase contrast microscope. Inside the AFM microscope an AFM probe holder with the NADIS probe is mounted. The probe holder is connected with elastic tube to the microinjector. b) A detailed view on the AFM probe holder. The holder is mounted inside the AFM microscope from the top. The bottom of the probe holder with the NADIS probe is inserted inside the Petri Dish, where the Petri Dish is placed in the Petri Dish heater (not shown). There are two fluidic connectors coming out from the holder from which one is connected to the microinjector via the tube. c) Top view of the Petri Dish with the Petri Dish heater. The heater has an opening in the middle through which a lens from the inverted phase contrast microscope has an access to the bottom of the Petri Dish.

attach the NADIS probe to the holder and to ensure a sealed connection between the probe and the holder channels a biocompatible double-sided tape was used (Figure 5.3).

Once the probe is mounted on the holder, placed on the AFM microscope and connected to the microinjector, the system is ready to be used. In order to work with the system, further information about its properties is required.

5.2 Characterization of the system

During the cell injection experiments, the NADIS tip will first penetrate the cell membrane. When inserted inside the cell, an aqueous liquid can be injected. To control the interaction forces between the tip and the cell, the spring constant of the cantilever has to be known. To control the liquid delivery passing into the cell, details on filling of the probe, flow of the liquid through the probe as well as volume control of the ejected liquid is required.

Figure 5.2: a) Design of the AFM holder with two fluidic channels. The inlets of the channels are on the side and the outlets on the top of the holder, where the NADIS probe will be placed. b) Top view and c) bottom view of the holder with mounted connectors for the flexible tubes.

5.2.1 Calibration of the spring constant of the NADIS cantilevers

The spring constant was measured using the cantilever-on-cantilever (COC) method [86–88]. The COC is a static deflection method using a reference cantilever with a well-defined spring constant and a test cantilever with unknown spring constant. The principle of this method is to measure the deflection of the test cantilever pushed against the reference cantilever as a function of the AFM stage displacement. The accuracy of this method is reported to vary from 5 % to 30 % [86–88].

Table 5.1 shows the measured values of the spring constant for two fabricated cantilever types, the single beam and the double beam. The single beam cantilevers had either short or medium length. The measured post-fabrication cantilever length of 50 randomly chosen short single beam cantilevers varied from 120 μm to 140 μm . The spring constant of these probes varied from 14.3 N m^{-1} for 120 μm long cantilevers to 7.8 N m^{-1} for 140 μm long cantilevers. The double beam cantilevers had one type of the cantilever length – the medium type. The measured post-fabrication cantilever length of 50 randomly chosen double beam cantilevers varied from 220 μm to 320 μm . The spring constant of these probes varied from 3.2 N m^{-1} for 220 μm cantilever length and 1.4 N m^{-1} for the 320 μm cantilever length.

Table 5.1: Measured values of the spring constant for a single and double beam type cantilevers.

Type of the cantilever	Free length [μm]	Measured spring constant k [N m^{-1}]
Single beam short	120-140	14.3 – 7.8
Single beam medium	150 -180	5.8 – 4.2
Double beam medium	220-320	3.2 – 1.4

Stiffness of the fabricated cantilevers is higher compared to the stiffness evaluated in the design (Section 3.2). The difference is caused by two factors: the free length of the cantilever

Figure 5.3: a) The AFM holder with the double–side tape. The tape has two openings for the outlets of the holder channels. b) The NADIS probe is placed on the tape in a way so the openings in the tape and the NADIS reservoirs are aligned.

and the cantilever height. The fabricated length of the cantilevers was shorter than expected for the single beam cantilevers. The expected free length of the single beam cantilevers was in the range from 115 μm to 215 μm for the short type and from 215 μm to 315 μm for the middle type. The expected free length of the double beam cantilevers was in the range from 215 μm to 315 μm and it was in accordance with the designed values. However, the stiffness of these probes is higher than predicted. This is due to the second factor – the cantilever height. In the design, the height of all the cantilever types was 3.8 μm , while the height of the fabricated probes is larger and varies from 4.4 μm to 5.6 μm . As explained in Chapter 3 this variation arose from inhomogeneous dry etching along the wafer.

For the proof-of-concept microinjection experiment, NADIS probes with single beam cantilevers were chosen. Based on the measured values of the cantilevers spring constant, this choice was limited to single beam medium type probes. In next section, characterization of fluid flow through this probe is described.

5.2.2 Filling of the system with liquid

Once the cantilever stiffness is calibrated the system is filled with an aqueous liquid. To fill the system, the flexible tube attached to the microinjector is first pre-filled (the liquid is aspirated into the tube by means of an underpressure) and then connected to the AFM holder. When a pressure is applied to the system, the AFM holder channel is filled first before the NADIS probe. To control if the probe is correctly filled, the resonance frequency of the cantilever is measured during the process.

By measuring the resonance frequency of the cantilever, a decrease in its frequency value

5.2. Characterization of the system

should be observed once the cantilever channel is filled based on the following equation [89]:

$$\vartheta = \frac{1}{2\pi} \cdot \sqrt{\frac{c}{m_{eff} + m_l}} \quad (5.1)$$

where, k is the cantilever spring constant, m_{eff} is the effective mass of an oscillating cantilever calculated as 23% of the cantilever mass, and m_l is the 23% value of the liquid mass inside the cantilever.

While the probe is being filled, the resonance frequency of the cantilever decreases until the channel and the tip are completely filled with liquid. To analyze how much the resonance frequency will decrease, 15 medium, single beam probes were filled with liquid. The average decrease in the cantilever resonance frequency after being filled with liquid was measured to be (26 ± 9) kHz. Table 5.2 shows measured values for individual cantilevers and Figure 5.4 shows an example of a measured decrease in the resonance frequency for the first probe.

Table 5.2: Resonance frequency measurements of the NADIS probe before and after being filled with liquid. The average decrease in resonance frequency is (26 ± 9) kHz

Probe number	Resonance frequency ϑ [kHz] for		Difference ϑ [kHz]
	Empty probe	Filled probe	
1	118	90	28
2	130	95	35
3	102	76	26
4	93	70	23
5	104	82	22
6	118	86	32
7	124	94	30
8	121	100	21
9	94	72	22
10	116	99	17
11	144	114	30
12	77	59	18
13	127	99	28
14	131	96	35
15	87	65	23

The obtained average decrease in resonance frequency (26 ± 9) kHz was used to indicate if the probes were correctly filled with liquid. When the decrease was much lower than the average value, the probes were usually found to be blocked with residues or gas bubbles.

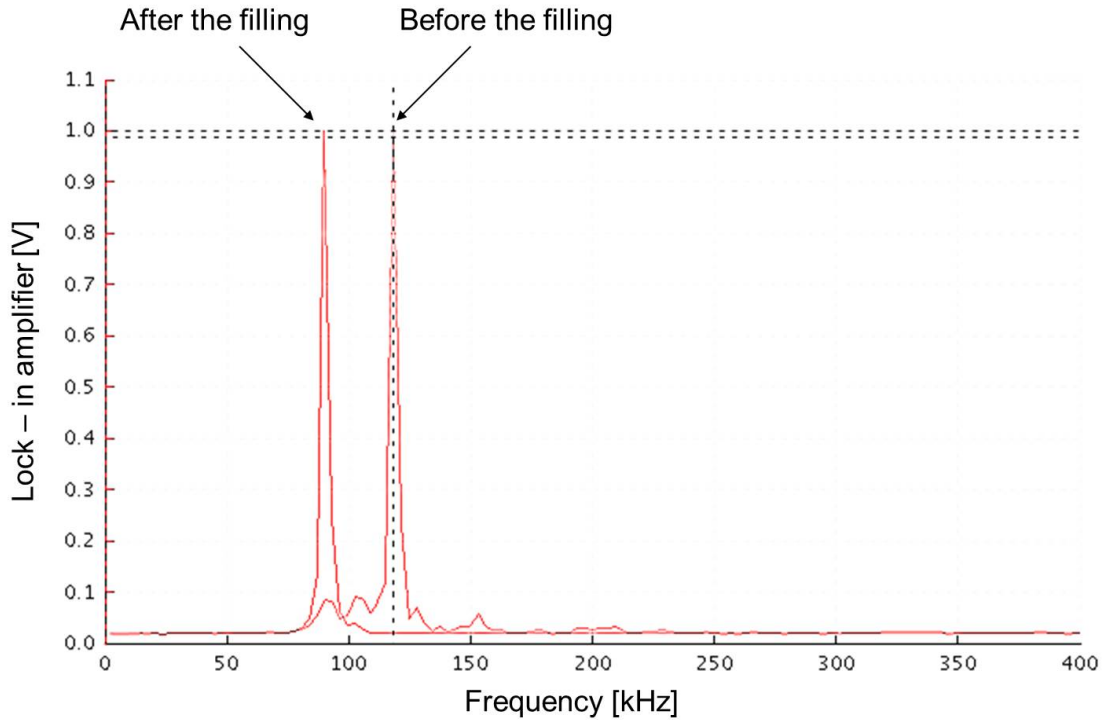

Figure 5.4: Measurement of the resonance frequency of a NADIS cantilever. When the cantilever channel is filled with liquid the resonance frequency is shifted to lower value.

5.2.3 Characterization of the fluid flow through the system

The goal of the flow characterization was to investigate whether the basic theoretical model can predict the behavior of the fluids in the fabricated system. The fluid flow was determined experimentally and the results were compared with the theoretical model based on the Navier–Stokes equation.

The theoretical flow of liquids through the system was described with the conventional theory in Chapter 3. By applying a constant pressure gradient Δp to the system, a steady state flow Q can be generated according to the Hagen–Poiseuille law:

$$\Delta p = R_{hyd} \cdot Q \tag{5.2}$$

where, R_{hyd} is the hydraulic resistance of the system, depending on the system geometry and liquid viscosity. The theoretical discussion showed that the hydraulic resistance of the system is entirely determined by the hydraulic resistance of the NADIS probe (outlined in Chapter 3, Section 3.4.2).

Experimentally, the hydraulic resistance of the NADIS probe was determined by measuring

5.2. Characterization of the system

the volumetric flow rate as a function of applied pressure through the fluidic system of the probes. The experimental apparatus is presented schematically in Figure 5.5. It consists of a microinjector connected to an optically transparent glass tube with an inlet to supply the liquid. The glass tube is then connected to a polymeric adapter with the NADIS probe. The flow measurements were based on an optical measurement technique described by Richter et al. [90]. The system with the glass tube was placed under an optical microscope connected to a CCD camera and a computer. The flow rate in the glass tube was measured by volumetric discharge of the fluid through the NADIS system as a function of time (details outlined in Chapter 3, Section 2.4.3).

Figure 5.5: Schematic of the experimental apparatus.

Pressure losses in the connectors and the glass tube were estimated to be a small fraction of the total pressure drop. The exit pressure was assumed to be equal to the atmospheric pressure. Before each measurement a number of readings were taken to verify that the flow is reasonably steady. The measurements were taken for monotonically increasing pressure. First, the results will be presented in the plot as a function $\Delta p(Q)$. Based on the linear approximation of the measured values, the hydraulic resistance R_{hyd} is determined. Further, the results are analysed through the Reynolds number Re defined as [91]:

$$Re = \frac{\rho Q d_h}{A_c \eta} \quad (5.3)$$

where, ρ is the fluid density, Q is the liquid flow, d_h hydraulic diameter of the channel calculated as four times cross-section of the channel divided by its wetted perimeter, A_c is the cross-sectional area of the channel and η is the fluid viscosity.

And the entrance length L_e , the length of the channel required to achieve fully developed flow,

defined as:

$$L_e = 0.06Re d_h \quad (5.4)$$

The fluid flow was measured for two cases: first, for a NADIS probe without a tip and with an embedded rectangular channel (Figure 5.6a)), and second, for a NADIS probe with a tip and a complete fluidic system consisting of the channel connected to the hollow tip including an opening (Figure 5.6b)).

Figure 5.6: Schematic drawing of a) NADIS probe without tip with embedded rectangular channel, b) NADIS probe with a tip and fluidic system consisting of embedded channel connected to hollow tip with an opening.

5.2.3.1 Flow measurements of gas

First, the flow of nitrogen (N_2) through the NADIS probes was measured. To trace the movement of the N_2 in the glass tube, a thin column of deionized water was introduced into the glass tube via the liquid inlet. The flow of gas was measured based on the displacement of the thin water column as a function of time. The hydraulic resistance of the water column was negligible.

Figure 5.7 presents a graph showing the measured and calculated dependency $\Delta p(Q)$ of nitrogen gas flowing through the NADIS probe without the tip. The size of the rectangular channel embedded inside the probe was: 1200 μm in length, 23.8 μm in width and 3.2 μm in high. For the calculation, a nitrogen viscosity of $\eta_{N_2} = 17.81 \times 10^{-6} \text{ Pa s}$ at 25 $^\circ\text{C}$ was used. For the applied pressure ranging from $2 \times 10^4 \text{ Pa}$ to $1 \times 10^5 \text{ Pa}$, the measured flow values varied from 51 nL to 285 nL. The measured values were in close proximity to the theoretical values and could be approximated with a linear model.

From the linear fit, the hydraulic resistance was extracted and compared with the theoretical value. Table 5.3 shows the comparison. It can be seen that the values are in a very good agreement.

Based on the measured flow values, the Reynolds number was calculated to be in the range of $0.2 < Re < 1.5$, and the entrance length was in the range of $82 < L_e < 468 \text{ nm}$. The values of the Reynolds number show that the flow is laminar. A comparison of the entrance length with

5.2. Characterization of the system

Figure 5.7: Theoretical and measured flow values for rectangular channel of the NADIS probe without the tip. The experimental values were approximated with a linear model.

Table 5.3: Comparison of theoretical and measured values of hydraulic resistance for the NADIS probe without the tip.

Hydraulic resistance	Theoretical R_c	Experimental R_m
Values [Pa s m^{-3}]	3.29×10^{14}	3.27×10^{14}

the length of the channel shows that the flow was fully developed. Also the Knudsen number Kn was calculated to investigate if, for the absolute pressure range considered ($105 < \Delta p < 2 \times 10^5$ Pa), behavior of nitrogen falls well inside the Navier–Stokes equation regime [92]. The calculated values were in the range of $0.032 > Kn > 0.016$, which verifies that the nitrogen behavior can be described by the Navier–Stokes equation.

In addition, the flow of nitrogen through the NADIS probes with the tip was measured. The tip had a square opening of $6 \mu\text{m} \times 6 \mu\text{m}$ measured with SEM. The size of the rectangular channel was assumed to have the following values: length $L = 1200 \mu\text{m}$, width $w = 23.8 \mu\text{m}$ and height $h = 2.6 \mu\text{m}$. Figure 5.8 presents the measured and theoretical values of the flow. The measured flow was in the range of $72 < Q < 418 \text{nL}$ and was higher than predicted by the theoretical model.

Approximation of the measured flow values with a linear fit allowed extraction of the hydraulic resistance value. Table 5.4 shows a comparison between the experimental value of the hydraulic resistance with the theoretical value. It can be seen that the measured values are approximately 3 times smaller than the theoretical values.

The flow of nitrogen through the square $6 \mu\text{m} \times 6 \mu\text{m}$ tip opening with a wall length of $0.15 \mu\text{m}$ was described by Reynolds number Re and entry length L_e . The Reynolds number varied

Figure 5.8: Theoretical and measured flow values for NADIS probe with the tip. The tip had a square $6 \mu\text{m} \times 6 \mu\text{m}$ opening. The experimental values were approximated with a linear model.

Table 5.4: Comparison of theoretical and measured values of hydraulic resistance for the NADIS probe with $6 \mu\text{m} \times 6 \mu\text{m}$ tip opening.

Hydraulic resistance	Theoretical R_c	Experimental R_m
Values [Pa s m^{-3}]	6.13×10^{13}	2.35×10^{14}

from $0.78 < Re < 4.56$ depending on the flow value, which suggests laminar flow through the opening. The entry length was in $0.27 < Le < 1.55 \mu\text{m}$ range, which was larger than the $0.15 \mu\text{m}$ length of the opening, indicating that the flow through the tip opening was not fully developed. The Knudsen number was in $0.03 > Kn > 0.02$ range, which falls inside the Navier-Stokes equation regime [92].

As a next step, flow of nitrogen through NADIS probes with circular openings of $1.78 \mu\text{m}$ in diameter was measured. The size of the rectangular channel was assumed to have the following values: length $L = 1200 \mu\text{m}$, width $w = 23.8 \mu\text{m}$ and height $h = 2.6 \mu\text{m}$. The flow measurements of the N_2 was unsuccessful as the flow was decreasing in time for a constant pressure. This problem did not occur when the N_2 was replaced with carbon dioxide ($\eta_{CO_2} = 14.5 \times 10^{-6} \text{ Pa s}$ at 20°C). Figure 5.9 presents measured and theoretical flow values for the pressure ranging from $2 \times 10^4 \text{ Pa}$ to $1 \times 10^5 \text{ Pa}$. The measured flow was in the range from $81 < Q < 312 \text{ nL}$ and was higher than the theoretical values.

The measured flow values were fitted with a linear model to extract the value of the hydraulic resistance. Table 5.5 shows comparison between the theoretical and experimental values of the hydraulic resistance. It can be seen that the measured values are approximately 2 times smaller than the theoretical values.

5.2. Characterization of the system

Figure 5.9: Theoretical and measured flow values for NADIS probe with the tip. The tip had a circular opening of 1.78 μm in diameter. The experimental values were approximated with a linear model.

Table 5.5: Comparison of theoretical and measured values of hydraulic resistance for the NADIS probe with 1.78 μm diameter tip opening.

Hydraulic resistance	Theoretical R_c	Experimental R_m
Values [Pa s m^{-3}]	5.08×10^{14}	2.35×10^{14}

The flow of carbon dioxide through the circular tip opening with a wall length of 0.15 μm was described by Reynolds number Re and entry length Le . The Reynolds number varied from $3.8 < Re < 14.6$ depending on the flow value. The range of the Reynolds number falls in the laminar flow regime. The entry length was in $1.28 < Le < 4.9 \mu\text{m}$ range, which shows that the gas flow through the 0.15 μm long and 1.78 μm in diameter circular opening was not fully developed. The Knudsen number values were in $0.032 > Kn > 0.016$ range for the absolute pressure range of $10^5 < \Delta p < 2 \times 10^5 \text{ Pa}$, which falls inside the Navier–Stokes equation regime [92].

Finally, the flow of carbon dioxide through a NADIS probe with 200 nm in diameter tip opening was measured. The size of the rectangular channel was assumed to have following values: length $L = 1200 \mu\text{m}$, width $w = 23.8 \mu\text{m}$ and height $h = 2.6 \mu\text{m}$. Figure 5.10 presents the measured and theoretical values of the flow for the pressure varying from $1 \times 10^4 \text{ Pa}$ to $2 \times 10^5 \text{ Pa}$. The measured flow values were in the range from $0.7 < Q < 14.8 \text{ nL}$ and were higher compared to the theoretical values.

The measured flow values were approximated with a linear model to extract the hydraulic resistance value. Table 5.6 shows a comparison of the theoretical and experimental values of the hydraulic resistance. It can be seen that the measured values are 5 times smaller than the

Figure 5.10: Theoretical and measured flow values for NADIS probe with the tip. The tip had a needle like opening of 0.2 μm in diameter. The experimental values were approximated with a linear model.

theoretical values.

Table 5.6: Comparison of theoretical and measured values of hydraulic resistance for the NADIS probe with 0.2 μm diameter tip opening.

Hydraulic resistance	Theoretical R_c	Experimental R_m
Values [Pa s m^{-3}]	5.59×10^{16}	1.15×10^{16}

The flow of carbon dioxide through the 200 nm diameter tip opening was described by Reynolds number Re and entry length L_e . The Reynolds number varied from $0.3 < Re < 6$, which falls into the laminar flow regime. The entry length was in the range of $0.1 < L_e < 2.1 \mu\text{m}$. The wall length of the tip opening has $0.15 \mu\text{m}$ which suggests that for the smallest applied pressure of $1 \times 10^4 \text{ Pa}$ the flow was fully developed after $0.1 \mu\text{m}$. However, for the higher pressure values, the calculated entrance length was larger than the length of the opening, indicating not fully developed flow. The Knudsen Number values calculated for the absolute pressure range $1 \times 10^5 \text{ Pa}$ to $3 \times 10^5 \text{ Pa}$ were $0.29 > Kn > 0.09$, which shows that the gas behavior falls into the transition regime and should be described with the Burnett equation [92].

In general, the flow of gas through a rectangular channel of a NADIS probe without the tip was in very good agreement with the theoretical model. Calculation of the Reynolds number and the entrance length showed that the flow was laminar and fully developed. Flow measurements of gas through a rectangular channel connected to a tip with an opening had few times higher values than predicted by the theory. The gas flow through the tip openings was not fully developed.

5.2.3.2 Flow measurements of liquid

Since aqueous liquids are desired for the cell injection, the flow of deionized and filtrated water was measured.

The water flow was first measured through 3 NADIS probes without tip. The flow measurements were carried out in an ambient atmosphere and each system was first flushed with nitrogen before water was introduced. The 3 NADIS probes had a similar length of 1200 μm and width of 23.8 μm . The height of the first cantilever was 3.2 μm , the second 3.0 μm , and the third 3.2 μm . For the calculations, a water viscosity of $\eta_{H_2O} = 1.002 \times 10^{-3} \text{ Pa s}$ at 20 $^\circ\text{C}$ was considered. Figure 5.11 presents a plot showing the measured and calculated flow values for pressures ranging from $2 \times 10^4 \text{ Pa}$ to $2 \times 10^5 \text{ Pa}$. For the first probe, the measured flow values varied from 3.6 nL to 20.4 nL over the pressure range of $2 \times 10^4 < \Delta p < 2 \times 10^5 \text{ Pa}$. For the second probe, the flow values varied from 3.0 nL to 16.7 nL over the pressure range of $2 \times 10^4 < \Delta p < 17.2 \times 10^4 \text{ Pa}$, and for the third probe, the flow values varied from 4.5 nL to 26.5 nL over the pressure range of $2 \times 10^4 < \Delta p < 13.7 \times 10^4 \text{ Pa}$. For all the 3 probes, the measured values were higher than the theoretical values.

Figure 5.11: Theoretical and measured flow values for 3 NADIS probe without the tip. The experimental values were approximated with a linear model.

The measured flow values were approximated with a linear model to extract the values of the hydraulic resistance for each of the 3 probes. Table 5.7 shows comparison between the theoretical and experimental values of the hydraulic resistance. It can be seen that the measured values are approximately 2 to 3 times smaller than the theoretical values.

The water flow through the 3 probes was characterized by the Reynolds number and the entrance length. Table 5.8 presents summary of the Reynolds number values and the entrance length values together with the measured flow values for a given pressure range for each probe.

Chapter 5. AFM – based microinjection system: assembly and characterization

Table 5.7: Comparison of theoretical and experimental hydraulic resistance values for the 3 NADIS probes without the tip.

Hydraulic resistance	1	2	3
Theoretical R_c [Pa s m^{-3}]	18.5×10^{15}	22.5×10^{15}	18.5×10^{15}
Experimental R_m [Pa s m^{-3}]	9.3×10^{15}	10.5×10^{15}	5.2×10^{15}

Table 5.8:]

[Summary of the measured flow, Reynolds number and entrance length] Summary of the measured flow values, Reynolds number values and entrance length values for a given pressure range for each probe.

Probe	1	2	3
Pressure range Δp [Pa]	2×10^4 to 2×10^5	2×10^4 to 17.2×10^4	2×10^4 to 13.7×10^4
Flow range Q [nL s^{-1}]	3.6 to 20.4	3.3 to 16.7	4.5 to 26.5
Reynolds number Re	2×10^{-4} to 1×10^{-3}	2×10^{-4} to 1×10^{-3}	3×10^{-4} to 2×10^{-3}
Entrance length [μm]	0.09 to 0.5	0.07 to 0.4	0.11 to 0.66

The Reynolds number values and the entrance length values show that the water flow in the rectangular channels is laminar and fully developed. In next step, water flow measurements through a NADIS probe with square $6\mu\text{m} \times 6\mu\text{m}$ tip opening was measured. The size of the rectangular channel was assumed to have following values: length $L = 1200\mu\text{m}$, width $w = 23.3\mu\text{m}$ and height $h = 2.6\mu\text{m}$. However, the measured flow decreased with time when a constant pressure was applied. In order to measure the flow of water in these systems, two modifications were introduced: the probes were pre-filled with carbon dioxide and the water was de-gassed. Carbon dioxide dissolves in water which decreases probability of gas bubble nucleation in the channels. These modifications allowed the water flow to be measured. Figure 5.12 presents a graph with the theoretical and experimental flow values measured for pressure range ($2 \times 10^4 < \Delta p < 2 \times 10^5$ Pa). The measured flow varied from 0.2 nL to 6 nL depending on the applied pressure. The values were higher compared to the values calculated from theory.

The measured flow values were fitted with a linear model to extract the value of the hydraulic resistance. Table 5.9 shows a comparison between the theoretical and experimental values of the hydraulic resistance. It can be seen that the measured value is 0.7 times smaller than the theoretical values.

Table 5.9: Comparison of theoretical and measured values of hydraulic resistance for the NADIS probe with $6\mu\text{m} \times 6\mu\text{m}$ tip opening.

Hydraulic resistance	Theoretical R_c	Experimental R_m
Values [Pa s m^{-3}]	45.1×10^{15}	32.5×10^{15}

5.2. Characterization of the system

Figure 5.12: Theoretical and measured flow values for NADIS probe with the tip. The tip had a square $6 \mu\text{m} \times 6 \mu\text{m}$ opening. The experimental values were approximated with a linear model.

Table 5.10 presents a summary of the flow values, the Reynolds number values and the entrance length values for water flowing through the tip opening with a wall length of $0.15 \mu\text{m}$.

Table 5.10: Summary of the measured flow values, Reynolds number values and entrance length values for water flowing through the square $6 \mu\text{m} \times 6 \mu\text{m}$ tip opening with a wall length of $0.15 \mu\text{m}$

Pressure range Δp [Pa]	Flow range Q [nL s^{-1}]	Reynolds number Re	Entrance length L_e [μm]
2×10^4 to 2×10^5	0.2 to 6	3×10^{-5} to 1×10^{-3}	0.01 to 0.3

The Reynolds number values and the entrance length values show that the water flow in the rectangular channels is laminar and fully developed. Next, measurements of the water flow through a NADIS probe with circular tip opening of $1.78 \mu\text{m}$ in diameter was assessed. Again, the measured flow decreased with time for a constant applied pressure. The introduced modifications: pre-filling with carbon dioxide and water de-gassing did not improve the flow stability. A similar situation was observed for NADIS probes with $0.5 \mu\text{m}$ and $0.2 \mu\text{m}$ diameter tip openings. Since the flow measurement required longer lasting measurements, it is possible that the gas bubbles plugged the system and prevented the measurements. Therefore, the water flow measurements through these probes were abandoned.

All the successfully measured flow values for the 3 NADIS probes without the tip and for the NADIS probe with square $6 \mu\text{m} \times 6 \mu\text{m}$ tip openings were higher than predicted by the theory.

5.3 Control of ejected liquid volume

During the concept study (Chapter 3) of the liquid delivery into living cells, two main advantages of using an AFM-based injection system over standard microinjection were determined: control of the tip-cell membrane interactions during cell penetration and control of the amount of liquid delivered into the cell.

In the first approach, it was assumed that aqueous based solutions will be injected into the cytosol, which mainly consists of water (thus injecting water into water). As the liquid delivery is generated by an external pressure, the amount of ejected liquid from the tip opening depends on the pressure value and the ejection time (the length of the pressure pulse). In order to determine range of values for the two parameters several assumptions have been made:

1. injected liquid is not impeded by cell organelles;
2. the cytosol is assumed to behave like water, thus surface tension effects between the injected aqueous liquids and cytosol are not present;
3. the viscosities of the aqueous liquids are equal to the viscosity of water at 37 °C;
4. the tip apex is inserted into the cell in such a way that the entire tip opening is enclosed inside the cell; and
5. during liquid injection, the liquid flow is in a steady state fully developed laminar flow.

With these assumptions the injected volume ΔV of liquid depends on the injection parameters, the pressure Δp and the length of the pressure pulse Δt according to the formula:

$$\Delta V = \frac{\Delta p \Delta t}{R_{hyd}} \quad (5.5)$$

where, R_{hyd} is the hydraulic resistance of the NADIS probe.

For cell injection experiments, NADIS probes with tip openings 0.2 μm in diameter (needle like type) were addressed. Water flow measurement through openings smaller than 1.87 μm in diameter resulted in a system with gas bubbles. However, as the theoretical model proved to be realistic, it was further used as indication of the flow rate through systems with small tip apertures. Figure 5.13 presents a graph with theoretical flow values for a pressure range between 0 and 1×10^5 Pa for a probe with a 0.2 μm diameter, needle like opening. The calculated flow is in the femto liter range and the value of the hydraulic resistance is 26.7×10^{17} Pa s m^{-3} .

Knowing the hydraulic resistance and the value of the applied pressure, the length of the pressure pulse can be calculated for a known amount of liquid. In Chapter 3 (Concept study),

5.3. Control of ejected liquid volume

Figure 5.13: Theoretical values of the steady state flow of water through needle like opening type in the NADIS probe.

the volume range of liquid that can be injected into a cell without causing cell damage was calculated to vary from 5 fL to 400 fL. Table 5.11 presents the calculated length of pressure pulses Δt for given pressure values Δp required to inject the minimum and the maximum liquid volume into a cell.

Table 5.11: Values of the applied pressure and calculated length of the pressure pulses required to inject the minimum and the maximum liquid volumes.

Injected volume ΔV [fL]	Pressure Δp [Pa]	Pressure pulse length Δt [s]
5	700	19
5	1000	13
5	1300	10
400	10000	106
400	20000	53
400	30000	35

The duration of the pressure pulses was calculated for a pressure setting range and the time setting range of the microinjector used in the system. The pressure setting range starts from 689.5 Pa and goes to 413 685.5 Pa with a resolution of 689.5 Pa. The time setting range starts from 10 milliseconds and goes to 327.6 seconds with resolution of 10 milliseconds over the whole range.

5.4 Discussion

Characterization of the AFM-based microinjection system focused on three main aspects: cantilever spring constants, specifications of properly filled probes (with water) and fluid flow measurements through the probes.

First, the stiffness of the cantilevers was measured. It was found that the probes are stiffer than expected. The single beam probes assigned to the proof-of-concept microinjection experiments had spring constants varying from 8 N m^{-1} to 15 N m^{-1} for the short length type and 4 N m^{-1} to 6 N m^{-1} for the medium length type. Since cell indentation experiments with AFM probes should be performed with flexible cantilevers, it was decided to use only the single beam probes with the ‘medium’ length type.

In the next step, filling of the probes was controlled by measuring the resonance frequency of the vibrating cantilever. Due to the cantilever filling with water, its resonance frequency decreased. It was determined that the average decrease is 26 kHz. This value will be used in future experiments as an indication of a correctly filled system.

Finally, the volumetric flow rate Q of fluids through NADIS probes was measured. Two types of probes were used: one where the fluidic system consisted only of a rectangular channel, and a second where the channel was connected to a hollow tip with an aperture. The measured flow values were used to find the value of the hydraulic resistance for each probe. The measured hydraulic resistance was further compared with the theoretical value.

The flow of nitrogen through the rectangular channel, with known geometry and without a tip was in an excellent agreement with the theoretical model. In the theoretical model, the nitrogen is treated as a continuous medium. For the absolute pressure range ($10^5 < \Delta p < 2 \times 10^5 \text{ Pa}$), Knudsen numbers Kn were in the range between 0.032 to 0.016, which falls well inside the Navier–Stokes equation regime [92]. The calculated Reynolds numbers Re and entrance length L_e based on the measured flow were from 0.2 to 1.4 and 82 nm to 468 nm, respectively, indicating fully developed laminar flow.

The value range of the Knudsen number indicates, according to Roy et. al [92], a slip flow regime. However, the experimental data fit well with the ones reported by Harley et al.[93] and Pfahler et al. [94], where no slip flow of nitrogen was reported.

Measurements of the nitrogen flow through NADIS channels connected to a hollow tip with a square $6 \mu\text{m} \times 6 \mu\text{m}$ tip opening were 3 times higher than predicted by theory. Based on the values of the Knudsen number, nitrogen flowing through the tip opening behaves as a continuous medium. The entrance length however shows that the flow cannot be fully developed due to the small length of the tip opening. This could explain the difference between the measured and theoretical values, since the theoretical model assumed a fully developed laminar flow.

An attempt to measure the flow of nitrogen through probes with tip openings smaller than

the $6\ \mu\text{m} \times 6\ \mu\text{m}$ opening resulted in decreasing flow over time for a constant pressure. At this point it is not certain, why this effect occurred. When nitrogen gas was replaced with carbon dioxide this effect was not present. Flow of carbon dioxide through a NADIS probe with a circular tip opening of $1.78\ \mu\text{m}$ was measured. The measured hydraulic resistance was 2 times smaller than predicted by the theoretical model. In addition the values of the entrance lengths showed that the flow was not fully developed which could explain the difference between experiment and theory. Calculated values of the Knudsen number show that nitrogen flowing through the tip opening behaves as a continuous medium.

The flow measurements of carbon dioxide through the 200 nm needle like tip opening showed 5 times smaller value of the hydraulic resistance than predicted by the model. The difference could be explained by the values of the Knudsen number showing that the flow values fall into the Burnett equation regime and also by the fact that the flow was not fully developed, as shown by the values of the entrance length.

Water flow measurements were first conducted on 3 similar NADIS probes without a tip. The rectangular channel inside the probe had length of $1200\ \mu\text{m}$ and width of $23.8\ \mu\text{m}$. The first probe had a channel height of $3.2\ \mu\text{m}$, the second $3.0\ \mu\text{m}$, and the third $3.2\ \mu\text{m}$. The measured values of the hydraulic resistances were 9.3×10^{15} , 10.5×10^{15} and 5.2×10^{15} , respectively, which shows acceptable repeatability of the measurement system. However, the values differ from 2 to 3 times compare to the calculated values of the hydraulic resistance. The values of the Reynolds number and the entrance length showed that the flow was fully developed and laminar. The difference in hydraulic resistance values could have been caused by the viscosity value used for the theoretical calculations. During the experiments, only the temperature of the atmosphere surrounding the experimental system was measured. However, the system was placed under an optical microscope, which could have heated the system and therefore changed the liquid viscosity.

Following, the flow measurements through the 3 NADIS probes without tips, the water flow measurements through probes with fluidic channels connected to the tip with an opening were assessed. First experiments failed due to the blockages formed in the system. This effect might have had two sources.

As air is always present in water it is assumed that the presence of the tip may have caused nucleation of air bubbles. Nucleation and stabilization of air bubbles in liquids has been examined by Crum [95]. Free air bubbles cannot cause nucleation as it would increase their liquid–vapour interface and make them unstable. Crum suggested that the nucleation must be associated with mechanisms stabilizing the bubbles such as impurities on the surface or surface defects. Meng et al. [96] described a bubble capture mechanism for large bubbles already present in the system. A moving bubble is trapped in a ‘bubble sink’ which minimizes the surface energy of the bubble. As an example, a concave pit was presented. In such a ‘sink’, the total energy of the bubble is reduced as the liquid–vapour interface is reduced. Figure 5.14a) presents SEM micrograph of a cross–sectional view of the NADIS tip. The geometry of the

hollow tip fulfills the requirements of a 'bubble sink'. In addition, inside the tip, as a result of the fabrication process, two smaller concave pits are present, enhancing nucleation and capturing of the gas bubbles.

Figure 5.14: SEM micrograph presenting cross-sectional view of the hollow tip a) and its schematic drawing with marked positions of the 'bubble sinks'.

The bubble nucleation and/or capturing occurred in the system due to the tip geometry. In order to diminish these effects, the water was either degassed with nitrogen gas, boiled or both before each experiment. However, these methods did not eliminate the problem.

In addition to the presence of the air bubbles it is possible that the nitrogen gas was also trapped in the system causing blockages. Before each experiment the fluidic system was flushed with nitrogen gas. When the system was being filled with water part of the nitrogen gas could have been captured by the 'bubble sinks' in the tip. To diminish this effect the nitrogen was replaced with carbon dioxide due to its high solubility in water.

Combination of the water degassing and pre-filling of the system with carbon dioxide allowed the flow of water to be measured through a tip with a square $6\ \mu\text{m} \times 6\ \mu\text{m}$ opening.

Obtained values of the hydraulic resistance were 0.7 times smaller than theoretical values. The values of Reynold number and entrance length suggest fully developed laminar flow. At this point, it is rather uncertain whether the differences in the hydraulic resistance were caused by the heating of the system as for the water flow measured through the 3 NADIS probes without the tip or if it was due to an effect connected with presence of the tip.

The water flow measurement through smaller tip apertures required longer lasting measurements. Large time periods required to obtain repeatable flow read-outs through openings smaller than $1.78\ \mu\text{m}$ in diameter were held responsible for allowing the gas bubbles to plug the system and prevent the measurements. It is suspected that the geometry of the tip is enhancing the plugging effect.

The fluid flow measurements through the NADIS probes were designed to determine if the theoretical model created in Chapter 3 adequately predicts fluid behavior. The theoretical

model was based on a few assumptions:

1. the flow is a fully developed laminar flow;
2. the Knudsen number is in the range of 0.001 to 0.1;
3. there is no slip flow effects;
4. the fluids behave like incompressible Newtonian fluids;
5. the walls of the channels are smooth and straight; and
6. the heat transfer and energy dissipation is negligible.

These assumptions permitted a very simple analytical solution to be found. However, their presence caused quite significant deviation of the model when the flow of gases was measured. Nevertheless, for the water flow measurements, the theoretical model proved to be realistic and it could be used as an indication of the flow rate through systems with small tip apertures.

Based on the above conclusion, values of the pressure pulses required to inject a specific amount of liquid into a cell were calculated theoretically. It is clear that due to the large spectrum of assumptions used in the calculations, the parameters found contain a rather large uncertainty. However, it should be noted that the prediction from chapter 3 of the volume of liquid that can be injected into a single cell without causing damage varies from 5 fL to 400 fL resulting in a large variation of volume allowed to be injected. Thus, although knowledge on the amount of liquid ejected from the tip opening is theoretical, it is assumed to fall within the required volume range.

5.5 Conclusions

The AFM-based microinjection system was assembled and characterized. First, the spring constant of the NADIS probes was experimentally determined. The cantilever stiffness was higher compared to the values assigned in the design. The difference was caused by two factors: the free length of the cantilever and the cantilever height. Based on the measured spring constant values, it was decided to use single beam NADIS probes with spring constants lower than 7 N m^{-1} for the cell injection experiments.

Filling the system with liquid was tested through measurements of the cantilever resonance frequency. It was found that due to the water presence in the cantilever, a decrease in the resonance frequency of 26 kHz in average can be measured. This method was critical in determining whether the probes were correctly filled with liquid, or blocked due to residues or gas bubbles.

Chapter 5. AFM – based microinjection system: assembly and characterization

Water flow measurement through NADIS probes with tip openings smaller than $1.78\ \mu\text{m}$ in diameter resulted in system blockages; therefore, the theoretical model was used as indication of the flow rate through systems with small tip apertures.

6 AFM-based microinjection system: biophysical analysis of probe indentation

6.1 Introduction: Mechanical penetration of a cell membrane

In order to deliver liquid into a cell via an AFM tip, it is crucial to understand the complex tip-cell interactions. These interactions have been studied via ‘force spectroscopy’ as a function of the tip-sample distance. The results are shown on a force-distance curve, which gives the force on the tip at each point as it approaches (or is withdrawn) from an object. A typical curve for a hard surface is shown in Figure 6.1a): when the AFM tip is far from the surface there is no force on the tip. When the tip is in contact with the surface a rapid increase in the force is observed (vertical line on the graph). If instead of a hard substrate one uses a living cell, the shape of the force- distance curve changes (Figure 6.1b)) due to the viscoelastic properties of cell. When the tip touches the cell and applies a force, the cell deforms. As the force applied increases, so does the deformation [97]. Analysis of the force-distance curve allows this deformation to be correlated with the mechanical properties of the cell and its elastic modulus to be calculated [35].

Figure 6.1: Force-distance curve measured on a hard substrate a), on a cell b), c) and d). Curves c) and d) have force ‘peaks’ (force drops) known to be the footprints of the cell membrane penetration.

Force-distance curves for cell deformation sometimes show an abrupt drop in the force observed on the AFM tip as shown in Figure 6.1c). This peak, clearly indicating a discontinuity

Chapter 6. AFM-based microinjection system: biophysical analysis of probe indentation

in the cell-tip interactions, has been associated with penetration of the cell membrane by the AFM tip [41, 42, 49, 98]. However, while Figure 6.1c) is representative of many force-distance curves observed for cell deformation, much more complex curves are also obtained: an example is shown in Figure 6.1d). This complexity can be understood as resulting from the complexity of the eukaryotic cell, which contains a complex cytoskeleton and a large number of organelles (Figure 6.2). Thus abrupt changes in the force-distance curve may be caused by membrane penetration, but it is also possible that movement of organelles or elements of the cytoskeleton within the cell may change the local mechanical regime [97].

Figure 1-30 Molecular Biology of the Cell 5/e (© Garland Science 2008)

Figure 6.2: Schematic of an animal cell and its components [63].

If the AFM-based microinjection is to be well-controlled the tip insertion mechanism should be understood. In this chapter experiments to study AFM tip interactions with the cell membrane will be described and discussed. The results obtained have been divided into the following aspects:

1. Determination of tip insertion into the cell:

To date it has been assumed that when the AFM tip breaks the cell membrane, this can be observed in the force-distance curve as an abrupt force drop or peak and that all such peaks imply penetration of the cell. However, given the complexity of the tip-cell interactions, it is worth asking if every peak is indicative of penetration and how to determine true tip insertion.

2. Probability of cell membrane penetration:

Once a method of determining the penetration is defined; the probability of cell pene-

6.2. How to determine cell membrane penetration

tration can be quantified. The probability depends on several factors like: tip sharpness applied force, and cell morphology. Influence of these factors is shown and discussed.

3. Analysis of probe indentation with 5A method:

Force-distance curves contain more information than just that of penetration. Little attention has been given to analysing and understanding this information. Here the force-distance curve analysis is brought further. Five possible parameters that can be read from a force-distance curve are discussed here and called the 5 parameter analysis (5A). Breakage of the cell membrane under different experimental conditions is described here with the 5A method.

4. 5A analysis of actin cytoskeleton modifications:

In this study the analysis of cells with modified and unmodified actin cytoskeletons is presented and applications of the 5A method for single cell studies are discussed.

6.2 How to determine cell membrane penetration¹

To insert the tip inside the cell, the tip has to rupture the plasma membrane that encloses the cell. The plasma membrane is a fluid-lipid bilayer spanned with transmembrane proteins and held together by interfacial-hydrophobic interactions and van der Waals interactions [63] (Figure 6.3).

Figure 10-1c Molecular Biology of the Cell 5/e (© Garland Science 2008)

Figure 6.3: Drawing of three-dimensional view of a cell membrane [63].

When the membrane is “subjected to a persistent tension, an unstable (nanoscale) hole will emerge at some time to cause a rupture” [99]. In this way an AFM tip can cause membrane rupture during cell indentation. As the indentation is monitored via the ‘force spectroscopy’, the rupture event is registered as an abrupt force drop on the force-distance curve. However, during an indentation experiment, a force drop might also occur due to other reasons – for example, tip interactions with membrane proteins, and not necessarily due to rupture. The

¹“Proof of a cell membrane penetration with an AFM tip on a force-distance curve.” J. Bitterli, S. Ahmed, M. Giazzon, N. Matthey, Ph. Renaud, M. Liley; manuscript in preparation.

Chapter 6. AFM-based microinjection system: biophysical analysis of probe indentation

open question is: When does a force drop (a peak) indicate cell rupture? In the literature, Kagiwada et al. [98] decided that for their experimental conditions the success of tip insertion was measured for force drops larger than 500 pN, Obataya et al. [41] used 100 pN as a rupture threshold. Other authors [42, 47, 49, 97, 100] considered only whether the force drop is present or not. A consistent definition of a penetration peak is required in order to produce consistent data on tip insertion into living cells. Here the criteria and possibility of such a definition are assessed.

6.2.1 Analysis of tip insertion

A hypothesis is proposed based on the assumption that when an AFM tip ruptures the cell membrane and passes from outside the cell to inside of it, a change in elastic modulus should occur and that this change should be observable on the force-distance curve. Thus, the penetration of the cell membrane occurs when both a force drop and an elasticity change are measured.

This hypothesis was tested experimentally by bringing AFM tips into contact with a large number of living cells and by analyzing the resulting force-distance curves.

Force spectroscopy measurements were carried out on individual live human osteosarcoma cells from the SaOs-2 cell line. In total 350 cells were investigated with applied forces varying from 1 nN to 18 nN (50 cells per condition, each indented only once). Two different tip types were used: commercially available probes with sharp tips with a tip radius of 10 nm, and NADIS probes with a mean tip radius value of 100 nm (the tip radius can vary from 50 nm to 150 nm). The obtained 350 force-distance curves obtained were converted into force-separation curves.

Two parameters were extracted from each curve: the force drop (Figure 6.4a)) and the change in elastic modulus (ΔE) associated with each force drop. A force drop was considered to be present when its value was higher than 3 times the standard deviation of the noise. To measure ΔE the curve was divided into two regions, the first region-before the peak up to its apex (region A-B in Figure 6.4b)) and the second region C-D (marked black) after the force drop. An elastic modulus (Young's Modulus) was fitted to the first region using a Herzian model for pyramidal tips. Then, the C-D region of the curve was displaced, so that point C meets point B (Figure 6.4c)). When the elastic modulus fitted to the first region does not follow the second region of the curve, as shown in the example, a change of the elastic modulus occurred. Figure 6.4d) shows the same curve with two elastic modulus fits, E_1 and E_2 . The E_1 fit shows the elastic modulus before the force drop. The elastic modulus after the peak is determined using the same baseline and contact point as for E_1 . In the example shown E_1 has a larger value than E_2 showing elasticity decrease after the force drop.

Based on the above method, the 350 force-separation curves were classified into 4 characteristic types (Figure 6.5).

Type I curves (Figure 6.5a)) show no Force drop (F_d is smaller than 3 times the standard

6.2. How to determine cell membrane penetration

Figure 6.4: Force-separation curve with a Force drop a), divided into two regions (red and black). An elastic modulus fitted to the red part b). Displaced black part of the curve does not follow the fit c). The elasticity fit for both regions shows the decrease in elasticity after the force drop, $E_1 > E_2$.

Figure 6.5: Type I force-separation curve with no change in elastic modulus and no Force drop (F_d) a) Type II, with no change in the elastic modulus but a force drop b) Type III, with a decrease in elastic modulus and a force drop c) Type IV, with an increase of elastic modulus and a force drop d).

deviation of the noise, σ) and no change in elastic modulus and are known in the literature as the indentation curves.

Type II curves have a Force drop but no change in the elastic modulus (Figure 6.5b)).

Type III curves have a Force drop and show a decrease in elastic modulus after the peak (Figure 6.5c)).

Type IV curves have a Force drop and show an increase in the elastic modulus after the peak (Figure 6.5d)).

Once the curves had been classified, a comparison was made of the percentage of each curve type obtained for the different tip and force conditions of the measurement. Figure 6.6 presents the results. Figure 6.6a) shows the results obtained for the 10 nm sharp tips at forces of 1 nN, 3 nN and 5 nN, while Figure 6.6b) shows the results for 100 nm sharp NADIS tips at forces of 3.5 nN, 7 nN, 13.5 nN and 18 nN. It can be seen that in both cases, when the force increases the percentage of the type I curves, ('indentation curves'), decreases and the percentage of

Chapter 6. AFM-based microinjection system: biophysical analysis of probe indentation

the type II and type III curves increases. The percentage of the type IV curves seems to not depend on the applied force for both 10 nm and 100 nm tip sharpness.

Figure 6.6: Chart showing distribution of the force distance curves as a function of maximum applied force for 10 nm sharp tip a) and 100 nm sharp tip b).

As the number of curves with peaks (type II to IV) increases with the applied force for both tip types, it is assumed that the peak is associated with penetration. Within these curves, the curves with a change in elastic modulus (type III and IV) dominate. This is especially the case for the 10 nm tip radius. The data tends to confirm the hypothesis that tip indentation is usually associated with a change in elasticity. However, it is not clear that a change in elasticity is 'required' to determine tip penetration. Further investigation with direct evidence of tip insertion by transport of material into the cell will be presented in Chapter 8.

During the experiment a 'blunt tip effect' was observed caused by the cell residues (e.g. cell membrane, and also internal components of the cell due to the tip insertion) attaching to the tip apex. Each time a tip was brought in a contact with the cell, a small amount of residue was transferred to the tip. After a significant number of cell indentations the tip apex was covered with residues causing an increase in the tip radius. To understand this effect the tips were investigated with SEM after different numbers of cell indentations. It was found out that for 10 nm sharp tips the 'blunt tip effect' can significantly influence the measurements after 50 indentations. For 100 nm sharp NADIS tips this effect was significant after more than 100 indentations. The difference between these tip types might arise from the fact that the 10 nm sharp tip penetrates the cell membrane more often than the NADIS probe, increasing the probability of the residue transfer from the cell to the apex and also from the fact that a smaller tip is more sensitive to residue accumulation. For the final measurements each 10 nm sharp tip was used for maximum 50 and NADIS tip was used for maximum 100 indentations. Figure 6.7 presents SEM images of two NADIS tips before and after indentations. It was concluded that the amount of cell residues depends more on the amount of cell indentations than on the applied force.

6.3. Probability of cell membrane penetration

Figure 6.7: SEM micrograph of two NADIS tips are presented before and after cell indentation experiments. a) First NADIS tip before measurements, b) after 50 indentations with an applied force of 3.5 nN, and c) after additional 50 indentations with the applied force of 7 nN. D) Second NADIS tip before measurements, e) after 50 indentations at applied force of 13.5 nN, and f) after additional 50 indentations at applied force of 18 nN.

6.2.2 Proposed specifications of tip insertion

Given the previous discussion and analysis of the force drop and elasticity change the following definition of cell membrane penetration with an AFM tip will be used throughout this thesis.

First, the presence of the Force drop is defined as being when the height of a peak is higher than 3 times the standard deviation of the noise:

$$F_d > 3\sigma \quad (6.1)$$

Second, an elasticity change has to occur after the force drop:

$$E_1 \neq E_2 \quad (6.2)$$

Table 6.1 summarizes the conditions for which a tip will be considered to indent or penetrate a cell.

6.3 Probability of cell membrane penetration

As the conditions required to determine cell membrane penetration have been defined, the probability of cell membrane penetration can be measured. Penetration of cell membrane

Chapter 6. AFM-based microinjection system: biophysical analysis of probe indentation

Table 6.1: Tip–cell membrane interaction determined by the Force drop and the change in elastic modulus.

Cell indentation		Cell penetration	
Type I	Type II	Type III	Type IV
$F_d < 3\sigma$	$F_d > 3\sigma$	$F_d > 3\sigma$	$F_d < 3\sigma$
$E_1 = E_2$	$E_1 = E_2$	$E_1 > E_2$	$E_1 < E_2$

can be expected to depend on many parameters such as: the tip sharpness [41], the applied force [100], the position (above nucleus or cytoplasm) [42, 97], and cell morphology [42, 98].

6.3.1 Influence of tip sharpness

In this study the force spectroscopy measurements used to analyze tip insertion in Section 6.2.1 were used to demonstrate influence of the tip sharpness. In total 350 force-separation curves were obtained with two tip types: 10 nm sharp tips and 100 nm sharp NADIS tips, for applied forces varying from 1 nN to 18 nN, and SaOs-2 cells seeded on a Petri dish. For both probes, the total travel distance of the cantilever was the same – 10 μm (approach and retract motion) and the speed was 2 $\mu\text{m s}^{-1}$. The tip position was always above the nucleus. The data were completed with additional 50 force-distance curves measured with 10 nm sharp tip and applied force of 15 nN.

The results are presented in the form of a graph (Figure 6.8e)). The result for the 10 nm sharp tips at forces of 1 nN, 3 nN, 5 nN and 15 nN are marked with blue dots while the results for 100 nm sharp NADIS tips at forces of 3.5 nN, 7 nN, 13.5 nN and 18 nN are marked with red dots. Probability of cell membrane penetration with 10 nm sharp tip for the maximum applied force of 15 nN is more than 90 %. When the 100 nm sharp NADIS probe is used at maximum applied force of 18 nN the probability is found to be less than 50 %.

The result confirm the expectation that the sharper the tip apex the higher the probability of the cell membrane penetration.

6.3.1.1 Force distance–curves with multiple force drops

Within the experimental results force-distance curves with multiple force drops were found (Figure 6.9).

The experimental data were analyzed in terms of the number of force drops and their dependency on the applied force. Table 6.2 shows the results. It was observed that the number of force drops (F_d) depends on both the applied force and the tip sharpness. The higher the applied force and the sharper the tip, the larger the number of force-distance curves with multiple force drops.

6.3. Probability of cell membrane penetration

Figure 6.8: SEM images of a) sharp tip with 10 nm radius a) and NADIS tip with 100 nm tip radius b). Schematic drawing of tip geometry for c) 10 nm sharp tip and d) 100 nm sharp tip. e) a graph showing the probability of cell membrane penetration as a function of applied force for the two types of tip.

Table 6.2: Tip–cell membrane interaction determined by the Force drop and the change in elastic modulus.

Applied Force	10 nm tip				100 nm tip				
	0 F_d	At least F_d	At least $2 F_d$	At least $3 F_d$	Applied Force	0 F_d	At least $1 F_d$	At least $2 F_d$	At least $3 F_d$
1 nN	96 %	4 %	0 %	0 %	3.5 nN	96 %	4 %	0 %	0 %
3 nN	60 %	40 %	2 %	0 %	7 nN	86 %	14 %	6 %	0 %
5 nN	16 %	84 %	48 %	28 %	13.5 nN	64 %	36 %	16 %	2 %
15 nN	8 %	92 %	52 %	34 %	18 nN	56 %	44 %	16 %	6 %

Force–distance curves with more than one force drop have been already described in the literature [42, 45, 97]. As the first force drop is always attributed to the penetration of the cell membrane, the origin of the other force drops is still not confirmed. It has been suggested that the presence of the second and further force drops could be explained by penetration of the nuclear membrane [97]. Since there is not enough evidence confirming or rejecting this possibility, it will be considered during the cell injection experiments using NADIS probes in chapter 8.

In order to inject biomaterial into the cytoplasm, the tip should penetrate the cell membrane. Penetration of further membranes might result in injection into the nucleus or another organelle, potentially damaging the cell. The choice of applied force therefore needs to be based on a compromise between high probability of tip insertion and probability of obtaining only one force drop on the force–distance curve.

Figure 6.9: Example of a force–separation curve with 1 force drop a), 2 force drops b), 3 force drops c) and at least 3 force drops d).

6.3.2 Influence of cell–surface interactions

In these experiments, the probability of cell membrane penetration for the SaOs-2 cells seeded on three types of substrates was measured. The first substrate was a plastic Petri dish. The second substrate was glass coated with fibronectin, and the third type was glass patterned with PLL-g-PEG/fibronectin spots. On the patterned substrate, the fibronectin spots were circular with a diameter of $45\ \mu\text{m}$; the pitch between the discs was $130\ \mu\text{m}$. The entire surrounding surface was PLL-g-PEG, a surface chemistry which discourages cell spreading.

Cells on a Petri dish (Figure 6.10a) or on a glass surface coated with fibronectin (Figure 6.10b)) have more space to spread in all directions. The resulting cells have a heterogeneous morphology and a large area in contact with the substrate. In contrast, on the glass surface patterned with PLL-g-PEG/fibronectin spots (Figure 6.10c)) the cells are spatially restricted in the area in which they can grow. It can be seen that the cells have a round morphology with the dimensions of the spot size.

Figure 6.10: Cells viewed via phase contrast microscopy on: a) a Petri dish, b) a glass surface homogeneously coated with fibronectin, and c) on $45\ \mu\text{m}$ diameter PLL-g-PEG/fibronectin spots.

The comparison study was initially done with the 100 nm NADIS tips and an applied force of 20 nN. The tip insertion probability for cells grown on the Petri dish substrate was measured to be 50 %. However on the glass substrates patterned with PLL-g-PEG/fibronectin spots the

6.3. Probability of cell membrane penetration

probability was 0 %. Increasing the applied force to 100 nN did not change this: the tip still did not penetrate the cell membrane.

When commercially available probes with 10 nm sharp tips were used, the penetration events were observed. A comparison study for all three culture surfaces was therefore done for the 10 nm sharp tips and a constant applied force of 5 nN. The results are presented in Table 6.3. The highest probability of tip insertion (84 %) was measured for cells grown on the Petri dish substrate. Very similar penetration probabilities were observed for glass surfaces coated with a uniform coating of fibronectin (55 %) and with a pattern of fibronectin spots in a PLL-g-PEG background (54 %).

Table 6.3: Probability of cell membrane penetration for cells seeded on 3 types of substrates.

		Percentage of penetration events of SaOs-2 cells grown on:		
Tip Sharpness	Applied force	Petri dish	glass coated fibronectin	glass patterned with PLL-g-PEG/fibronectin spots
10 nm	5 nN	84 %	55 %	54 %
100 nm	20 nN	50 %	-	0 %

The results show that very different probabilities of penetration can be found depending on the chemistry of the cell culture substrate. However, these differences are not necessarily linked to the morphology of the cells. Cell morphologies on the Petri dish and glass coated with fibronectin are similar but the penetration probability is much higher for cells seeded on Petri dish. The morphologies of the cells on the uniform fibronectin surface and on the fibronectin spots are very different, but the penetration probabilities are almost identical. These results suggest that the penetration probability depends not only on cell morphology but on cell–surface interactions in general.

6.3.3 The influence of ethylenediaminetetraacetic acid (EDTA)

The probability of tip insertion into cells on glass coated with fibronectin and glass patterned with PLL-g-PEG/fibronectin spots was further studied. The SaOs-2 cells were seeded on the two types of substrates with medium containing (25 mmol of EDTA (details in chapter 2, section 2.5). EDTA is a chelator; it binds to metal ions like Ca^{+2} and makes them unavailable for cells. It has been shown that EDTA induces denaturation of G-actin [101–104] and F-actin [102, 104], that make up the actin cytoskeleton.

Probability of cell membrane penetration was measured with 10 nm sharp tip and the same experimental conditions as in section . Obtained results were compared with the probability of tip insertion on samples not treated with EDTA (described in section) as presented in Table 6.4 . It is shown that addition of EDTA into the cell media changes the probability of tip insertion into cells. For cells spread in all direction on glass coated with fibronectin addition of EDTA decreases the probability from 55 % to 36 %. However, when cells are spatially restricted in the

Chapter 6. AFM-based microinjection system: biophysical analysis of probe indentation

area on the PLL-g-PEG/fibronectin spots the probability increases from 54 % to 75 % after the addition of EDTA.

Table 6.4: Probability of cell membrane penetration for cells treated and without EDTA treatment. Percentage of penetration events of SaOs-2 cells with 10 nm sharp tip and applied force of 5 nN

Treatment	glass coated with fibronectin	glass patterned with PLL-g-PEG/fibronectin spots
No EDTA	55 %	54 %
With EDTA	36 %	75 %

Kagiwada et al.[98] showed that the cell actin cytoskeleton of plays a significant role in probability of tip insertion. The actin skeleton consists of actin mesh and stress fibres. It has been shown that actin mesh, localized under the cell membrane, has a direct influence on the cell membrane penetration and the stress fibres might facilitate the insertion by giving the cell a mechanical stability.

It is known that EDTA influences G- and F-actin. However its effect on the actin cytoskeleton of the SaOs-2 cells in general is not yet understood. Taking into consideration results presented by Kagiwada et al. [98] it is possible that EDTA has modified the actin cytoskeleton of the SaOs-2 cells which influenced the penetration probability.

6.4 Analysis of probe indentation: 5A method ²

Force-distance curves contain more information than just that of tip insertion. When an AFM tip penetrates a cell, additional information can be extracted from the force-distance curve. Yokokawa et al. [97] extracted a 'penetration force' parameter from the force-separation curves and showed its analysis. Kim et al. [42] discussed a 'penetration distance' parameter. Kagiwada et al.[98] and Obataya et al.[41] discussed a 'force drop' parameter. In this section five parameters that can be read from a force-separation curve are described. The parameters are further used in a simple biophysical analysis of the cell membrane penetration for different experimental conditions. As the analysis is based on the 5 parameters therefore the name is: 5 parameter analysis (5A).

6.4.1 Description of the 5A method

The five parameters were divided into two groups, macro and microparameters.

²"Analysis of approach curve after cell membrane penetration with a 5A method." J. Bitterli, A. Meister, S. Ahmed, M. Giazzon, N. Matthey, Ph. Renaud, M. Liley; manuscript in preparation.

6.4.1.1 Macroparameters

The macroparameters are presented in the Figure 6.11. The tip is brought in contact with a cell and starts to deform the cell, until its membrane ruptures. The cell deformation is called the penetration depth, D_1 , and gives information on how far the tip indented the cell before the rupture. Force at which the rupture was detected is called the penetration force, F_1 . After the penetration the tip continues to indent the cell until the force reaches the value of the force setpoint. Cell indentation measured from the contact point till the maximum indentation point is called the indentation depth, D .

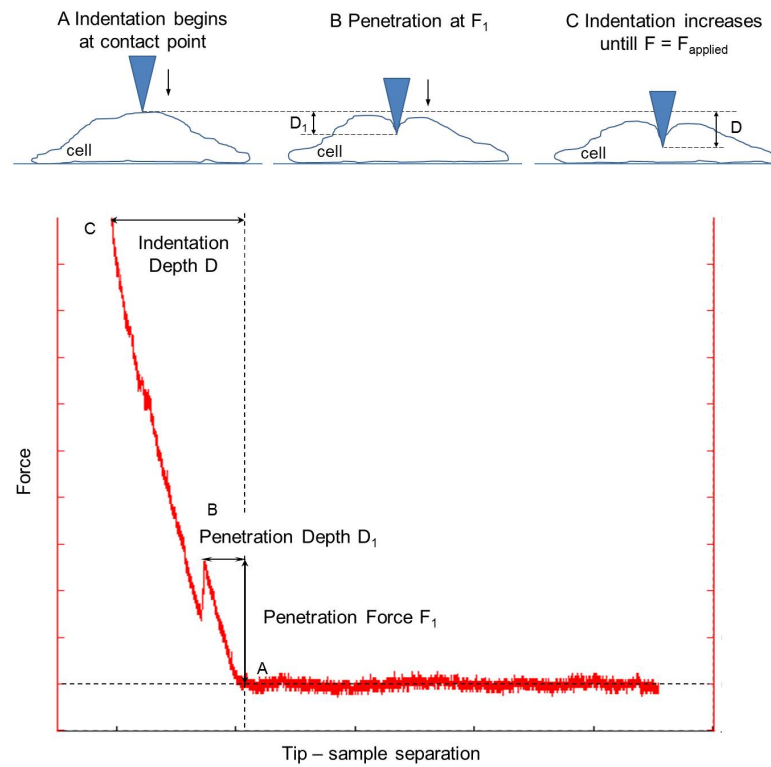

Figure 6.11: Schematic representation of the macroparameters and their representation on a force-separation curve.

Table 6.5 contains a summary of the parameters with their definitions

6.4.1.2 Microparameters

Figure 6.12a) shows a schematic representation of the AFM tip indenting and penetrating the cell. Figure 6.12b) shows a detailed representation of the tip interacting with the cell membrane during penetration: A) just before the membrane is ruptured by the tip and B) just after the rupture. The distance that the membrane slips along the AFM tip is given by d , the membrane slip parameter. The force F_1 felt by the tip is due to deformation of the cell and stretching of the cell membrane, and the change in the force to F_2 is due to relaxation of the

Chapter 6. AFM-based microinjection system: biophysical analysis of probe indentation

Table 6.5: Macroparameters and its definitions

Parameter	Symbol	Definition
Indentation Depth	D	Cell deformation, measured on the z-axis from the contact point until the maximum deformation point.
Penetration Depth	D_1	Deformation of the cell, measure on the z-axis from the contact point until the rupture point.
Penetration Force	F_1	Force at which rupture occurred

membrane on rupture. A very simple mechanical model of this interaction is presented on Figure 6.12c). The cell is represented by a spring with a known rigidity k_c . Directly after the membrane rupture the rigidity of the cell changes due to the membrane relaxation to k'_c .

Based on this simple elastic model force, the force, F acting on the cell can be described as:

$$F = k_c x \quad (6.3)$$

where, k_c is the cell rigidity and x is the cell indentation caused by the force. The force acting on the cell, causing cell membrane penetration is defined as:

$$F_1 = k_c D_1 \quad (6.4)$$

Where D_1 is the penetration depth – a measure of how much the cell was indented before its membrane broke (a macroparameter presented in the nsection above).

After rupture the measured force acting on the tip has decreased:

$$F_2 = k'_c (D_1 - d) \quad (6.5)$$

where, k'_c is rigidity of the cell after the tip insertion, and d is a measure of how much the membrane moved up on the tip after rupture, called the membrane slip.

To a first approximation, the changes in cell rigidity due to tip insertion are negligible:

$$k'_c(D_1) = k_c(D_1 - d) \quad (6.6)$$

6.4. Analysis of probe indentation: 5A method

Figure 6.12: Schematic representation of an AFM tip indenting the cell to the point where the cell membrane breaks at measured penetration force F_1 and penetration depth D_1 a). Directly after cell membrane rupture the measured force decreases to value F_2 and the broken cell membrane moves up to distance d b). Membrane rupture described with a mechanical model. The cell is represented by a spring with known rigidity k_c c).

The difference in the force before and after the cell membrane penetration, the force drop F_d , is therefore described as:

$$F_d \equiv F_1 - F_2 = k_c d \quad (6.7)$$

The ratio of the force drop F_d to the penetration force F_1 is therefore directly proportional to the membrane slip d over the penetration depth D_1 :

$$\frac{F_d}{F_1} = \frac{d}{D_1} \quad (6.8)$$

Figure 6.13: Force–distance curve showing dependency between the force drop F_d and the penetration force F_1 to the membrane slip d and the penetration depth D_1 .

Figure 6.14 presents the force-distance curve with two parameters: force drop F_d and membrane slip d . These two parameters are called microparameters as they describe tip interacting with the breaking cell membrane, compared to the macroparameters which describe cell deformation during tip insertion.

Figure 6.14: Schematic representation of the microparameters on a force–separation curve.

6.4.2 5A analysis of probe indentation

The 5A method was first applied to analyse the indentation results presented in section . In total, 400 force-separation curves were obtained on SaOs-2 cells seeded on a Petri dish with two tip types: 10 nm sharp tips with tip half angles of 25° and 100 nm NADIS tips with tip half angles of 35°, for applied forces varying from 1 μm to 18 μm . The force-separation curves were previously analysed in terms of probability of cell membrane penetration. In the present section the 5A method is used to bring the analysis of the curves further and understand the dependence of the 5 parameters on the tip geometry.

Figure 6.15 shows an analysis of the indentation depth parameter (D) for the two tip types. The results are presented as histograms. Figure 6.15a) shows the histograms for 10 nm sharp tips at forces of 1 nN, 3 nN, 5 nN and 15 nN and 100 nm NADIS tip at forces of 3.5 nN, 7 nN, 13.5 nN and 18 nN. The same results are shown in Figure 6.15b) in the form of a graph of the indentation depth versus the applied force for the two tip types. Values of the indentation depths are average values obtained from the histograms and the error bars are sample standard deviations of these values. It can be seen that in both cases, when the force acting on the cell increases the indentation depth increases as well. Comparison of the indentation depth for the 10 nm and 100 nm sharp tips shows a dependency of the indentation depth on the tip geometry: the smaller the tip radius and the tip half angle the higher the indentation depth.

Figure 6.16 shows penetration depth (D_1) and penetration force (F_1) for 10 nm sharp tips and 100 nm NADIS tips. A statistical analysis of the results showed no significant difference between the penetrations depths measured for the two tip types. However, there is a difference between the penetration forces. The penetration of a cell membrane with 10 nm sharp tip requires a little over half as much force compared to the 100 nm sharp tip. As a result in order to penetrate a cell membrane of a SaOs-2 cell a 10 nm sharp tip has to first indent the cell to 1.16 μm depth and apply a force of 2.5 nN, whereas a 100 nm sharp tip has to apply 4.4 nN to obtain a similar indentation and penetration (Figure 6.17a)).

Chapter 6. AFM-based microinjection system: biophysical analysis of probe indentation

Figure 6.15: Comparison of indentation depth results obtained for 10 nm and 100 nm sharp tips, presented in the form of a) histograms, and b) a graph. The bullets on the graph are average values presented on the histograms, and the error bars show sample standard deviation of the values.

6.4. Analysis of probe indentation: 5A method

Figure 6.16: Comparison of a) penetration depth (D_1) and b) penetration force (F_1) histograms for 10 nm sharp tips and 100 nm NADIS tips. Values on the histograms represent average values and their sample standard deviations. (* $p < 0.05$).

Figure 6.17: Schematic of cell membrane rupture with 10 nm and 100 nm sharp tip. a) shows the influence of the tip geometry on the penetration force F_1 and penetration depth D_1 . b) shows the influence of the geometry on the force drop F_d and the membrane slip d .

Chapter 6. AFM-based microinjection system: biophysical analysis of probe indentation

Figure 6.18a) shows an analysis of the force drop parameter F_d . It can be seen that cell membrane rupture with 10 nm sharp probes results in a force drop F_d twice as high as that of the 100 nm NADIS tip. Higher force drop is caused by larger cell membrane relaxation after the membrane breakage, which is possible due to the geometry of the 10 nm sharp tip. The influence of the tip geometry on the membrane rupture is also shown on the graph (Figure 6.18b)), where the force drop F_d is plotted as a function of penetration force F_1 . Results obtained for 10 nm sharp tip are marked with red points; the blue points show 100 nm NADIS tip results. It can be seen that cell membrane rupture with the sharp tips occurs at low penetration forces F_1 and high force drops F_d , whereas for the NADIS tips the penetration forces F_1 are large and the force drops F_d are small. This is also schematically shown on the Figure 6.18b).

Figure 6.18: Comparison of the Force drop F_d for two 10 nm sharp tips and 100 nm NADIS tips (* $p < 0.05$) a). Graphical representation of the force drop F_d dependence on the penetration force F_1 for the two tip types b).

Figure 6.19 shows histograms of the membrane slip parameter d for the two tip types. It can be seen that breakage of a cell membrane with the 10 nm sharp and 25° half angle tip results in 250 nm membrane slip along the tip, while with the 100 nm sharp and 35° half angle tip the value is 3 times smaller. The influence of the tip geometry on this parameter is schematically shown on Figure 6.17b). The higher the membrane slip, the larger is the membrane relaxation.

The slippage of the membrane upwards the tip during the membrane rupture measured with the d parameter was described with the simple elastic model presented in section . This model was used to derive the relationship that the ratio between the force drop F_d and penetration force F_1 should be equal to the ratio of the membrane slip d and penetration depth D_1 :

$$\frac{F_d}{F_1} = \frac{d}{D_1} \quad (6.9)$$

Figure 6.19: Comparison of the membrane slip parameter d (* $p < 0.05$).

If this is true then F_d/F_1 divided by d/D_1 should be equal to 1 on every force distance curve:

$$\frac{F_d D_1}{F_1 d} = \frac{d}{D_1} \tag{6.10}$$

Figure 6.20a) and b) shows graphs presenting F_d/F_1 and d/D_1 in the form of points measured for each force-separation curve. Figure 6.20a) shows these ratios for 10 nm sharp tips. Figure 6.20b) shows these ratios for 100 nm NADIS tips. A statistical analysis of the approach curves showed that there were no significant differences between the F_d/F_1 and d/D_1 ratios for the 10 nm sharp tips and in contrast significant differences were found for the approach curves obtained with the 100 nm NADIS tips.

Figure 6.20c) and d) show histograms of the ratio of F_d/F_1 to d/D_1 obtained for each force-separation curve in the form of histograms. Figure 6.20c) shows the histogram for 10 nm sharp tips and Figure 6.20d) for 100 nm sharp tips. There is a clear difference between the two histograms: Figure 6.20c) is close to a normal distribution with a mean slightly higher than 1 (1.15); Figure 6.20d) has less regularly distributed data a broader distribution and a mean value 1.46.

These results shows that the simple elastic model used to describe the rupture of a cell membrane by an AFM tip is a good model for the 10 nm sharp tip with a 25° half angle and support the concept of a membrane slip parameter d . A value close 1 indicates that the approximation $k'_c(D_1) = k_c(D_1 - d)$ is appropriate: any non-linearity in the membrane

Figure 6.20: Graphical representation of the F_d/F_1 and d/D_1 ratios for a) 10 nm sharp tip and b) 100 nm sharp tip.

response—for example, a rapid stiffening of the system before rupture like a balloon – is small on the length scales relevant for membrane penetration. However, for membrane rupture by the 100 nm NADIS tip (35° half angle tip), the fit to the model is less good. Different factors may play a role here: firstly, the poor reproducibility of the AFM tip size and shape; secondly the membrane slip determined from the model, at 75 nm, is smaller than the nominal tip radius. Further investigation of the relevance of the model using a variety of different tip shapes might contribute to our understanding of the processes involved.

6.5 5A analysis of actin cytoskeleton modifications³

The actin cytoskeleton consists of the actin mesh (or cell cortex) and stress fibres (Figure 6.21). The actin mesh can be found mostly just below the cell membrane – an interaction site of cytoskeleton and the cell membrane [105], whereas stress fibres are located in the entire cell.

Kagiwada et al.[98] showed that actin mesh has a direct influence on the cell membrane penetration, and that stress fibres might facilitate the insertion by giving the cell a mechanical

stability (Figure 6.22). In their experiments they performed cell penetration with an AFM tip on 8 cell types and liposomes and observed that they could insert a tip into all cell types but not the liposomes (Figure 6.22a)). Only the liposomes did not possess actin structures. They concluded that actin structures allow tip insertion and designed further experiments to determine which of these structures have a direct influence on the tip insertion. They showed that the actin mesh has a direct influence on tip insertion. They have measured the probability of cell membrane penetration using cell types with varying sizes of actin meshwork and found that the smaller the actin meshwork the higher the probability of penetration (Figure 6.22b)). The influence of stress fibres on tip insertion is indirect and plays a role in situations when the stress fibres are well developed (Figure 6.22c)).

Figure 6.22: Schematic of a) an AFM tip inserted through a cell membrane with actin mesh undercoat. Without the actin mesh the tip undergoes invagination by a lipid bilayer and cannot penetrate the cell. b) A small size of the actin mesh (denser actin mesh) increased probability of tip insertion. c) diagram explaining how different actin structures influence the penetration probability. All the figures presented here are from Kagiwada et al. [98]

The conclusions of this research group inspired the experimental analysis described in this section. In Section 6.3.1.1 and Section 6.3.2 the dependency of the tip insertion probability on

Chapter 6. AFM-based microinjection system: biophysical analysis of probe indentation

the cell–surface and cell–EDTA interactions were discussed. It was shown that, using a 10 nm sharp tip, the probability of cell membrane penetration of SaOs–2 cells seeded on glass coated with fibronectin, and on glass patterned with PLL-g-PEG/fibronectin spots is the same at 55 %. The addition of EDTA to the medium decreases the penetration probability of cells seeded on glass coated with fibronectin to 36 %, while it increases it to 75 % for cells seeded on the patterned glass.

Table 6.6: Probability of cell membrane penetration (taken from Section 6.3.1.1)

		Percentage of penetration events of SaOs-2 cells grown on:		
Tip Sharpness	Applied force	Petri dish	glass coated fibronectin	glass patterned with PLL-g-PEG/fibronectin spots
10 nm	5 nN	84 %	55 %	54 %
100 nm	20 nN	50 %	-	0 %

To understand the penetration probability results, the force–separation curves were analysed with the 5A method and the cells were stained against F-actin and viewed by confocal microscopy in order to show the organisation of the actin cytoskeleton. A comparative analysis with the 5A method combined with the confocal observations was done for 3 conditions:

1. Cells spread on the glass coated with fibronectin and glass patterned with PLL-g-PEG/fibronectin spots
2. Cells spread on the glass coated with fibronectin, with and without EDTA
3. Cells spread on the glass patterned with PLL-g-PEG/fibronectin spots, with and without EDTA

Based on the results and the conclusion presented by the Kagiwada et al.[98] that actin cytoskeleton is responsible for tip insertion it is proposed that the 5A method allows to measure actin cytoskeleton modifications of single living cells.

6.5.1 Comparative analysis between cells spread on fibronectin and patterned fibronectin

Cells spread on glass coated with fibronectin are allowed physically more space to spread in all directions resulting in a heterogeneous morphology and a larger contact area with the substrate. Cells spread on the glass patterned with PLL-g-PEG/fibronectin spots are spatially restricted in the area in which they can grow resulting in round morphology with dimension of the spot size. Cells on both substrates were stained against F–actin and investigated with confocal microscopy. Figure 6.23 presents single cells at varying z-axis heights. Figure 6.23a) shows a cell spread on the glass coated with fibronectin. It can be observed that the actin cytoskeleton is mostly built up from well-developed thick stress fibres. There is a small amount

6.5. 5A analysis of actin cytoskeleton modifications

of actin mesh present at the upper side of the cell membrane. Figure 6.23b) shows single cell on the glass patterned with PLL-g-PEG/fibronectin spot. A large amount of dense actin mesh can be observed in a ring shape. Stress fibres although present are not as well developed and can only be seen at the bottom of the cell.

Figure 6.23: Cells viewed via confocal microscopy (from z-axis) top to bottom: a) show cell spread on glass coated with fibronectin, b) shows cell spread on glass patterned with PLL-g-PEG/fibronectin spot. Green–Alexa Fluor 488 Phalloidin, marker for Actin.

Further, the cells were stained with DAPI to label cell nuclei. Three parameters were measured by confocal microscopy: the cell height, the nuclear height and the membrane–nucleus distance. Figure 6.24 shows the results. The cells spread on glass coated with fibronectin are in average 4.6 μm high while cells spread on the fibronectin spots are 6.5 μm high. The nuclei of the cells spread on fibronectin are 3.6 μm high, whereas the nuclei of cells spread on fibronectin spots are 5.2 μm high. The distance between the cell membrane and the nucleus is also smaller for cells spread on plain fibronectin. These observations can be explained by the limited area in which the cells on fibronectin spots can grow. As the cells are limited in their spreading potential in the x-y axis, the cells grow in the z-axis.

Based on the distribution of actin structures and measured values of cell and nucleus height, and a membrane–nucleus distance a schematic drawing of cell spread on the glass coated with fibronectin and glass coated with fibronectin spots was made to demonstrate the difference in the distribution of actin mesh and stress fibers. Figure 6.25a) shows a cell spread on the glass coated with plain fibronectin. It can be seen that well developed stress fibers dominate in the actin cytoskeleton. The actin mesh is present only below the upper cell membrane. Figure 6.25b) shows a cell spread on the glass coated with fibronectin spots. The stress fibres are present only on the bottom part of the cell and are not as well developed. The dominating component of the actin cytoskeleton is the actin mesh.

The probability of cell membrane penetration of 50 cells per substrate type in the absence of EDTA was measured in section . Now, the force–separation curves obtained during these experiments were analysed with the 5A method. Table 6.6 presents the results. A statistical

Figure 6.24: Comparison of cell height, nucleus height and membrane–nucleus distance between cells spread on glass coated with fibronectin and glass coated with fibronectin spots. 6 to 8 cells per condition were measured.

Figure 6.25: Based on the confocal microscope measurements a schematic drawing of cell spread on the glass coated with fibronectin a) and cell spread on the fibronectin spot b) was created.

analysis showed no significant difference between the values obtained on the different substrates. Despite the differences in morphology and actin cytoskeleton of cells spread on the glass coated with fibronectin and cells spread on the glass with fibronectin spots the indentation mechanism with 10 nm tip remains the same. First, the tip applies a 2.3 nN force (F_1) to indent the cells to approximately 1 μm depth (D_1) to achieve cell membrane rupture. After the rupture the cell membrane undergoes relaxation causing a force drop (F_d) of 300 pN to 400 pN and the membrane slips (d) around 150 nm up the tip. As the indentation continues to reach the setpoint of 5 nN the tip indents the cells further to reach the same value of indentation depth (D) of 2 μm . For comparison the mechanism of cell membrane rupture for cells spread on the two substrate types is presented in Figure 6.26.

The difference in the cell morphology and actin cytoskeleton of the cells is caused by the area occupied by fibronectin (as the glass used to fabricate the substrates and the fibronectin were the same). Cells spread on plain fibronectin have an actin cytoskeleton dominated mostly by stress fibers and the actin mesh is present only under the upper part of the cell membrane. When a cell is spread on a restricted to a fibronectin spot area this ratio changes, and the actin mesh is a dominating component, whereas the stress fibers are present only on the

Table 6.7: Comparison of penetration probability and the 5A parameters between cells spread on the two substrates. Statistical analysis showed no significant difference between the values.

Measured factors	Cells spread on:	
	glass coated with fibronectin	glass patterned with PLL-g-PEG/fibronectin spots
Penetration probability	55 %	54 %
Indentation depth D	$(1.85 \pm 0.26) \mu\text{m}$	$(1.98 \pm 0.19) \mu\text{m}$
Penetration depth D_1	$(1.17 \pm 0.21) \mu\text{m}$	$(0.94 \pm 0.12) \mu\text{m}$
Penetration Force F_1	$(2.23 \pm 0.43) \text{nN}$	$(2.30 \pm 0.26) \text{nN}$
Force drop F_d	$(310 \pm 60) \text{pN}$	$(443 \pm 58) \text{pN}$
Membrane slip d	$(122 \pm 23) \text{nm}$	$(163 \pm 21) \text{nm}$

bottom of the cell. Surprisingly, the presented indentation analysis shows no difference in the penetration process between cells spread on the two substrates.

6.5.2 Comparative analysis between cells spread on fibronectin, with and without EDTA

In section Section 6.3.2 EDTA was added to the cell medium and decreased the penetration probability from 54 % to 36 %. It was mentioned that EDTA binds to metal ions like Ca^{+2} making them unavailable for cells and inducing denaturation of G-actin [101–104] F-actin [102, 104]. However its influence on the actin cytoskeleton is not yet understood. Measurements of the penetration probability suggest that EDTA has modified the SaOs-2 cells so as to reduce tip penetration.

F-actin staining results of cells with and without added EDTA are shown at varying z-axis heights on Figure 6.27. Figure 6.27a) shows cells without EDTA and Figure 6.27b) shows cell with EDTA. Very little actin mesh is visible at the top of the actin cytoskeletons of cells with EDTA compared to those without. Instead the stress fibres are very well developed and are much thicker compared to the cells without added EDTA.

Additional staining with DAPI was used to measure the cell height, the nuclear height and the membrane nucleus distance. Figure 6.28 shows the results. The average heights of cells and nuclei without EDTA are $4.6 \mu\text{m}$ and $3.6 \mu\text{m}$ respectively and for cells with EDTA these values are $5.8 \mu\text{m}$ and $3.6 \mu\text{m}$ respectively. The value of the membrane–nucleus distance for cells without EDTA is $0.75 \mu\text{m}$ on average. The measured values of this distance for the cells with EDTA were less than $0.5 \mu\text{m}$ - the minimum distance that can be determined by the confocal microscope. Therefore it was assumed that the membrane–nucleus distance for the modified cells was less than this and its value was defined as $0.25 \mu\text{m}$.

Based on the stained actin cytoskeleton and measured values of cell, and nucleus height, and a membrane–nucleus distance a schematic representation of the cells was proposed

Chapter 6. AFM-based microinjection system: biophysical analysis of probe indentation

Figure 6.26: Schematic of cell membrane rupture of a cell spread on a) plain fibronectin and b) on fibronectin spots. A statistical analysis showed no significant difference in the measured values.

(Figure 6.29). Figure 6.29a) shows a cell without EDTA, with well developed stress fibres and well-developed actin mesh under the upper cell membrane. Figure 6.29b) shows a cell with EDTA. The stress fibres are thicker and their presence is even more dominating compared to the previous cell.

The results of the 5A analysis of the force–separation curves together with the penetration probability are presented in Table 6.8. The statistical analysis showed significant differences between the values of 3 parameters: both the indentation depth D and the penetration depth D_1 were measured to be about half as big for the cells with EDTA as for the cells without EDTA. The membrane slip d was measured to be twice as big for the cells with EDTA as for those without EDTA. The penetration force F_1 and the force drop F_d were the same. Figure 6.30 shows a schematic representation of membrane rupture for both cells.

These results show that when a cell is exposed to EDTA membrane rupture occurs at the same penetration force F_1 as for a cell with EDTA but at half the penetration depth D_1 . The membrane breaks despite the fact that the cell is less deformed and the membrane is less stretched. Such conditions seem to be less prone to membrane breakage and could explain decrease of the penetration probability to 36 % compare to unmodified cells.

Stress fibers play an important role in modulating cell elasticity [106] and maintaining cell

6.5. 5A analysis of actin cytoskeleton modifications

shape. Charras and Horton [107] suggested that the stress fibres in addition apply a pre-stress onto the cell interior. The confocal microscopy results showed that stress fibres dominate in the actin cytoskeleton of all cells. In cells with EDTA the stress fibres were more developed and thicker compared to those in cells not exposed to EDTA suggesting higher cell stiffness. This assumption is in agreement with the 5A analysis showing smaller indentation D and penetration depth D_1 for the same applied force compare to cells without EDTA. The much larger force drop F_d might be explained by higher pre-stresses caused by the more prominent stress fibres. As the actin mesh in all the cells was not well developed it was assumed that its influence on the membrane rupture was minor.

6.5.3 Comparative analysis between cells spread on patterned fibronectin, with and without EDTA

In this section differences between cells with and without EDTA on glass with a pattern of PLL-g-PEF/fibronectin spots were analyzed with the 5A method and confocal microscopy. The penetration probability of cells exposed to EDTA increased from 54 % to 75 % compared to cells in the absence of EDTA. F-actin staining results of cells with and without EDTA are shown at varying z-axis heights on Figure 6.31. Figure 6.31a) shows a cell in the absence of EDTA and Figure 6.31b) shows a cell in the presence of EDTA. In both cases the actin mesh is a dominant component of the actin cytoskeleton. The presence of EDTA increases the density of the actin mesh. Stress fibres are present only at the bottom of the cell and are well developed and thicker than stress fibers without EDTA.

Figure 6.32 shows the measured height of the cells, their nuclei, and the membrane-nucleus distances after DAPI staining. Cells treated with EDTA are $8 \mu\text{m}$ high, while untreated cells are $6.5 \mu\text{m}$ high in average. The nuclei of the treated cells are also higher, $6.6 \mu\text{m}$ compared to $5.2 \mu\text{m}$ in untreated cells. The EDTA treatment has also decreased the membrane – nucleus distance from $1.4 \mu\text{m}$ to $0.9 \mu\text{m}$.

6.5. 5A analysis of actin cytoskeleton modifications

Figure 6.30: Schematic of cell membrane rupture of a cell a) without and b) with EDTA.

Based on the confocal observations of actin cytoskeleton and measured values of cell, and nucleus height, and a membrane – nucleus distance a schematic representation of cells was proposed (Figure 6.33). Figure 6.33a) shows a cell in the absence of EDTA and Figure 6.33b) shows a cell with EDTA. Exposure to EDTA increased the density of the actin mesh, and the stress fibres present at the bottom of the cell are better developed and thicker compared to the cell in the absence of EDTA.

The results of the 5A analysis of the force–separation curves and the penetration probability are presented in Table 6.9. The statistical analysis showed significant differences between the values of the microparameters: the force drop F_d and the membrane slip d of the cells with EDTA are significantly higher. The force drop increased from 443 pN to 647 pN and the membrane slip increased from 163 nm to 242 nm. The macroparameters: indentation depth D , penetration depth D_1 and penetration force F_1 are the same for both conditions.

The rupture of the cell membrane measured with the 5A method is presented schematically in Figure 6.34. For an applied force of 2.5 nN both cells undergo an indentation of approximately 1 μm and membrane rupture occurs. The relaxation of the broken cell membrane treated with EDTA is significantly higher as the force drop F_d is larger. Also the cell membrane slips 100 nm more up the tip compared to the untreated cell.

Figure 6.31: Cells spread on the glass coated with fibronectin spots viewed via confocal microscopy (from Z-axis top to bottom: a) cell in the absence of EDTA, b) cell with EDTA. Green –Alexa Fluor 488 Phalloidin, marker for Actin.

Figure 6.32: Comparison of cell height, nucleus height and membrane–nucleus distance between cells unmodified and modified with EDTA. 6 to 8 cells per condition were measured.

Confocal imaging of the actin cytoskeleton showed small amount of stress fibres located mostly at the cell bottom in all the cells, thus their influence on the cell indentation can be expected to be negligible, which is in agreement with the 5A analysis. Although EDTA modifies the stress fibres making them better developed and thicker, this does not change the cell elasticity: an AFM tip with a force of 2.5 nN indents both cells with and without EDTA to the same extent. Confocal imaging of the actin mesh showed denser structures in cells treated with EDTA. This may be visible in the rupture behaviour of the cell membrane. The results of Kagiwada et al. [98] show that a denser actin mesh results in a higher penetration probability. This is in agreement with this result, as the probability of penetration increased from 54 % to 75 % in the presence of EDTA. The larger force drop F_d measured for cells in the presence of EDTA suggests that a denser actin mesh may also influence the membrane relaxation.

6.5.4 Discussion

Kagiwada et al. [98] demonstrated that the size and density of a cell's actin mesh, and amount and level of development of its stress fibers contribute to the efficiency of tip insertion. This study investigated the use of a 5A analysis of force–separation curves of tip insertion to analyse modifications of the actin cytoskeleton. Based on this hypothesis 3 comparative analyses of cell penetration with an AFM tip combined with confocal imaging of actin cytoskeleton were demonstrated.

In the first analysis, the indentation of SaOs-2 cells spread on glass coated with fibronectin and glass coated with fibronectin spots was compared. Confocal imaging of the actin cytoskeleton showed that cells spread on restricted fibronectin spots have actin cytoskeleton consisting mostly of actin mesh while the few stress fibres are present only at the bottom of the cell. The cells spread on the uniform fibronectin surface have large amounts of well-developed stress fibres and the actin mesh is present only under the upper cell membrane. The differences in the proportion of actin cytoskeleton components did not influence the penetration probability and statistical analysis showed no significant differences in any of the values of the 5 parameters. These results show that changes in cell morphology and cytoskeleton are not always reflected in the tip-cell interactions on cell rupture.

The second analysis was of tip insertion into cells spread on a glass surface uniformly coated

Figure 6.34: Schematic of cell membrane rupture of a cell a) unmodified and b) modified with EDTA.

with fibronectin: cells spread on this substrate were analysed in the presence and absence of EDTA, a chelator that binds to metal ions like Ca^{+2} and makes them unavailable for cells. It has been shown in the literature that EDTA denatures G-actin [101–104] and F-actin [102, 104]. Studies of the influence of EDTA on the actin cytoskeleton of single living cells are not available. However, the denaturation of G- and F-actin suggests that EDTA modifies the actin cytoskeleton of cells. The confocal images of EDTA treated cells stained against F-actin presented in this chapter showed better developed and thicker stress fibres compared to untreated cells. In both cases the actin mesh was present only under the upper part of the cell membrane and in small amounts. Despite the fact that the analysis of the confocal images was only qualitative the differences in the actin cytoskeleton were clear.

In EDTA treated cells with an actin cytoskeleton dominated by stress fibres the tip insertion probability was reduced from 55 % to 36 %. Analysis of the force–separation curves and a comparison of the 5 parameter values between untreated and treated cells showed that the EDTA treated cells were stiffer: for the same applied force the indentation depth D was half as big for the treated cells as for the untreated cells. In addition the penetration depth D_1 for the treated cells was half as big as for the untreated cells, while the force drop F_d parameter, which describes cell membrane relaxation after cell membrane rupture, was twice as big for the EDTA treated cells.

It has been shown that the presence of F-actin in cells influences cell elasticity [106, 107] and causes a pre-stress onto the cell interior [107, 108]. It is thus easy to conceive that the increase in the presence of stress fibres could lead to the observed increase in cell stiffness. The reduced penetration depth D_1 can also be associated with the increased cell stiffness and the fact that the penetration force F_1 remains unchanged. Any explanation of the higher value of the force drop F_d , and the reduced probability of penetration is, however, more speculative.

The third analysis concerned tip insertion on cells spread on fibronectin spots on a glass surface: cells in the presence and absence of EDTA were compared. Confocal imaging of the actin cytoskeleton of cells spread on fibronectin spots showed that in such conditions stress fibres are present only on the bottom of the cells and that the actin mesh is the dominant component. EDTA treated cells had denser actin mesh compared to untreated cells.

Analysis of the force–separation curves and comparison of the 5 parameters showed no significant difference between the macroparameters: indentation depth D , penetration depth D_1 and penetration force F_1 . However, a statistical analysis showed significant differences between microparameters: the force drop F_d and the membrane slip d . Both parameters had higher values for EDTA treated cells, indicating larger membrane relaxation and membrane slippage after rupture. The differences in the microparameters was attributed to the EDTA modifications of the actin mesh: a denser actin mesh facilitated tip insertion (in agreement with Kagiwada et al. [98]), membrane slip up the tip and membrane relaxation.

The 5A method presented here can be used to obtain more information about the mechanical characteristics of the tip insertion process. The data presented here suggest the potential of this approach while underlining the complexity of all aspects of the living cell. They are an open invitation to the interested scientist to take this approach further.

One interesting extension of this work would be the investigation of healthy and unhealthy cells using cell penetration experiments and the 5A analysis. In particular, a number of specific diseases have been linked to actin cytoskeleton defects [109]. For example, dystrophic muscle cells, “due to the defects in dystrophin’s ability to link the actin to cell surface” cause muscular dystrophy diseases.

6.6 General discussion

6.6.1 Determination of tip insertion

A hypothesis was proposed for determining when an AFM tip has penetrated a cell membrane based on the assumption that penetration of the cell membrane occurs when a force drop and an elasticity change occur at the same time on a force-separation (f-s) curve. To support this hypothesis cell indentation experiments were performed with 10 nm and 100 nm sharp tips and forces were applied on cells ranging from 1 nN to 18 nN. After analysis of the f-s curves, the curves were classified into 4 types:

Chapter 6. AFM-based microinjection system: biophysical analysis of probe indentation

1. Type I: F-s curves without a force drop, known in literature as indentation curves
2. Type II: F-s curves with a force drop and no change in elasticity
3. Type III: F-s curves with a force drop and a decrease in elastic modulus after the force drop
4. Type IV: F-s curves with a force drop and an increase in elastic modulus after the force drop

For both tip sharpness the number of f-s curves with a force drop increases when the maximum force applied on a cell increases. Since, intuitively, it is expected that the harder the tip presses on a cell membrane the more probable is the cell penetration, it can be assumed that the force drop can be related to membrane rupture (Figure 6.6).

It can be also expected that when a tip passes through a stiff cell membrane into a softer cell cytoplasm an elasticity change should occur as well. Analysis of the elasticity change on the f-s curves with force drop showed that an elasticity change occurred on most of the curves. For the 10 nm sharp tip and the highest force setpoint of 5 nN, 90 % of the f-s curves had characteristic force drops from which only 6.6 % of the curves showed no elasticity change. For the 100 nm NADIS tip and the highest force setpoint of 18 nN, 54 % of the f-s curves had force drops from which 18.5 % showed no elasticity change. The presence of a force drop with no elasticity change might for example be due to interactions of a tip with proteins associated with the cell membrane.

Within the f-s curves with a force drop and a change in elasticity, two types of elasticity change were observed, first, when the elasticity decreases after the tip penetrates the cell (type III f-s curves), and second, when the elasticity increases once the tip is inside the cell (type IV f-s curves). A decrease in the elasticity could be explained by AFM tip breaking a stiff cell membrane and entering in contact with a softer cytoplasm. The f-s curves analysis show that the number of type III f-s curves have tendency to increase with increasing force setpoint for both tip sharpness.

An increase in elasticity (type IV f-s curves) suggests that after the membrane breakage the tip has encountered a stiffer component of the cell. Such a component might be, for example, the nucleus or another organelle. It has been shown [110] that the nucleus can be stiffer than a cell. Thus, it could be possible that when an AFM tip ruptures a cell membrane, it comes directly into contact with a stiff organelle. The percentage of type IV f-s curves is higher for the 100 nm NADIS tip (out of all the f-s curves with a force drop and a change in elasticity, 37 % of the curves were type IV curves, compared to 10 nm sharp tip, where in total only 11 % of the curves were classified as type IV), suggesting an influence of the tip sharpness on probability of encountering a stiffer component of the cells after the penetration.

The analysis of the f-s curves for 10 nm and 100 nm sharp tips in terms of force drop and elasticity change support the presented hypothesis. However they provide only indirect

evidence. Further confirmation would be required, for example by injection of a fluorescent dye into living cells using the NADIS probes. Comparison of the force-distance curves obtained on successful injection into the cell with those obtained where no injection occurred would show if the penetration was always associated with an elasticity change in the f-s curve.

6.6.2 Force-separation curves with multiple force drops

Within the f-s curves analysis, curves with multiple force drops were found. It was shown that the number of force drop increases with the maximum applied force (Table 6.2). F-s curves with multiple force drops have been already described in the literature [42, 45, 97]. The first force drop is associated with membrane rupture; however origin of the other force drop is not certain at the moment. Yokokawa et al. [97] suggested that presence of the second and more force drops could be explained by penetration of the nuclear membrane. To confirm this assumption a nuclear injection experiment could be carried out using for example the NADIS probes. The injection into a cell of a fluorescent dye that stains the nucleus and an f-s curve analysis of the successfully injected dye might show if the presence of the first and second force drops is due to penetration of the cell membrane followed by the nuclear envelope.

Another possible explanation for the multiple force drops is slippage of the tip inside the cell. It is possible that after penetration of the AFM tip into the cell, further indentation results in enlarging of the opening of the membrane which could result in additional force drops on the f-s curve as the membrane slips up the tip. This hypothesis might be tested using for example, an AFM tip with different surface chemistries e.g. an antifouling layer to penetrate the cell membrane and investigate the presence and characteristics of multiple force drops.

6.6.3 5A method

5 parameters were defined from a force-separation curve with a penetration peak. Four of these parameters have already been mentioned in the literature: the indentation depth (D) [97], the penetration depth (D_1) [42] the penetration force (F_1) [42], and the force drop (F_d) [41, 98]. The fifth parameter, the 'membrane slip' (d) has not yet been discussed in publications on AFM/cell interactions.

A simple mechanical model was presented, based on the assumption that d represents the movement of the cell membrane up the AFM tip during rupture of the membrane. In this model the forces of the membrane on the tip are represented by a linear spring where it was assumed that cell spring constant just before the cell penetration is the same as the cell spring constant directly after the penetration (Figure 6.12).

Further, the 5 parameters were tested on f-s curves obtained on SaOSs-2 cells with 10 nm and 100 nm sharp tips. It was shown that the penetration force (F_1) depends on the size of the tip radius. The larger the radius the higher the force required to rupture a cell membrane. The penetration depth (D_1) does not depend on the tip size. It was measured that breakage of a

Chapter 6. AFM-based microinjection system: biophysical analysis of probe indentation

SaOs-2 cell membrane occurs at penetration depth D_1 of approximately $1\ \mu\text{m}$, and penetration force F_1 of 2.5 nN for 10 nm sharp tip and 4.4 nN for 100 nm sharp tip. The indentation depth D , the penetration depth D_1 and the penetration force F_1 were here called macroparameters, as they describe the behaviour of the entire cell upon a contact with the tip. The force drop F_d and the membrane slip d were called microparameters, as they describe breakage of the cell membrane.

It was shown that the force drop F_d and the membrane slip d depend on the geometry of the tip. When the tip radius and the half tip angle are small (the 10 nm sharp tip had half angle tip of (25°) , the 100 nm sharp tip half angle tip of (35°)) the values of the microparameters are high.

According to the simple mechanical model describing cell membrane rupture, the ratio of F_d/F_1 (force drop over penetration force) divided by ratio of d/D_1 (membrane slip over penetration depth) should be equal to 1. An analysis of this dependency for every f-s curve is presented in Figure 6.20. This shows that the mechanical model is in very good agreement with the results obtained with the 10 nm sharp tip, but that the agreement is less good for the 100 nm NADIS tip. This can be clearly seen from the histograms, where for the 10 nm sharp tip most of the $F_d/F_1 \div d/D_1$ values are close to 1, whereas for 100 nm sharp tip the values are range from 1 to 1.6. The results suggest that the simple elastic model perfectly describes rupture of a cell membrane with a sharp and narrow AFM tip. To confirm this assumption further experiment would be required with tip radii of for example 20 nm, 50 nm and 80 nm sharp tip. Another interesting point is the influence of the half angle tip on the membrane rupture. In experiments presented here two tip sharpness with two different half tip angles were used. More experiments would be required to investigate how variation of the half angle, while keeping the same tip sharpness, is influencing the cell membrane penetration and if the presented here model can be used to describe the penetration.

6.7 Conclusions

Three main aspects of mechanical cell membrane penetration were presented here: determination of tip insertion into a cell; dependence of the probability of penetration on tip geometry, cell-substrate interactions and the presence of EDTA; biophysical analysis of the penetration.

To determine tip insertion the hypothesis was proposed that when an AFM tip breaks the cell membrane and passes from outside the cell to inside of it a change in elastic modulus should occur and that this change in elastic modulus should be observable in the force separation curve. Indirect evidence of this hypothesis was provided through analysis of 350 force-separation curves obtained for 10 nm and 100 nm sharp tips with applied forces varying from 1 nN to 18 nN. For most of the force-separation curves the peak was associated with change in elastic modulus (in total, for 10 nm sharp tip 91.5 % f-s curves, and 77.8 % for 100 nm sharp tip. Based on the hypothesis a specification of cell penetration with an AFM tip was proposed: a force drop is considered to be present when its value is higher than 3 standard deviation of the noise, and an elasticity change has to occur.

Based on this proposed specification, the probability of penetration of SaOs-2 cells was measured for 10 nm and 100 nm sharp tips and three different substrates: a Petri dish, glass uniformly coated with fibronectin and glass coated with patterned PLL-g-PEG/fibronectin. For 10 nm sharp tips and an applied force of 5 nN the penetration probability of cells spread on a Petri dish was 84 % and 55 % and 54 % when cells on the uniform fibronectin and on the patterned PLL-g-PEG/fibronectin respectively. For 100 nm NADIS tips and an applied force of 20 nN the penetration probability of cells spread on a Petri dish was 50 % and on patterned PLL-g-PEG/fibronectin was 0 %.

A biophysical analysis of cell membrane penetration was shown here using 5 parameters obtained from a force-separation curve. Four parameters are known from the literature, the fifth parameter-the membrane slip, was proposed based on a simple mechanical model. The influence of the tip geometry on the different parameters was investigated with 10 nm and 100 nm sharp tips. It was shown that indentation depth, penetration force, force drop and membrane slip depend on the tip sharpness and the penetration depth is independent of the sharpness. An analysis of the $F_d/F_1 \div d/D_1$ values, for 10 nm and 100 nm sharp tips, supports the association of the fifth parameter with the slip of the membrane up the AFM tip during rupture.

In conclusion, the success of cell penetration strongly depends on the tip geometry and the surface on which the cell is spread. The biophysical analysis of the penetration gives insight into the mechanical tip-cell interactions. This analysis will be of great use during microinjection experiments and will help to distinguish effects that due to the tip-cell interaction from the effects caused by liquid delivery.

7 Quantification of single cell damage ¹

Since AFM allows the interaction between the tip and the sample to be controlled precisely, very little or no damage is expected to be done to the cell by the tip during penetration. To confirm this assumption invasiveness of an AFM tip was investigated and will be described in this chapter. Very few studies have been dedicated to investigating cell necrosis and apoptosis due to breakage of the cell membrane with an AFM tip. Han et al.[50] showed that no cell damage can be expected for a tip diameter smaller than 200 nm. This demonstration was based on a single melanocyte cell. To form a better view on the possible tip invasiveness, more studies with a significant number of cells is required. However experiments using larger number of single cells are challenging, as every individual cell has to be first indented with an AFM tip and a force-separation curve has to be recorded and analyzed in order to know if the cell was penetrated or not. After the indentation of each cell, the sample with the cells has to be checked for possible cell damage. If a cell is damaged, analysis of the force–separation curve attributed to this cell will show whether the damage could be triggered by the tip penetration. To study tip invasiveness on a large number of cells two methods were proposed:

1. When the cells are spread on a Petri dish
2. When the cells are spread on glass patterned fibronectin

With these methods invasiveness of tip insertion was investigated for two situations:

1. when the tip penetrates only the upper part of the cell (Figure 7.1a))
2. when the tip penetrates the cell entirely (Figure 7.1b))

amples with cells were investigated for possible damage either directly after the last cell was indented with a tip, or 20 hours after the last indentation. By investigating cell damage directly

Figure 7.1: Schematic drawing of an AFM tip positioned above the nucleus and penetrating a) only upper part of the cell, and b) the entire cell.

after the penetration, presence of severe cell membrane damage or necrosis was assessed. By investigating cell damage 20 hours after the last cell penetration, possible triggering of cell apoptosis by tip indentation was assessed.

7.1 Method 1: Cell damage quantification using Petri dish

In the first method quantification of tip invasiveness of SaOs-2 cells spread on Petri dish was assessed. To be able to localize individual cells, a specific grid with squares was designed and printed on optically transparent foil and glued to the bottom of the Petri dish on which the cells were spread. Each square was marked with a letter and a number. Figure 7.2a) shows an optical image of a Petri dish with such grid with squares, and Figure 7.2b) shows a phase contrast image of a single square with seeded cells. For tip invasiveness measurements it was preferable to have from 60 to 100 single cells seeded inside one square. To fulfill this requirement, 10000 to 20000 cells were seeded on a Petri dish. After the seeding the samples were incubated for 24 hours. Squares containing an ideal number of cells was chosen for indentation experiments with an AFM tip. Phase contrast images of the square were saved and printed for cell identification. The sample was placed in the AFM sample holder for cell indentation experiment.

During the cell indentation experiment contact time between an AFM tip and a cell was set

7.1. Method 1: Cell damage quantification using Petri dish

to 5 seconds, the same value that will be used during cell injection experiments with NADIS probes. The contact time between an AFM tip and a cell is the time during which the AFM tip stays in the cell after reaching the force setpoint value. When that time is set to 0 seconds the AFM tip comes in contact with a cell, indents the cell until the given force setpoint is reached, and retracts from the cell immediately after. Figure 7.3 shows examples of a) force-time curve demonstrating indentations with 0 seconds contact time, and b) shows force-time curve with 5 seconds contact time. The force-time curves show changes in interaction forces between the tip and the cell as a function of time, compare to the force-separation curves which show interaction forces as a function of tip-cell distance.

Figure 7.3: Force–separation curve with a) 0 s contact time and b) 5 s contact time. The peaks present on both curves show tip penetration of the cell membrane.

After the penetration experiment the sample with cells is checked for cell damage. The cell damage is investigated with a LIVE/DEAD kit. The LIVE/DEAD kit contains two components. The first component was Calcein-AM. This is a highly lipophilic and cell membrane permeable. Although CAM is not a fluorescent molecule, when it enters viable cells it is metabolized by the cell to a dye that emits a strong green fluorescent signal. The second component is propidium iodide. This is a nuclear stain which cannot pass through the membranes in a living cell. It passes only through a dead cell's membranes and intercalates with the DNA in the nucleus to emit a strong red fluorescence. After applying the kit to the cells, the cells are viewed by fluorescence microscopy. Cells emitting in the green are counted as live cells. When a cell emits red light, it means that the cell membrane was severely damaged upon contact with the AFM tip. Figure 7.4a) shows a fluorescence image of a control sample treated with the LIVE/DEAD kit. Most of the cells emit green fluorescence, except for one red cell which was counted as a dead cell.

Last step of tip invasiveness investigation is counting of the alive and dead cell. A phase contrast image of cells taken before the penetration experiment is overlapped with confocal

Figure 7.4: a) Confocal image of cells treated with the LIVE/DEAD kit. Cells emitting green fluorescence are alive and the red cell is counted as dead. b) Phase contrast image of cells taken before the penetration experiment overlapped with confocal images of cells treated with the LIVE/DEAD kit after the penetration experiment.

images of cells after staining with the LIVE/DEAD kit. Figure 7.4b) shows an example of such overlapped pictures. Based on the analysis of the overlapped pictures the number of damaged cells is extracted. Force–distance curves of every damaged cell is analyzed in order to investigate if the dead cells were penetrated with an AFM tip.

The methods presented here consist of 3 main steps:

1. Seeding of the SaOs-2 cells on a Petri dish, attaching the mapping grid with squares and choosing a square containing from 60 to 100 cells for indentation experiment.
2. Performing cell indentation experiment on a defined number of single cells with a defined force setpoint and a contact time of 5 seconds.
3. Staining the sample with the LIVE/DEAD kit, imaging with confocal microscope and comparing phase contrast images before the indentation experiment with the fluorescence images after the experiment to count dead cells.

7.1.1 Cell damage analysis after cell membrane penetration

With such defined method invasiveness of 100nm sharp NADIS tip was measured on 50 SaOs-2 cells. First invasiveness of tip penetrating only upper part of a cell was measured. In Chapter 6 Section 6.3.1.1 the probability of penetration of SaOs - 2 cells spread on Petri dish was measured with the 100 nm sharp NADIS tip. It was shown that for 18 nN force setpoint (the highest setpoint used) the penetration probability is 50 %. Analysis of the force–separation curves allowed to measure indentation depth (D) of the tip. It was shown that for this setpoint value, the tip indents the cells up to 2.7 μm on average. Measured via confocal microscopy, the height of the cells was on average 4.6 μm (chapter 6 section 6.5.5). Based on these results, in order to have a high probability of penetration in the upper part of the cell, a force setpoint of 20 nN was set.

7.1. Method 1: Cell damage quantification using Petri dish

In order to investigate cell damage, each sample was treated with the LIVE/DEAD kit immediately preceding the last cell indentation. Total time needed to indent 50 cells is 3 hours, which means that the first indented cell was stained 3 hours after, and the last cell, was stained 5 minutes after the indentation.

Preparation of the sample took place in sterile conditions, whereas cell indentation experiment with an AFM and treatment with the kit were done in non-sterile conditions.

Figure 7.5 shows the results. A phase contrast image of cells before the indentation experiment is overlapped with confocal images of cells treated after the experiment. Only cells emitting green fluorescence are present. On the image 8 individual cells are highlighted and their force-separation curves are demonstrated. 5 cells are shown as tip insertion examples, with penetration peak marked with black arrow on each force-separation curve, and 3 cells are shown as indentation examples. Two cells on the image marked with red circles do not emit fluorescence signal. These cells were not indented during the experiment. Their absence was probably caused by the sample treatment with the LIVE/DEAD kit, which required washing steps.

Analysis of the force-separation curves showed that 28 cells were penetrated, from which 12 cells had more than one peak present.

Based on the overlapped images all the cell indented with an AFM tip survived, and managed to repair their cell membranes before treatment with the LIVE/DEAD kit. Lack of cells emitting red fluorescence is a proof that during the sample treatment cell membrane of the penetrated cells was impermeable for propidium iodide.

To study cell death another sample with cells was prepared. After indentation of 50 cells with the 100 nm sharp NADIS tip, the sample was placed in the incubator for 20 hours and then treated with the LIVE/DEAD kit. Figure 7.6 shows the results. It can be seen that after 20 hours the number of cells increased and the cells changed their position which made the cell identification very difficult. Cells marked with red circles were present before treatment with the LIVE/DEAD kit. Their absence on the fluorescence images can be explained by many factors: they were washed from the samples during treatments, or they died due to tip indentation.

Obtained results showed that this method cannot be used to investigate tip invasiveness 20 hours after the indentation experiments. In order to perform such experiments a new method was proposed.

Figure 7.5: Overlapped phase contrast image before tip indentation experiment with confocal images of cells after the experiment (applied force 20 nN) and treated with the LIVE/DEAD kit directly after the experiment. 8 cells are pointed and their force-separation curves are demonstrated. Black arrow on a curve shows penetration event.

7.2 Method 2: Cell damage quantification using patterned fibronectin

In this method the cells were seeded on commercially available glass substrates patterned with fibronectin. The pattern of the fibronectin had a disc shape of a diameter of $45\ \mu\text{m}$ (further called fibronectin spot); the pitch between the discs was $130\ \mu\text{m}$. The entire surrounding surface was PLL-g-PEG, a surface chemistry which discourages cell spreading. The sample contains marked sections, each containing 81 fibronectin spots.

The cells were seeded on the glass slide in a way to obtain a high number of fibronectin spots occupied by only one cell. The high number of fibronectin spots occupied by one cell was achieved by addition of 25 mmol EDTA to cell medium during regular culture. Once the cells had attached they were washed with PBS and then left in regular culture media supplemented with 25 mmol HEPES buffer. EDTA was used here as it prevents cells in suspension from

7.2. Method 2: Cell damage quantification using patterned fibronectin

Figure 7.6: Overlapped phase contrast image before tip indentation experiment with confocal images of cells after the experiment (applied force 20 nN) and treated with the LIVE/DEAD kit 20 hours after the experiment.

clustering. Single cell on a fibronectin spot was physically restricted in the area in which it could spread. This allowed the position of the cell 20 hours after the indentation experiment to be controlled. Figure 7.7 presents a phase contrast image of one section with 81 fibronectin spots. It can be seen that not every spot is occupied by a cell and some spots have more than one cell. For the tip indentation experiments sections containing more than 50 spots with single cells were chosen. The spots are arranged in an array to allow individual cells to be located.

During the penetration experiment the contact time between the tip and the cell was set to 5 seconds. Also the same LIVE/DEAD kit was used to investigate possible cell damage after the indentation experiment.

In the summary, the second method consisted of 3 steps:

1. Seeding of the SaOs-2 cells on glass coated with fibronectin spots, and choosing a section containing more than 50 spots occupied by single cells for indentation experiments (sterile conditions).
2. Performing cell indentation experiments on a defined number of single cells with a defined force setpoint and a contact time of 5 seconds (non-sterile conditions).
3. Staining the sample with the LIVE/DEAD kit and imaging with confocal microscope

Figure 7.7: Phase contrast image of a section with 81 fibronectin spots. The spots are transparent and cannot be seen on the picture. Most of the spots are occupied by cells and empty spaces show locations of spots to which cells did not attached.

(non-sterile conditions).

With such defined methods tip invasiveness was investigated. However, in Chapter 6, Section 6.3.1.1 it was shown that penetration probability of cells spread on the fibronectin spots for 100 nm sharp NADIS tip was 0 %. This means that this method is not suitable for AFM tips with large tip radius. However, the penetration probability for 10 nm sharp tips was measured to be 84 % at force setpoint of 5 nN. Based on this results further investigation of tip invasiveness will be done with the 10 nm sharp tip.

7.2.1 Cell damage analysis after cell membrane penetration

Tip invasiveness of 10 nm sharp tips was first investigated for a situation when the tip penetrates only the upper part of the cell. Penetration probability for the 10 nm sharp tip at 5 nN force setpoint was 75 %. Analysis of the force –separation curves shows that for this setpoint value, the tip indents the cells up to 1.92 μm in average. Measured with a confocal microscope the height of the cells was 8 μm on average (Chapter 6, Section 6.5.4). Based on these result, the 5 nN force setpoint value was used in further experiments.

The possible cell damage due to cell penetration was investigated both directly, and 20 hours after the last cell indentation. The direct measurement of the cell damage was done to investigate if the cell is able to recover and repair its membrane in a short time. Analysis of the cell damage 20 hours after the penetration was done to investigate if the tip insertion can

7.2. Method 2: Cell damage quantification using patterned fibronectin

induce cell apoptosis.

Figure 7.8a) shows tip invasiveness measured directly after the indentation experiment. It can be seen that all cells emit green fluorescence. Analysis of the force-separation curves showed that 35 cells were penetrated with the tip. 4 examples of cell emitting the green fluorescence are presented with their force-separation curves. Each curve has a penetration peak. Lack of cell stained red on the picture shows that cells managed to repair their membranes before the treatment with the LIVE/DEAD kit.

Figure 7.8b) shows the results measured 20 hours after the indentation experiment. 43 cells were emitting green signal, 7 cells were either emitting red signal or missing. Any cells which were missing were assumed to be dead as the SaOs-2 cell line is an adherent cell line. Analysis of the force-separation curves showed that 40 cells were penetrated with the tip. Not all of the dead cells were penetrated. As an example cell 1c and its force-separation curve is presented. It can be seen that the tip only indented the cell. Another example, cell 8i was also only indented and 20 hours after the indentation two cells were found there, suggesting that the cell went through mitosis. Two additional examples are shown as well: cell 6h with its force-separation curve showing penetration peak, and cell 8g with its force-separation curve showing multiple penetration peaks.

In summary, no cell damage was observed on the first sample treated with the LIVE/DEAD kit directly after the indentation experiment. 7 cells were missing on the second sample, first incubated for 20 hours and after treatment with the kit. The cells that detached from the sample are assumed dead.

Figure 7.8: Confocal images of cells after indentation experiment (applied force 5 nN) and stained with the LIVE/DEAD kit; a) shows cells stained directly and b) 20 hours after the experiment. Positioning of the cells allows attributing the force-separation curves to individual cells and identifying whether the cell was penetrated or only indented. Alive cells are stained with green marker; dead cells are stained with the red die. Positions marked with red circle show cells that were indented and got detached during the treatment with the kit.

7.2.2 Cell damage analysis after penetration of the entire cell

In this experiment possible tip invasiveness was investigated for situation when the tip penetrates entire cell and touches the bottom of the substrate on which the cell has spread. In order to obtain a high amount of such situations a high value of 30 nN force setpoint was chosen. The possible cell damage due to cell penetration was investigated like in the previous section immediately, and 20 hours after the last cell indentation.

Figure 7.9a) shows tip invasiveness the results measured directly after the indentation experiment. It can be seen that all cells emit green fluorescence. Analysis of the force-separation curves showed that 50 cells were penetrated with the tip. 4 examples of cells emitting green fluorescence are presented with their force-separation curves. Each curve has several penetration peaks. Peaks shown in the circle are due to the tip penetration of the bottom cell membrane. After penetrating the entire cell the tip is pressing on the glass substrate, indicated by the 90° steep part of the force-separation curve.

Figure 7.9b) shows the results measured 20 hours after the indentation experiment. 46 cells were emitting green signal, 4 cells were missing, marked with a red circle, and 5 cells divided into two cells, marked with a green circle. Analysis of the force-separation curves showed that all the cells were penetrated with the tip. 2 examples of missing cells are presented, cell 2b and 5f, and 2 examples of cells that went through the mitosis, cell 1i and 2g. Force-separation curves of the 4 cells show penetration peaks of the bottom cell membrane followed by 90° steep part of the curve indicating tip pressing on the substrate.

Chapter 7. Quantification of single cell damage

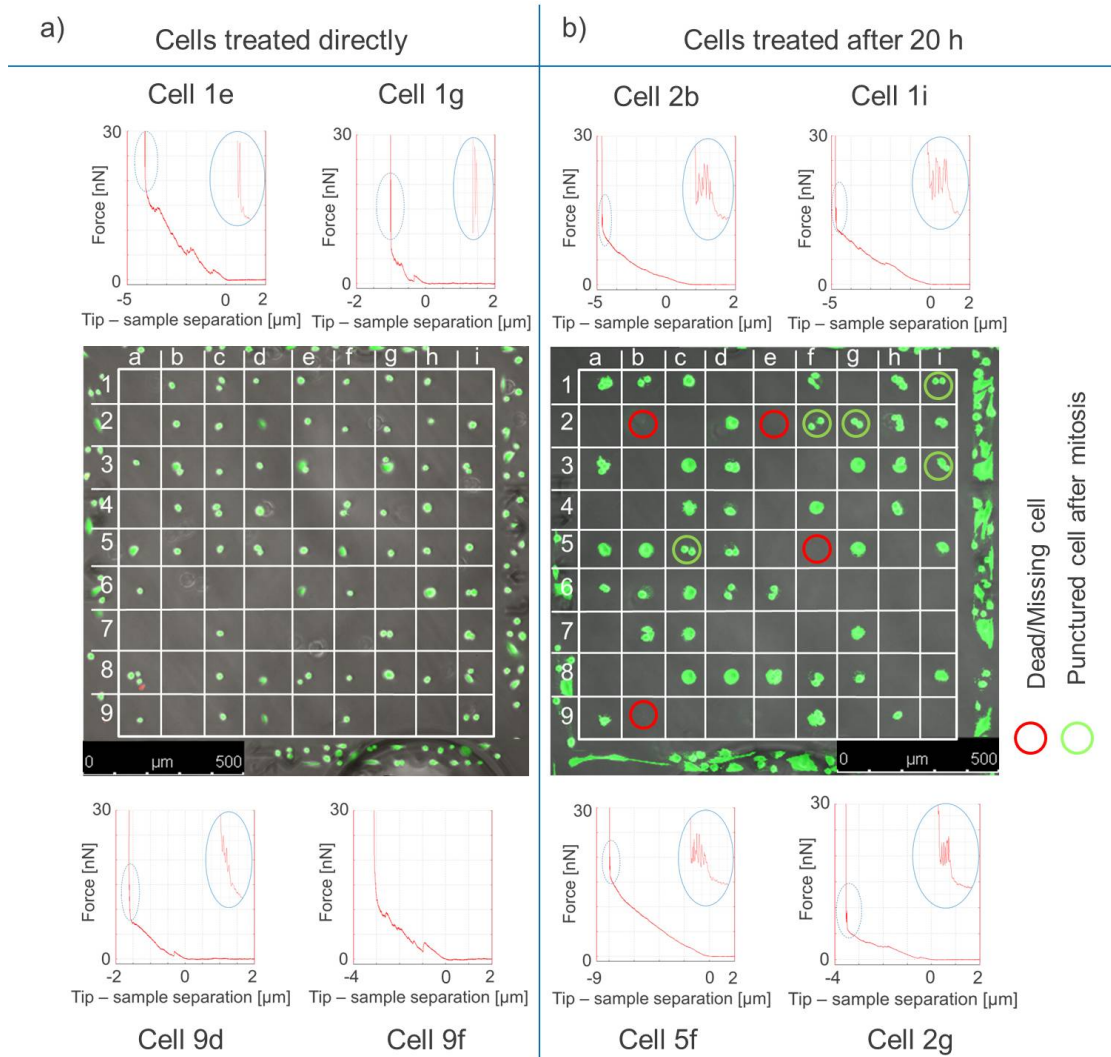

Figure 7.9: Confocal images of cells after indentation experiment (applied force 30 nN) and stained with the LIVE/DEAD kit; a) shows cells stained directly and b) 20 hours after the experiment. Positioning of the cells allows attributing the force-separation curves to individual cells and identifying whether the cell was penetrated or only indented. Alive cells emit green fluorescence; dead cells emit red fluorescence. Places marked with red circles show positions of cells that were indented and now are missing. Green circles show cells that divided during the 20 hours.

7.2. Method 2: Cell damage quantification using patterned fibronectin

In summary, no cell damage was observed on the first sample treated with the LIVE/DEAD kit directly after the indentation experiment. This allowed us to assume that cells are capable of fast recovery and membrane repair even after extreme invasiveness of the AFM tip. Analysis of the fluorescence images of the second sample showed 4 cells were missing and 5 cells went through mitosis 20 hours after the last cell penetration. Any cells which were missing were assumed to be dead. These results show that after penetration of the entire cell with a 10 nm sharp tip, all the cells were alive directly after the penetration and only 4 cells were found dead on a sample investigated 20 hours after the last cell penetration. Based on these results it can be assumed that cells are able to recover and repair damage caused by mechanical penetration of a tip very quickly. Observation of the cells 20 hours after the experiment shows that although the tip punctured the cells from their top to bottom, in 92 % of the cases the cells were alive. This shows that it is highly improbable that tip insertion can trigger biochemical reactions in the cell that would cause apoptosis. To confirm this assumption a control sample was prepared. The cells were seeded on the glass patterned with fibronectin spots and was placed inside the AFM microscope for 3 hours. No indentation experiment was performed. The sample was only exposed to the same non-sterile conditions like discussed in the above samples. After the exposure the sample was left in the incubator for 20 hours and treated with the LIVE/DEAD kit.

Figure 7.10 shows overlapped confocal images of the sample. After 20 hours 4 cells were missing (marked with red circles).

Figure 7.10: Overlapped confocal images of control sample exposed to non-sterile conditions for 3 hours and after treated with the LIVE/DEAD kit. Alive cells emit green fluorescence; dead cells emit red fluorescence. Places marked with red circles show positions of cells that were indented and now are missing.

Chapter 7. Quantification of single cell damage

Confocal imaging of the control sample showed that amount all the cells 4 died due to natural cell death. This result suggests that missing cells on the previous samples (where each cell was penetrated with the tip) might have died due to natural cell death and not upon a contact with an AFM tip.

7.3 Discussion

The cell damage caused by tip insertion was investigated in two ways: Firstly, when the cells were spread on a Petri dish, and second, when the cells were spread on glass patterned with fibronectin spots. In both cases, after the sample preparation, 50 cells were indented with an AFM tip. Directly after or 20 hours after the indentation the cells were investigated for cell damage with a LIVE/DEAD kit. The results are summarized in Table 7.1 and Table 7.2 .

Table 7.1: Results of the force-separation curves analysis combined with the amount of dead and alive cells spread on Petri dish and indented with 100 nm sharp NADIS probe with applied force of 20 nN.

	0		50		0		50	
	Alive	Dead	Alive	Dead	Alive	Dead	Alive	Dead
	-	-	50	0	-	-	46	4

With the first method the 100 nm NADIS tip invasiveness was analyzed directly after the last cell indentation. During the cell indentation experiments the force setpoint was set to 20 nN in order to achieve high probability of tip penetrating only upper part of a cell. Analysis of the

force-separation curves showed that 22 cells out of 50 were penetrated with the tip. Confocal imaging of the sample showed that all the 50 cells were alive after the experiment. All the penetrated cells repaired their ruptured membranes as no red fluorescence was emitted during confocal imaging of the cells. The results obtained show that cell membrane penetration with a 100 nm sharp tip does not create any immediate damage to cells.

It was not possible to assess cell damage 20 hours after indentation due to cell division preventing identification of the individual cells.

In the second method cells were spread on fibronectin spots. Single cells on fibronectin spots are physically restricted in the area in which they can spread. This allows the position of the cell to be controlled 20 hours after an indentation experiment. Since the penetration probability of 100 nm NADIS tip is 0 % when cells are spread on the fibronectin spots cell damage was investigated with 10 nm sharp tip. The indentation experiments were performed with 5 nN and 30 nN force setpoint value. 50 cells were indented for each condition. In each case cell damage was investigated directly after, or 20 hours after the indentation experiment.

When a 10 nm sharp tip penetrates a cell with 5 nN force setpoint, the tip penetrates only the upper part of the cell. Analysis of the force-separation curves showed that 35 out of 50 cells were penetrated with the tip. Treatment with the DEAD/LIVE kit directly after indentation followed by imaging of the sample showed that all 50 cells were alive. In a second sample the force-separation curves showed that 40 out of 50 cells were penetrated with the tip. Analysis 20 hours after the penetration/indentation and fluorescence imaging of the sample showed that 43 cells were alive and 7 cells were missing. Since the SaOs-2 cells are adherent cells, the 7 missing cells were counted as dead cells. When a 30 nN force setpoint was used, the tip penetrated the entire cell and hit the bottom of the substrate. Fluorescence imaging of cells treated with the LIVE/DEAD kit directly after the penetration showed that all cells were alive and managed to repair their ruptured membranes. Imaging of cells treated 20 hours after penetration showed 46 live cells emitting green fluorescence and 4 cells missing.

Analysis of the control sample 20 hours after exposure to non-sterile conditions revealed 4 cells missing. This result shows that even under conditions where cells are not exposed to mechanical stress and cell membrane penetration, around 8 percent of the cell population can be expected to die. This value can be compared with the values obtained after indentation: with a 5 nN force setpoint 14 % of cells were dead after 20 hours with a 30 nN force setpoint 8 % of cells were dead. This comparison suggests that cell penetration (even most drastic, when an AFM tip penetrates entire cell) with a 10 nm sharp tip does not trigger cell death.

These results show that SaOs-2 cells are surprisingly resistant to AFM tip penetration, clearly possessing suitable mechanisms that allow to repair their ruptured membranes and recover rapidly after tip insertion. SaOs-2 cells – an osteosarcoma cell line – are robust adherent eukaryotic cells. It is possible, perhaps likely, that other cell types are more sensitive to AFM tip penetration. Therefore, extension of this work to other cell lines and primary cells could give a more general overview on the invasiveness of the AFM tips.

Different tip shapes (cylindrical or conical) could be used to test the limits of cell robustness. In this study the tip was inserted in the cell for 5 seconds and left static. It would be interesting to see how the cell would react to the tip being inserted in the cell for a longer period of time and how if moving the tip whilst inside the cell would influence cell damage.

A limiting factor in using SaOs-2 cells for long term studies is their capacity to divide very quickly and make identification of individual cells that have been penetrated impossible. Using a cell type that divides more slowly, such as nerve cells, would allow the long term effects of cell penetration to be studied.

7.4 Conclusions

Two methods on how to measure possible single cell damage were demonstrated.

The first method allows cell damage to be measure a few hours after tip insertion into cells which are spread on a petri dish. The second method allows cell damage to be measured on cells grown on glass patterned with PLL-g-PEG/fibronectin spots, 24 hours after tip insertion.

Measurement of tip invasiveness directly after the cell penetration showed no cell damage, even when the tip was penetrating the cell entirely and touching the substrate. Measurement of tip invasiveness 20 hours after the cell penetration showed maximum 14 % of cell death. This is similar the rate of natural cell death measured on the control sample.

Results obtained here show that cell penetration with an AFM tip does not cause severe damage to cells. This result will be further utilised in the analysis of microinjection of liquids into cells with the NADIS probe.

8 Microinjection using the AFM-based system

Once the AFM-based microinjection system had been fabricated and characterized (Chapters 4 and 5), and AFM tip insertion into single living cells had been studied (Chapters 6 and 7), the system was used to inject liquids into cells. These experiments were used to test the feasibility of the system and investigate which technological aspects require further development. Two types of experiments were designed, first to investigate feasibility of intracellular injection, and second, to inject liquid directly into a cell nucleus.

8.1 Experimental design

The intracellular injection experiments were designed to investigate different aspects concerning successful liquid delivery after tip insertion into a single cell. In previous chapters theoretical values of the volume of liquid that can be delivered into a single cell were discussed; experimental values of the injection parameters: the pressure and the length of the pressure pulse were proposed; the probability of cell membrane penetration was measured to find optimal conditions for tip insertion; and finally possible cell death due to tip insertion was investigated in order to understand the effect of tip invasiveness into cells. All these results presented in Chapters 4 to 7 were used to design the intracellular injection experiments.

Figure 8.1 presents schematically the experimental design. The experiment consists of 6 steps. The first step is the preparation of a sample with cells and liquids used for injection. In Chapter 6, Section 6.3.1.1 it was shown that the highest probability of cell penetration with NADIS tips was measured for cells seeded on a Petri dish. Based on this result it was decided to use cells seeded on this substrate. Two liquids were used: sterile water and fluorescent sodium salt dissolved in PBS at a concentration of 0.1 mg mL^{-1} . The water injection experiment was designed to check for possible leakage of the fluidic connectors, clogging of the tip opening due to cell membrane residues, and to study tip interactions with the cells during liquid injection via force-time curves. Injection of the fluorescent solution was dedicated to study the most suitable values of the injection parameters (pressure and length of the pressure pulse).

Chapter 8. Microinjection using the AFM-based system

Figure 8.1: Diagram showing the planning of the experiment.

The second step is the filling of the system with liquid, according to the method presented in Chapter 5, Section 5.2.2. When the NADIS probe is filled the resonance frequency of the vibrating cantilever decreases until the channel and the tip are completely full of liquid. An average decrease of (26 ± 9) kHz (as measured in Section 5.2.2) indicates that the probes are correctly filled. Once the NADIS probe is filled, the sample with cells is placed in the Petri dish heater mounted on the AFM stage.

Steps 3 to 5 concern the movement of the NADIS probe: cell indentation (the tip approach), the tip pause (the time during which the tip is not moving and stays in contact with the cell) used for injection, and tip retraction from the cell.

The tip approach was designed based on the approach parameters used during the penetration probability measurements presented in Chapter 5. The cantilever approaches each cell with a speed of $2 \mu\text{m s}^{-1}$. The force setpoint was chosen based on the penetration probability results measured in chapter 6. For a 20 nN setpoint, the penetration probability was measured to be 50 %. For the cell injection experiments it was decided to use the same value.

When the force with which the tip is indenting a cell reaches the given setpoint, the probe is kept still for few seconds in a constant height mode. This pause is used to decide whether the tip has penetrated the cell or not and to inject liquid if penetration has occurred. To analyze tip penetration the tip-cell interactions are monitored in real time, with an oscilloscope, in the form of the force-time curve. If the force-time curve has a characteristic force drop, it is assumed that the tip has penetrated the cell and that liquid can be injected into the cell. During the water injection experiments different time values of the pause are tested to find an optimum value.

The injection parameters (step 4) were chosen based on the results presented in Chapters 5 and 6, and are used as a reference: a pressure of 5000 Pa ($2 \mu\text{m s}^{-1}$) and a length of the pressure pulse of 20 ms.

After the pause the tip is automatically retracted from a cell at the same speed of $2 \mu\text{m s}^{-1}$ (step 5).

The last step is dedicated to investigating with a fluorescent microscope the cell sample after

injection of fluorescent solution, in order to search for cells emitting fluorescent signal.

8.2 Preliminary experiments

The main goal of these experiments was to test the system for leakages, study tip interactions with cell during the injection, and test clogging of the tip opening. This was done by injecting water into the cell to cause the cell to explode. Cell explosion occurs immediately after the injection, making it a very efficient way to investigate if the AFM-based microinjection system works correctly.

Figure 8.2 shows optical images of a two cells before (Figure 8.2a) and Figure 8.2c)) and directly after (Figure 8.2b) and Figure 8.2d)) the injection. When too much liquid is injected into a cell, first, the cell membrane bursts due to the excess of water, and immediately after the cell starts to shrink and detach from the surface.

Figure 8.2: Injection of excess of water into a cell. Figure a)-c) show cells directly before injection, figure b)-d) directly after.

The injection of water was done with NADIS probes with needle-like openings approximately 300 nm in diameter. Resonance frequency measurements during filling of the system showed a decrease of the resonance frequency of 28 kHz. During the first cell indentation experiments 20 nN force setpoint was used, however only few tip insertion events were measured. In order to increase number of the insertion events force setpoint values of 50 nN, 80 nN and 100 nN were used.

Tested values of the tip pause-time during which the tip was kept still in constant height mode after reaching the force setpoint, were 5 s, 10 s and 30 s, depending on the length of the injection pulse.

The values of the injection parameters: the pressure Δp and the length of the pressure pulse Δt were chosen according to the reference values ($\Delta p = 50$ mbar, $\Delta t = 20$ ms). The reference values are theoretical values which should create a pressure pulse that injects a volume of liquid that a single cell can accommodate. In order to inject excess of water in a single cell it was decided to use higher values than the reference ones: $\Delta p = 200$ mbar, $\Delta t = 50$ ms. However, injection of water with these parameters did not damage any of the first 5 penetrated cells. The first cell explosion was observed for $\Delta p = 500$ mbar, $\Delta t = 500$ ms. These values were

used for injection into the next cells, however no cell explosion was observed. An additional increase of the values to $\Delta p = 700$ mbar, $\Delta t = 1300$ ms resulted in a successful cell damage. After 2 hours from the beginning of the experiment, cell damage due to injection occurred only when the length of the pressure pulse was set to 10 s ($\Delta p = 700$ mbar, $\Delta t = 10000$ ms).

Figure 8.3 shows force-time (f-t) curves (the tip approach, the pause and the retraction) obtained for the first and the last exploded cells. Figure 8.3a) shows force-time curve of the first successful cell damage. First the tip indented the cell with a force setpoint of 20 nN. As the tip reached the setpoint value, it was kept in contact with the cell at the constant height for 5 s (the 5 s pause). Once the presence of a force drop was confirmed on the detailed view of the approach f-t curve (Figure 8.3b)) a pressure pulse was generated ($\Delta p = 500$ mbar, $\Delta t = 500$ ms). After the pause the tip was retracted from the cell. Figure 8.3c) shows the force-time curve of the last successful cell damage. During the approach the tip indented the cell with 100 nN force setpoint. Figure 8.3d) shows a detailed view of the approach part of the f-t curve. The force drop suggests cell penetration. During the pause of 30 s a pressure pulse was generated with a pressure $\Delta p = 700$ mbar during time $\Delta t = 10$ s. When the pressure pulse was applied to the system a sudden increase in measured force of approximately 1 μ N was observed. The force stopped increasing when the pressure pulse ended. For the rest of the pause force fluctuations were observed until the tip was retracted from the cell.

The water injection experiment showed that: values of the injection parameters had to be much higher than expected, and had to be slowly increased with time to ensure that liquid was ejected from the system. In addition when during the pressure pulse a sudden apparent force increase was observed in the force-time curve. The shape of the apparent force peak depended on both applied pressure and length of the pressure.

8.2.1 Mechanical stability of probe/probe holder seal

The sudden increase in measured apparent force when applying a pressure pulse could be caused by the movement of the polymer tape used to attach the NADIS tip to the AFM probe holder. Figure 8.4 shows a schematic drawing of a cross sectional view of the NADIS tip, the tape and the holder. It is possible that when the microinjector applies a pressure pulse to eject the liquid from the tip, the polymer tape deforms, causing movement of the NADIS probe.

To test this hypothesis two experiments with NADIS probes were performed. In the first experiment the probes were kept still in a constant height mode 50 μ m above the substrates while the pressure pulses were applied to the probes and the force-time curves were registered. Two NADIS probes were used, one without an opening in the tip, and one with a 250 nm opening at the tip apex. The probes were kept in air at room temperature and they were filled with air. When a pressure pulse was applied to the NADIS probe without opening, the air could not be ejected, contrary to the NADIS probe with the 250 nm opening.

Figure 8.5 presents the force-time curves, the applied pressure varied from 0.2 bar to 2 bar,

Figure 8.3: Force–time curve of a) the first successfully exploded cell with b) a detailed view of the approach; c) the last successfully exploded cell (note the Force axis is in μN) with d) a detailed view of the approach fragment.

and the length of the pressure pulses varied from 0.25 s to 5 s. Figure 8.5a) shows results for the NADIS probe without the opening. The increase in the measured force was observed only when a pressure pulse was applied. It can be seen that even the smallest and the shortest pressure pulse used ($\Delta p = 0.2 \text{ bar}$, $\Delta t = 0.25 \text{ s}$), was causing an increase in measured force and that the higher the pressure the higher was the apparent force increase. Figure 8.5b) shows results for the NADIS probe with a 250 nm opening. It can be seen that, when the same injection parameters were used, the force increase was much lower, for the probe with opening than for the probe without opening. A clear peak in the apparent force occurs for pressure pulses higher than 0.4 bar. These measurements indicate that the apparent force increase during the pressure pulse is caused by deformation of the tape attaching the NADIS probe to the AFM probe holder.

Chapter 8. Microinjection using the AFM-based system

Figure 8.4: Schematic drawing of the NADIS probe attached to the AFM probe holder with the double-side polymeric tape. When a pressure pulse is applied to the system, the tape deforms and cause movement of the NADIS probe.

Figure 8.5: Force increase measurements when the system is kept still above the surface in constant height mode and a) the NADIS probe has a tip without opening, and b) the NADIS probe has a tip with a 250 nm opening.

8.2. Preliminary experiments

In a second experiment, the probes were first approached to glass substrates and were kept in contact with the substrates in a constant height mode while pressure pulses were applied to the probes and the force-time curves were registered. The applied pressure varied from 0.2 bar to 2 bar, and the length of the pressure pulses varied from 0.25 s to 5 s. After the pressure pulses the probes were retracted from the glass surfaces. The same two NADIS probes were used as in the previous experiments, one with no tip opening, and one with a 250 nm opening.

Figure 8.6 presents the force-time curves. Figure 8.6a) shows results for the NADIS probe without the opening. A sudden increase in apparent force was observed simultaneously with the applied pressure pulse for all pressure pulse conditions. The apparent force increased as the applied pressure increased. For the highest pressure pulse values the measured signal got saturated and the entire force increase could not be measured. Figure 8.6b) shows results for the NADIS probe with a 250 nm opening. It can be seen that the first force increase occurs for the pressure value of 0.8 bar and the pulse length of 0.25 s (marked with red arrow).

Figure 8.6: Apparent force increase when a tip is kept in constant height mode in contact with a glass substrate. Figure a) shows results for the NADIS probe without tip opening and figure b) shows results for the NADIS probe with a 250 nm tip opening.

These results seem to explain why during the injection a sudden apparent force increase appears on the force-time curves. The comparison between the probes without and with opening showed that the force increase depends on the applied pressure, which explains why on the force-time curve registered for the first cell explosion, the apparent force increase was not observed (Figure 8.3a); $\Delta p = 0.5$ bar, $\Delta t = 0.5$ s), but was present for the last cell explosion (Figure 8.3c); $\Delta p = 0.7$ bar, $\Delta t = 10$ s).

8.2.2 Origin of increasing resistance to liquid injection

However, it was still not clear why values of the injection parameters had to be slowly increased during the experiment. 3 possible options were considered: the tip opening clogging with cell residues; leakage in the system; the formation of gas bubbles in the microfluidic system of the NADIS probe discussed before in Chapter 5, Section 5.2.3.

In order to investigate if the increase in the values of injection parameters could be caused by clogging of the tip opening with cell residues, a tip was investigated with a SEM microscope directly after an injection experiment. The tip opening was free from residues. Clogging of the tip opening was further tested with another NADIS probe with a tip opening of 250 nm. The probe was used to indent 100 cells, out of which 50 cells were penetrated. SEM imaging after the indentation experiments also showed no tip clogging. Figure 8.7 presents images of the tip with the 250 nm opening after the experiment. Figure 8.7b) shows detailed view of the tip opening. It can be seen that while a small quantity of residue covers part of the tip opening, it does not appear to block the tip opening.

Figure 8.7: SEM images of a NADIS tip with 250 nm opening after indentation of 100 cells, from which 50 cells were penetrated.

To test for possible leakage through the microfluidic connectors, the system without the NADIS probe was partially filled with water. The outlets of the probe holder channels were blocked and a constant pressure of 2 bar was applied to the system. The system was immersed in a large water container and movement of the water meniscus inside the fluidic tubes of the system was investigated with an optical microscope. No movement was detected, indicating that possible leakage occurs below detection limit of 15 nL h^{-1} through the connectors.

To test for possible leakage through the tape sealing the NADIS tip to the AFM holder, the system with the NADIS probe of 200 nm opening was filled with air. As the AFM holder and the tape are optically transparent, the tape-NADIS probe behaviour was observed with an optical microscope. When the seal is tight, no air bubbles can be seen trapped between the NADIS probe and the tape and no nucleation of new air bubbles is observed. When a constant pressure of 2 bar was generated for 5 min no air bubbles were observed, suggesting that the seal remained tight. When the pressure was increased to 4 bar, after 5 min air bubbles begin to occur between the tape and the NADIS, which could be the origin of a leak. Since during the water injection experiments, the pressure was not higher than 2 bar it was assumed that no leakage occurred during the experiment.

Based on the SEM imaging of the tip apexes and the leakage tests it was concluded that most probably the constant increase in the values of the injection parameters is caused by nucleation of gas bubbles inside the hollow AFM tip.

8.2.3 Discussion

A water injection experiment was used to test the AFM-based microinjection system. The system was used to inject excess of water into cells to cause cell damage. The experimental results showed that the system can be used as a microinjection tool.

The water injection experiments also revealed that the 20 nN force setpoint value was not enough to achieve a 50 % penetration probability. During the injection experiment forces up to 100 nN were used. It is not clear why this higher setpoint is necessary. It might be due to the differences in radii of the NADIS tips. In the chapter 4 (Microfabrication of the NADIS probes) it was outlined that the tip radius can vary from 50 nm to 150 nm, which could cause a difference in penetration probability between the NADIS probes.

Several tip pause times used to confirm penetration events and inject the liquid were tested, ranging from 5 s to 30 s. It was verified that a 5 s pause was enough to check if the approach force-time curve had a force drop, and immediately after apply a pressure pulse. It was also found that the values of the injection parameters had to be slowly increased in order to inject an excess of water and cause cell damage. Leakage tests showed that the system is watertight. The SEM imaging of the tip openings suggest that it is improbable that the tip opening is blocked with cell residues. In the absence of a visible cause, the effect was attributed to possible nucleation of gas bubbles inside the tip. Table 8 compares values of the force setpoint and injection parameters proposed to be used at the beginning of the experiment with the values that were required to be used during the experiment.

Based on these results, values of the force setpoint, tip pause and the injection parameters were adapted for the injection of the sodium fluorescein experiment.

Chapter 8. Microinjection using the AFM-based system

Table 8.1: Comparison of the parameters values assumed in the experiment designed with the values used during the experiment.

	Force setpoint	Tip pause	Pressure Δp	Pulse length Δt
Assumed in the design	20 nN	5 s	0.2 bar	0.02 s
Used in practice	20 nN to 100 nN	5 s to 30 s	0.5 bar to 2 bar	5 s to 10 s

8.3 Intracellular injection of sodium fluorescein

The main goal of this experiment was to test values of the injection parameters allowing liquid delivery without causing cell damage. It was decided to deliver a fluorescent solution into individual cells, and use the fluorescent signal emitted by the cells as evidence of successful injection.

Before the experiment several NADIS probes were investigated with SEM in order to find a probe with a small tip radius. The injection of the sodium fluorescein was done with a NADIS probe with a tip radius of 75 nm and a needle-like opening approximately 200 nm in diameter. Cantilever resonance frequency measurement during the probe filling showed decrease of 21 kHz.

Table 8.2 presents values of the force setpoint, tip pause and injection parameters used in the experiment.

Table 8.2: Comparison of the parameters values assumed in the experiment designed with the values used during the experiment.

	Force setpoint	Tip pause	Pressure Δp	Pulse length Δt
Used in experiment	50 nN or 80 nN	5 s	0.8 bar	0.5 s

Figure 8.8 shows an example of overlapped phase contrast and fluorescence images taken after the experiment. In total 23 SaOs-2 cells were targeted. The number of cells was limited in order to reduce the time of the experiment and thus the possibility of gas bubble formation inside the tip. During the water injection experiment, which lasted 2 hours, the values of injection parameters had to slowly increase to cause cell explosion, which was attributed to the effect of the gas bubbles nucleation. In order to diminish this effect it was decided to shorten the time of the experiment to 0.5 h, which should allow to use constant injection parameters. In order to achieve high penetration probability 50 nN and 80 nN force setpoint values were used.

Two control measurements were carried out at the start of the experiment. The first measurement was to determine whether fluorescent solution could be ejected from the NADIS tip. The first cell was targeted (marked with the * on the Figure 8.8a), detail on the Figure 8.8b)) and the tip brought into contact with the cell. The system was paused for 5 s at the setpoint for the applied force. Since a force drop was observed on the force-time curve a pressure

8.3. Intracellular injection of sodium fluorescein

pulse was applied to the probe to deliver the solution. The values of the injection parameters ($\Delta p = 2 \text{ bar}$, $\Delta t = 1 \text{ s}$) were intentionally designed to eject a large liquid volumes. As a result the cell exploded (Figure 8.8c)) confirming that the injection system is working. The injected cell died, and detached from the surface.

The second cell was used to investigate the possibility of spontaneous diffusion from the tip, when no pressure pulse is applied. In this measurement, the tip was brought into contact with the cell (marked ** in the Figure 8.8a), detail in Figure 8.8d)) and a force drop was observed on the force-time curve. The tip stayed in contact with the cell for 5 s and no pressure pulse was applied to the probe. After that time the tip was retracted from the cell. In a further step the force setpoint was decreased to 10 nanoN and the tip was brought into contact with the same cell. The force-time curve showed no force drop. During the pause a pressure pulse ($\Delta p = 0.8 \text{ bar}$; $\Delta t = 0.5 \text{ s}$) was applied to the probe. Analysis of the sample with the confocal microscope showed that the cell was not emitting a fluorescent signal. Thus penetration of the cell without a pressure pulse does not result in the injection of liquid into the cell. Similarly ejection of liquid from the tip in the absence of force drop in the force-distance curve does not result in injection of liquid into the cell.

To deliver solution to the rest of the cells the following values of injection parameters were used: $\Delta p = 0.8 \text{ bar}$; $\Delta t = 0.5 \text{ s}$. When the tip was brought in contact with cell, a pressure pulse was applied independently of the presence of the force drop. After the experiment the sample was analysed with the fluorescent microscope and 14 of the 21 cells were found to be fluorescing.

Figure 8.8: Overlapped confocal and phase contrast images of SaOs-2 cells after the injection of fluorescent molecules a). The single * shows detached fluorescent body of the dead cell. The cell died due to injection of an excessive amount of molecules. Figure b) shows phase contrast image of the cell before the injection and figure c) shows phase contrast image of the cell directly after the injection. Cell marked with the double ** was used to test the diffusion of the material from the tip. The tip was inserted to the cell without applying pressure to the AFM probe. Further the cell was indented with the fluorescent molecules were ejected from the tip. The cell did not emit the fluorescent signal. Figure d) shows phase contrast image of the cell after the indentation.

Chapter 8. Microinjection using the AFM-based system

Within the 14 fluorescent cells some were among the last cells injected. Based on this observation it can be concluded that the system was injecting sufficient liquid volume throughout the entire experiment and no increase in the values of the injection parameters was required. This was perhaps due to the fact that the experiment lasted less than 40 minutes.

The values of the injection parameters $\Delta p = 0.8$ bar; $\Delta t = 0.5$ s, resulted in a sudden increase in apparent force when the pressure pulse was applied to the NADIS probe, which is in agreement with the water injection results and the tape deformation tests.

The results of this experiment were used to test the hypothesis that the penetration of the cell membrane is associated with both the force drop and the elasticity change, (presented in Chapter 6, Section 6.2.1). For this purpose the force distance curves of the 21 individual cells were analyzed in terms of the force drop and change in elastic modulus and classified into the types of the force - separation curves discussed in Chapter 6. Of the 7 cells that did not emit a fluorescent signal, 6 of them had the type I force-separation curves (Figure 8.9a) and 1 had type II force-separation curve (Figure 8.9b)). Of the 14 cells that were emitting a fluorescent signal, 9 of the cells had type III curves (Figure 8.9c)) and 5 had type IV curves (Figure 8.9d)). Figure 8.9 presents example of a force-separation curve for each curve type and Table 8.3 contains percentage of the analysed curves.

Table 8.3: Analysis of the force–distance curves after the delivery of biomolecules to SaOs-2 cells. F_d is a force drop parameters, E_1 is an elastic modulus measured before the force drop and E_2 is an elastic modulus measured after the force drop, σ is a standard deviation of the noise.

Types of force distance curves found for			
Cells that did not emit the fluorescent signal-33 %		Cells that did emit the fluorescent signal-67 %	
Type I $F_d = 0$	Type II $E_1 = E_2 F_d > 3\sigma$	Type III $E_1 > E_2 F_d > 3\sigma$	Type IV $E_1 < E_2 F_d > 3\sigma$
28 %	5 %	43 %	24 %

8.3. Intracellular injection of sodium fluorescein

Figure 8.9: Examples presenting 4 types of force distance curves found after the injection experiment.

8.3.1 Discussion

The injection of sodium fluorescein molecules into cells was used to investigate if the system can deliver liquid volumes into cells that do not cause cell death. The values of the injection parameters for this experiment were chosen based on the results of the water injection experiment. As a result out of 21 cells, 14 cells were emitting a fluorescent signal and none of the cells exploded during the experiment. All were apparently alive a few hours after the injection (the time during which the fluorescence analysis was done).

The experimental results were also used to test the hypothesis that the cell membrane penetration occurs when both a force drop and an elasticity change are present on a force-separation curve (discussed in Chapter 6, Section 6.2.1). The force-separation curves from the 21 cells used in the injection experiments were analysed in terms of the force drop F_d and change in elasticity E , and classified according to the four curve types. The force-separation curves from cells emitting fluorescent signal were falling into type III or type IV curves, indicating that the cell penetration is associated with the force drop and also with the change in elasticity. Out of the 7 cells that were not emitting the fluorescent signal, 6 cells had force-separation curves falling into type I curves, representing only cell indentation. One cell had a force-separation curve with a force drop value of 172 pN and no elasticity change was observed (shown on Figure 8.9b)). This example suggests that the type II curves show no tip penetration and support the proposed hypothesis. However, given the very small number of cells tested in this experiment, further experiments are required. Table 8.4 contains a summary of the conditions for which a tip is indenting or penetrating the cell membrane.

Table 8.4: Tip-cell membrane interaction determined by the force drop F_d and change in elastic modulus E .

Cell indentation		Cell penetration	
Type I	Type II	Type III	Type IV
$F_d = 0$	$E_1 = E_2$	$F_d > 3\sigma$	$E_1 > E_2$
		$F_d > 3\sigma$	$E_1 < E_2$
			$F_d > 3\sigma$

8.4 Intranuclear injection

The goal of this experiment was to test if the microinjection system with 200 nNtip opening can deliver liquid directly into cell nuclei.

To test this, a solution of both sodium fluorescein and propidium iodide was used. Propidium iodide intercalates with the DNA to emit a strong red fluorescence but cannot pass spontaneously through the nuclear envelope of a living cell. By injecting a solution of both sodium fluorescein and propidium iodide into a cell it was possible to test whether the tip had penetrated the cell membrane (the cell fluoresces in the green) and whether it also entered the cell nucleus (the nucleus fluoresces in the red). The concentration of propidium iodide in the mixture was very high (1 mg mL^{-1}) to ensure a strong fluorescent signal. Table 8.5 presents

values of the force setpoint, tip pause and injection parameters used in the experiment.

Table 8.5: Summary of the parameters values used during the injection of sodium fluorescein molecules.

	Force setpoint	Tip pause	Pressure Δp	Pulse length Δt
Used in practice	50 nN to 150 nN	5 s	0.4 bar to 0.8 bar	0.5 s

Forces up to 150 nN were used in order to increase the penetration probability of the nuclear envelope. The pressure pulse values were 0.4 bar and 0.8 bar. During the intracellular injection of sodium fluorescein it was shown that a pressure of 0.8bars was sufficient to successfully deliver liquid into the cells. For intranuclear injection it was decided to use pressure values not higher than 0.8 bar due to the possibility of damaging the cell nuclei.

Figure 8.10 shows fluorescent images taken after the experiment. In total 20 SaOs-2 cells were targeted, out of which 3 emitted a green fluorescent signal and 4 cells died immediately after the injection, presumably due to an excess of delivered volume. None of the 3 cells emitting green fluorescence also emitted in the red.

Figure 8.10: Confocal images of SaOS-2 cells after the injection of the sodium fluorescein and propidium iodide mixture. a) shows two neighbouring cells and b) shows single cell, all emitting green fluorescence after succesfull delivery of liquid.

Table 8.6 compares results of the force–separation curve analysis with the cell analysis. Four different force setpoints were used in the experiment: 50 nN, 80 nN, 100 nN and 150 nN. For 50 nN setpoint 4 curves out of 11 had a penetration peak. Out of the 4 cells penetrated, 3 exploded directly after injection and 1 emitted a green fluorescent signal (Figure 8.11b)). For the 80 nN setpoint 2 cells out of 4 were penetrated, of which one died due to the excess of injected liquid and 1 did not emitting a fluorescent signal. For the 100 nN setpoint 2 cells out of 3 were penetrated and both emitted a green fluorescent signal (Figure 8.11a)). Finally, for the 150 nN applied force 1 cell out of 2 was penetrated but did not emit a fluorescent signal.

Some insight into these results lies in the in depth analysis of the penetration events on the force-separation curves. Figure 8.11 shows the force-separation curves with penetration peak for the 50 nNsetpoint. The penetration peak occurs when the tip partially indents each cell. Liquid was injected into each cell, since, after the experiment one cell was emitting the fluorescent signal and 3 others exploded immediately after the injection.

Figure 8.12a)-b) show force-separation curves for 80 nN and Figure 8.12c)-d) - for 100 nN applied force. Figure 8.12a) shows penetration of a cell membrane after partial cell indentation.

Chapter 8. Microinjection using the AFM-based system

Figure 8.11: Force-separation curves measured for 50 nN applied force.

Figure 8.12b)-d) have also penetration events on their force-separation curves, however the tip has first indented the cell to the point that only thin part of the cell was kept between the tip and the hard substrate, and after the tip penetrated the cell and touched the substrate. It can be seen that injection into a cell in such situation can result in no liquid delivery into cells, since 1 cell out of 3 was not emitting the fluorescent signal. Similar results were obtained when the cell was penetrated with 150 nN applied force. The registered force-separation curve had similar shape to the force-separation curves presented on Figure 8.12b)-d).

Explosion of 4 cells out of 7 shows that too much liquid was injected into cells. At this point it is not clear, if the cell damage occurred because the cells could not accommodate the liquid volume or perhaps due to too large volumes delivered directly to the cell nuclei. During intracellular injection of sodium fluorescein injection parameters of 0.8 bar and 0.5 s were used and none of the 14 penetrated cells exploded after the injection. Here, 1 cell exploded after injection of liquid with pressure pulse of 0.4 bar and 0.5 s and 3 after injection with pressure pulse of 0.8 bar and 0.5 s. Out of the 4 exploded cells, two cells had force-separation curves with two force drops (Figure 8.12b) and Figure 8.12a)). In chapter 6, section 6.3.1 two possible meanings of the second force drop were discussed: penetration of the nuclear envelope and slippage of the tip into to cell. The results presented here suggest that the second peak may be associated with further membrane penetrations. It is interesting to observe, for example, that the f-s curve shown in Figure 8.12b) shows a second force drop that is clearly associated with a

8.4. Intranuclear injection

Figure 8.12: Force-separation curves measured for a) - b) 80 nN applied force, and c)-d) 100 nN applied force.

change in elasticity and results in cell death. However, for many of the f-s curves, the peaks are very close to the point where the AFM tip comes into contact with the cell culture support: they are therefore difficult to interpret. These results clearly show that the interpretation of the force-distance curves for cell penetration is complex, particularly at higher force setpoints or when the tip contacts the underlying cell culture support.

8.5 General Discussion

The three injection tests (water injection, sodium fluorescein injection, and mixture injection of sodium fluorescein with propidium iodide) were used to perform proof of concept experiments of the AFM-based microinjection system. The tests have shown that the AFM probe could penetrate the cell membrane and that liquid could be delivered into the cells. The liquid volume depended, as expected on the values of the injection parameters (pressure and time). It was shown that cell injection of water with 300 nm tip opening and high values of the injection parameters $\Delta p > 0.5$ bar and $\Delta t = 0.5$ s caused immediate cell death. Since in Chapter 6 it was shown that tip insertion does not cause cell death, it was concluded that during the injection experiment, the cells died due to excess injected liquid.

During the experiment design reference values of the injection parameters were proposed based on the predicted values of cell volume (Chapter 3, Section 3.2.1) and liquid flow through NADIS probes discussed in Chapter 5, Section 5.3. It was assumed that in order to successfully deliver liquid to cells with 200 nm opening, values of the injection parameters should be $\Delta p = 0.05$ bar, 16 times smaller compare to used $\Delta p = 0.8$ bar, and $\Delta t = 0.02$ s, which was 25 times smaller than used in the experiment. There are a number of possible explanations of the large differences in the injection values needed. One possible explanation relates to the position of the tip apex and its opening during tip insertion. The theoretical values of the injection parameters were calculated assuming that the entire tip opening is inside the cell during injection (Figure 8.13a)). However, the membrane slip parameter calculated in Chapter 6, Section 6.4.1, is 75 nm while the diameter of the tip opening is 200 nm. With a tip half angle of 35° , even a perfectly positioned opening and a perfectly sharp tip would require the cell membrane to be displaced by more than $200 \text{ nm} \times \cos(35^\circ)$ or 164 nm (Figure 8.13b)) for the tip opening to be entirely inside the cell. This suggests that the tip opening is not entirely enclosed in the cell during the injection (Figure 8.13c)) resulting in partial injection of liquid outside the cell. Thus, in order to deliver a given liquid volume into a cell, higher values of injection parameters are required compare to the theoretical situation.

To test the hypothesis that the experimental values of the injection parameters are higher than the theoretical ones due to the partial insertion of tip opening, an injection experiments could be performed with tip opening centrally located at the tip apex. Positioning the tip opening at the apex would decrease the penetration probability, however, once the tip was inserted, the probability that the entire tip opening was enclosed inside the cell would be much higher.

Another explanation for the difference between calculated and experimental injection parameters was proposed by Minaschek et al. [66]. The suggestion is that the delivered liquid might leak out from the cell during the injection. The leakage may be due to the cytoplasmic viscosity that is counteracting the injection, or due to weak adhesion or lack of it between the ruptured membrane and the tip. However, in presented here experiments cells explosion and their rapid recovery after the injection suggest otherwise. If the leakage had occurred it would have been difficult to cause cell explosion, since most of the liquid would escape. Also due to

Figure 8.13: Schematic drawing presenting a) a theoretical situation in which the tip is inserted inside the cell, in a way that the entire tip opening is enclosed inside the cell, resulting in liquid delivery only into the cell. b) Cell membrane rupture with the NADIS tip with opening of 200 nm. Directly after the rupture the membrane moves up along the tip, of a distance of 75 nm in average, for a NADIS probe with approximately 100 nm tip radius. The distance is called a membrane slip and it is a parameter that can be read from a force-separation curves. c) Probable situation during injection experiment, when the tip is inserted in a way that the tip opening is only partially inserted inside the tip. In such a situation the liquid only partially injected inside the cell and partially into the cell medium. d) Possible situation during intranuclear injection. The tip can penetrate the cell membrane and the nuclear envelope; however the tip geometry makes it unlikely to insert the tip opening inside the nucleus. As a result the liquid is delivered outside the nucleus.

the leakage the hole made by the tip in the cell would enlarge and caused more damage to the cells. Possibly, both hypotheses: partial insertion of the tip opening into cells and the leakage of liquid during injection might be right.

In the Section 8.2.1 (Mechanical stability of probe/probe holder seal) effect of sudden force increase during the liquid injection was discussed. It was proposed that this effect is caused by deformation of the polymer tape used to attach NADIS probe to the AFM probe holder. During the tape deformation the tip is pushed towards the cell causing uncontrolled tip-cell interactions. To eliminate this effect the polymeric tape would need to be replaced with more rigid material.

The possibility of only partial insertion of tip opening inside a cell might also play an important role during intranuclear injections with the NADIS probes. Even if the tip penetrates the nuclear envelope, it is could be unlikely that the tip opening will be inserted inside the nucleus

(Figure 8.13d)) resulting in liquid delivery only into the cell cytoplasm.

8.6 Conclusions

The proof of concept injection results clearly demonstrate that the AFM-based microinjection system can be used as a tool to deliver liquid into single living cells. During the preliminary injections of water, an excess of liquid was delivered to cells and caused cell explosion giving an instantaneous confirmation of successful injection. This approach allowed to successfully test system limitations, such as leakage and clogging of the tip aperture. It was shown that the system is tight for pressures up to 2 bar and no clogging was observed. The water injection results showed that during the pressure pulse an apparent force increase occurs. The results of the mechanical stability tests showed that this effect is caused due to the deformation of the polymer tape used to attach the NADIS probe to the probe holder. Further development of the seal between the probe and probe holder would be required to eliminate this effect.

The intracellular injection experiment demonstrated injection into cells without cell damage and was used to test the hypothesis presented in Chapter 6 on the determination of tip insertion. As a result out of 21 cells, 14 cells were emitting a fluorescent signal and none of the cells exploded during the experiment. Analysis of the force-separation curves showed that all force-separation curves of the cells emitting fluorescent signal showed a change in elasticity after a force drop. Among the 7 cells that did emit a fluorescent signal, one cell had a force-separation curve with a force drop but no elasticity change. These results are exactly as predicted by the hypothesis. However, given the very small number of cells tested in this experiment, further experiments would be needed to confirm the hypothesis.

Direct injection into cell nucleus was also attempted. It was shown that during the injection the tip could penetrate the cell membrane and deliver the liquid into the cell, but labelling of the nuclear DNA was not shown. It is, however, suggestive, that in these experiments-in which no damage to the cells was expected - cell death was observed 4 times. These experiments clearly demonstrated the difficulty of interpreting complex (and sometimes, simple) force separation curves where cell penetration is involved.

9 Conclusion & Outlook

The main objective of this thesis was to develop a micro injection system for single adherent cells based on AFM probes with a micro fluidic system. Additional objectives were the demonstration of injections into cells and a better understanding of the involved AFM/cell interactions.

The realized microinjection system was based on the Nanoscale Dispensing (NADIS) probes, an earlier development at CSEM. The existing micro fabrication process of the NADIS probes was adapted to improve the poor fabrication yield. A KOH etch mask made of parylene C was developed to address the KCl contamination of the etched fluidic channels of the probes. Extensive investigations of adhesion promotion methods such as thermal treatment and recrystallization of the parylene C mask proved its suitability as a polymer KOH etch mask that can be easily stripped, even from narrow structures such as the microchannels by thermal treatment at 700 °C for several hours.

Three tip apertures were developed for single cell manipulation: a needle like aperture for cell injection, where an ellipsoidal opening was located next to the tip apex in order to retain a sharp tip to break the cell membrane, and two flat apertures for labeling the cell membrane and other surfaces. The openings with a diameter between 200 nm and 500 nm were milled with a focused ion beam.

An attempt was made to characterize the fluidics properties of the system. Pressure dependent flows of gases and degassed water were measured through the NADIS probes with tip apertures up to 200 nm in diameter. The results for larger tip openings were successfully fitted with a linear model and can be approximated by simple theoretical model based on Hagen-Poiseuille law. The water flow measurement through tip apertures smaller than 2 μm resulted in tip clogging due to gas bubbles. Therefore the theoretical model was used as indication of the flow rate through systems with small tip apertures which allowed to determine reference values of the injection parameters for the proof of concept injection experiments.

A more in-depth analysis of force-separation curves was developed allowing the biophysical

Chapter 9. Conclusion & Outlook

analysis and interpretation of penetration phenomena. 5 parameters were defined from a force-separation curve with a penetration peak. Four of these parameters have already been mentioned in the literature, whereas the fifth parameter, the membrane slip has been proposed in this work. A simple mechanical model was presented, based on the assumption that the membrane slip parameter represents the movement of the cell membrane up the AFM tip during rupture of the membrane. The analysis of the force-separation curves with this model has shown that the mechanical model is in very good agreement with the results obtained with the 10 nm sharp tip, but that the agreement is less good for the 100 nm NADIS tip.

A study was made of the invasiveness of the different AFM tips, as well as possible cell death caused by tip penetration. The obtained results allow to claim that the cell penetration with an AFM tip does not cause a severe damage to cells. Directly after the cell penetration there is no cell damage and 20 hours after a maximum of 14 % of cell apoptosis was observed, a value similar to the natural cell death measured on the control sample.

The proof of concept liquid delivery into individual cells was studied. Intentional injection of a large water volume resulted in cell explosion which was used as confirmation that the injection system is working. No system leakage for pressure values up to 2 bar and no clogging of the tip opening with cell residues were observed. The sodium fluorescein injection was used to test values of the injection parameters. The values of the injection parameters were chosen based on the results of the water injection experiment. None of the cells exploded during the sodium fluorescein injection experiment and all were apparently alive a few hours after the injection. Direct injection into cell nucleus was also attempted. It was shown that during the injection the tip could penetrate the cell membrane and deliver the liquid into the cell, but labelling of the nuclear DNA was not achieved.

Combined technical development of the AFM based microinjection system with the study of cell membrane penetration allowed to propose for the first time a definition of a cell membrane penetration, discover the membrane slip parameter and define the 5A method for biophysical analysis of probe indentations.

The proposed AFM-based microinjection system could be a powerful tool for direct injection of molecules into nuclei of single cells. However, to achieve this goal further development of the NADIS probes is required. First of all, the geometry of the tip has to be re-considered to assure penetration of the nuclear envelope and complete insertion of the tip opening. Secondly, geometry of the microfluidic channels inside the NADIS probe has to be re-designed in order to gain control over the ejected from the tip liquid.

Acknowledgements

During all the years of my doctoral studies I have received an endless support from my colleagues, friends and family. I would like to use this part of my thesis to express my endless gratitude for their presence in my work and my life.

I am sincerely grateful to my sector – head Dr. Martha Liley, whose expertise directed me during my research, and her patience and understanding kept me going through all the years of my studies. I appreciated her great assistance in writing publications and this thesis, but first of all I appreciated her kindness and friendship I could always count on. Thank you Martha for all our precious discussions, your trust, and the time you always found for me despite your tight schedule.

Very special thanks go to my thesis supervisor Prof Philippe Renaud from EPFL. I appreciated his vast knowledge in microfluidics, physics and microfabrication. Thank you Philippe for you helping me shaping my fields of research (liquid flow, cell indentations, development of parylene mask), which gave a solid foundation for this thesis.

I would like also acknowledge Dr. André Meister, my thesis co-supervisor, for his technical assistance throughout the first three years of my studies. It was a great pleasure to work with a person who has unlimited sources of ideas, patience and kindness.

Many thanks go to the biologist I had the pleasure to work with: Martha Giazzon, Nadège Matthey and Sher Ahmed (the three musketeers) for introducing me into the world of cell biology, for their support, hard work and many great ideas which allowed me to succeed in my work.

I am grateful to Prof Herbert Keppner and his group in La Chaux-de-Fonds for the fruitful collaboration on parylene mask development. Special thanks go to fellow PhD student Jérôme Charmet, for his energy, enthusiasm and determination and most of all for his friendship.

I would like also to acknowledge Dr. Christian Santschi for introducing me to the focused ion beam technique and sharing with me his knowledge and experience in this field. Thank you Christian for your optimism and readiness to help each time I needed it.

Many sincere thanks to Dr. Emmanuel Scolan for his enormous support in the chemistry field

Acknowledgements

and Dr. Philippe Niedermann for introduction to the microfabrication techniques.

I am also very grateful to all my colleagues and friends from SAMLAB and LMTS group from EPFL for their never – ending support in my research: Dr. Dara Bayat, Dr. Fabio Jutzi and Dr. Robert Lockhart for support in the microfabrication, Blaise Guélat for his precious advices on microfluidics, Luc Maffli for electronics, Dr. Çağlar Ataman for his ideas, and last but not least Dr. Peter Van der Wall for allowing me to work in his laboratory to develop my microfluidic system and his expertise.

Special thanks go to Patrick Othenin–Girard and Laurent Beynon from the mechanical workshop for their enormous support and hard work on technical development. But most of all for supporting my crazy ideas.

I would like also to express my gratitude towards my colleagues from CSEM for all the fruitful discussions we had together, specially: Silvia Angeloni, Branislav Timotijevic, Andrea Dunbar, Rolf Eckert, Bastien Shyrr, Massoud Dadras and Mireille Leboeuf.

Many thanks go to Patricia Bingeli for helping me going through Swiss administration and French classes during the first two years of my studies.

As the last one I would like to express my gratitude to my family and friends and without whom I would not have accomplished my work.

First of all I would like to thank my mum Irena Przybylska and my mum-in-law Katrin Bitterli, to whom I have dedicated this thesis, for their sacrifice which gave me time to finish my thesis. Mamo dziękuję Ci za to że zawsze byłaś i za twoją wiarę we mnie. Mutti, thank you for all your love and affection to my daughter.

Many thanks go to my brother-in-law Sebastian and his wife Mariflore for all the help they have offered me during my studies. Most of all thank you for all the weekend during the last two months, it was priceless.

I would like to express my enormous gratitude toward the family Baborowski: Jacek, Rachel, Arno and Emma–Klara for their friendship and rescue every time I was in troubles. Many thanks to family Sereda: Olya, Andriey, Weronika and Alex and family Weber: Tordis, Stefan and Olivia for their affection and support no matter what.

Many thanks to all my friends who never forgot, even when I didn't remembered: Ksenija Delgado, Olaf Schleusing and his wife Shamla, Sara Talaei, Rahel Strässle, Samin Akbari, Budhaditya Banerjee, Philip Wägli and Olga Kubova.

Finally, many thanks to my husband Roland for keeping me going, no matter the cause.

P.S In case I have forgotten somebody, I would like to send him/her my thanks as well!

Neuchâtel, October 14th 2012

Curriculum Vitae

Joanna Katarzyna Bitterli (-Przybylska), MSc.

Chemin de Belleruche 3/12
2000 Neuchâtel

Technical Physics Engineer
Born 15 May 1983
Married, Polish, 1 daughter

Education:

09/2007 – 2012 Ecole Polytechnique Fédérale de Lausanne, Lausanne, CH

Studies towards PhD degree, Doctoral Program Microsystem and Microelectronics, Research held at CSEM SA at the Life Sciences & Nanotechnology Department. Provisory Thesis entitled ‘AFM based single cell microinjection: technological developments, biological experiments and biophysical analysis of probe indentation.’

10/2002 – 06/2007 Poznan University of Technology, Poznan, PL

Studies towards Master of Science degree at Faculty of Technical Physics
Specialization in Material Physics and Nanotechnologies. Master’s Thesis entitled ‘The Application of a Model for Energy Transfer between Monomolecular Centers to Describe Electroluminescence Kinetics of Copper in Polymer Structures’

04/2006 – 07/2006 Brandenburgische Technische Universität Cottbus, Cottbus, DE

Socrates – Erasmus Student Exchange Programme. Studies at the Faculty of Mathematics, Natural Science and Computer Science. Research: Project on Scanning Probe Based Electrical Characterization of Semiconductors

Prizes:

Doctoral Studies: **Oral Presentation Prize** AFM BioMed Conference Award 2011
Talk title: *AFM microinjection systems for operations on single living cells*

Master Studies: **J. A. Gorecki Scholarship** for excellent scientific achievements, attributed for five best students of University (obtained for three consecutive semesters)

Scholarship for outstanding records of studies and scientific results at Poznan University of Technology, obtained for four consecutive years

Socrates - Erasmus Scholarship

Individual Curriculum - a privilege to study according to the individual curriculum path
