(Received 12 September 2012; accepted 29 November 2012; published online 3 January 2013)

The solid solution of \((x)Ba_{0.7}Ca_{0.3}TiO_3-(1-x)BaZr_{0.2}Ti_{0.8}O_3\) is known to exhibit high piezoelectric constants. Discrepancies in the reported phase transitions and structure around room temperature, however, have complicated the understanding of the enhanced properties. Rietveld refinement of high-resolution X-ray diffraction is employed here to establish and refine the crystallographic structure at temperatures from \(-100\,^\circ C\) to \(150\,^\circ C\) for \(x = 0.5\). A combination of rhombohedral \(R3m\) and tetragonal \(P4mm\) is found to coexist at temperatures of \(20\,^\circ C\) and \(-25\,^\circ C\), bordered by single phase rhombohedral and tetragonal regions at lower (i.e., \(-100\,^\circ C\)) and higher (i.e., \(70\,^\circ C\)) temperatures, respectively. The diffractograms also show signs of strain and domain wall scattering that are linked to the sample history.

I. INTRODUCTION

The properties of ferroelectric compositions near morphotropic phase boundaries (MPBs) and polymorphic phase transitions are often superior to compositions far from these boundaries. Thus, the identification of phase transitions in ferroelectric solid solutions is of high relevance to identifying useful compositions. The \((x)Ba_{0.7}Ca_{0.3}TiO_3-(1-x)BaZr_{0.2}Ti_{0.8}O_3\) solid solution was recently shown by Liu and Ren to exhibit very high room-temperature piezoelectric coefficients of up to \(620\,\text{pC/cm}\). The enhanced piezoelectric performance has been attributed to vanishing polarization anisotropy and polarization rotation in the presence of a tricritical point. For \(50\%\) BZT-50\% BCT, the phase transition sequence upon decreasing temperature was originally proposed as cubic, tetragonal, then rhombohedral. Further investigation of the microstructure by transmission electron microscopy has revealed the coexistence of tetragonal and rhombohedral nanodomains around the MPB, a microstructure commonly associated with high piezoelectric performance. Recent work has also reported the room temperature structure as mixed-phase rhombohedral and tetragonal. The parent phase \(BaTiO_3\) has an intermediate orthorhombic phase at temperatures between the tetragonal and rhombohedral phases, a fact which has also motivated reports that \(50\%\) BZT-50\% BCT is mixed-phase rhombohedral and orthorhombic at room temperature. However, no orthorhombic crystallographic model has yet been shown to describe the data.

Property measurements also suggest the possibility of extra phase transitions, in addition to the expected cubic-tetragonal and tetragonal-rhombohedral transitions for \(50\%\) BZT-50\% BCT. For example, Benabdallah et al. observed peaks in the pyroelectric current at \(93\,^\circ C\), \(25\,^\circ C\), and \(-3\,^\circ C\), and Damjanovic et al. reported anomalies in dielectric and elastic properties at approximately \(90\,^\circ C\), \(34\,^\circ C\), \(8\,^\circ C\), and \(-60\,^\circ C\) (Fig. 1(b)). Thus, further crystallographic characterization of the BZT-BCT system and interpretation relative to the property coefficients is needed to fully understand the
phase diagram and properties. In materials containing multiple polymorphic phases and overlapping reflections, analysis of subtle structural differences using XRD requires high resolution and low instrumental contributions to peak broadening. Analysis of higher 2θ reflections is preferred to resolve subtle peak splitting, but doing so requires very high intensity X-ray sources to compensate for the lower intensity. Therefore, high-resolution powder diffraction data were recorded in this study at a synchrotron X-ray source in order to investigate the phase sequence in the composition 50BZT-50BCT from −100 °C to 150 °C. Crystallographic structure refinement using the Rietveld method was applied to resolve the structure at selected temperatures.

II. EXPERIMENTAL

Powder used in this investigation was produced by mixing high purity BaCO₃ (99.95%), CaCO₃ (99%), TiO₂ (99.8%), and Ba₂ZrO₃ (99.5%) powders (Sigma Aldrich) followed by calcining at 1350 °C for 2 h to produce uniform composition powders. The powders were uniaxially pressed into disks, and ceramic samples were obtained by sintering powder disks at 1450 °C. Sintered ceramic samples were crushed into powders again, and high-resolution powder XRD patterns were measured at beamline 11-BM at the Advanced Photon Source, Argonne National Laboratory. The powder was loaded into a 0.4 mm quartz capillary, mounted in the beam-path, and rotated continuously to enhance powder or orientation averaging.

Diffraction patterns were recorded in the temperature range −100 °C to 150 °C; the temperature was controlled by an Oxford Cryostream 700 + N₂ gas blower. For the applied measurement energy, the calibrated wavelength was 0.412953 Å and the resolution ΔQ/Ω = 1.7 × 10⁻³, corresponding to an instrumental contribution to the peak full width at half maximum of 0.005°. Simultaneous high-resolution and high-speed data collection was obtained by use of a state-of-the-art scintillator-based multi-analyzer detector system. Diffraction patterns were recorded using a 2θ range of 0.5° to 51° in 0.001° steps and a 0.1 s counting time at each step. A diffraction pattern was recorded at constant temperatures of 20 °C and 150 °C prior to cooling the sample to −100 °C and recording a sequence of patterns at incrementally increasing temperatures of −100 °C, −25 °C, 20 °C, 70 °C, 100 °C, and 120 °C.

Rietveld refinements were performed using the GSAS software with the graphical interface EXPGUI. Refined parameters included the lattice parameters, atomic positions, and atomic positions. A-site atoms (Ba and Ca) were constrained to the origin and equivalent isotropic displacements. The B-site atoms (Ti and Zr) were constrained to the same atomic position and isotropic displacements.

Space groups and starting values for lattice parameters and atomic positions were obtained from the literature, except for mixed phase patterns where refined parameters from neighboring temperatures were used as starting values. For the 20 °C pattern, a critical step was required in the routine in order to avoid a false minimum solution. This step was the exclusion of the pseudo-cubic (110)-type reflections (hereafter, referred to as (110)pc reflections) from the fit during the initial stage of the refinement. Without exclusion, this group of reflections dominates the refinement because of its high intensity, yet it has low resolution of the structural distortions because of its low diffraction angle. Because of the large number of reflections in refinements containing multiple phases, initial values of lattice parameters were adjusted manually to fit the higher order reflections at higher angles (e.g., (222)pc, (400)pc etc.), where peak splitting of subtle distortions is more clear. Phase fractions, atomic positions, isotropic displacements, and profile parameters were refined first. Then, lattice parameters were included in the refinement, before the (110)pc reflections were re-introduced and the entire pattern refined.

III. RESULTS AND DISCUSSION

All major reflections can be indexed to a perovskite structure, with a gradual change in peak shape with temperature, as shown in Fig. 2 for selected reflections. The patterns measured at 100 °C, 120 °C, and 150 °C appear consistent with the phase diagram and properties. In materials containing multiple polymorphic phases and overlapping reflections, analysis of subtle structural differences using XRD requires high resolution and low instrumental contributions to peak broadening. Analysis of higher 2θ reflections is preferred to resolve subtle peak splitting, but doing so requires very high intensity X-ray sources to compensate for the lower intensity. Therefore, high-resolution powder diffraction data were recorded in this study at a synchrotron X-ray source in order to investigate the phase sequence in the composition 50BZT-50BCT from −100 °C to 150 °C. Crystallographic structure refinement using the Rietveld method was applied to resolve the structure at selected temperatures.

FIG. 2. Selected high-angle reflections of 50BZT-50BCT as recorded by high-resolution X-ray diffraction.
with the cubic space group \( \text{Pm}3\text{m} \) and were refined within this space group. At 70 °C, the structure was refined to the tetragonal space group \( \text{P}4\text{mm} \).

The 20 °C pattern recorded during the heating sequence was fit to a combination of \( \text{P}4\text{mm} \) and the rhombohedral space group \( \text{R}3\text{m} \), converging at an \( R_p \) value of 5.0%. Using a quantitative phase fraction calculation,\(^{17}\) the phase fractions were found to be 58 wt. % \( \text{R}3\text{m} \) and 42 wt. % \( \text{P}4\text{mm} \). Refinement to pure \( \text{P}4\text{mm} \) only resulted in an \( R_p \) value of 8.9%. Selected reflections refined using both models are shown in Fig. 3. This result demonstrates that a phase combination at 20 °C better qualitatively describes the measured diffraction pattern than a single phase refinement. Refinement using the orthorhombic space group \( \text{Am}2\text{m} \) was also performed, but the experimental relative intensities could not be accounted for, and the refinement converged to an \( R_p \) value of 7.7%, higher than that obtained using the combined \( \text{R}3\text{m} \) and \( \text{P}4\text{mm} \) phases. Including the space group \( \text{R}3\text{m} \) with \( \text{Am}2\text{m} \) in a two-phase refinement did not result in a stable refinement. These results suggest that the orthorhombic phase is not present in this composition at these temperatures, in contrast to what has been proposed in Refs. 4 and 5.

The \( \text{R}3\text{m} \) phase in the 20 °C pattern refined to significantly broader peaks than the \( \text{P}4\text{mm} \) phase (see, Fig. S1, supplementary information\(^{16}\)). Constraining the width of the \( \text{R}3\text{m} \) phase to equal that of the \( \text{P}4\text{mm} \) phase (on the assumption that the microstructural contributions to broadening in the two phases are not significantly different) reduced the quality of the fit drastically. The refinement (shown in Fig. 4(a)) converged at an \( R_p \) value of 7.0% and a phase fraction of 23 wt. % \( \text{R}3\text{m} \). Because neither of these extremes (i.e., constrained or un-constrained broadening of each respective phase) is more justified than the other, we consider that the real phase fraction of the \( \text{R}3\text{m} \) phase at 20 °C is between 23 wt. % and 58 wt. %.

The sample history effect is also evident by comparing the two distinct diffraction patterns measured at 20 °C, both prior to and during the heating sequence. The intensity of the (h00)\(_\text{pc} \) reflections, as shown for (400)\(_\text{pc} \) in Fig. 4(b), is clearly dependent on thermal history as also shown by Ehmke et al.\(^3\) In the present case, the differences are mostly observed as changes in peak broadening and diffuse scattering between the peaks. These changes can be ascribed to differences in domain wall scattering in the tetragonal phase and/or microstrain in the rhombohedral phase.

The best refinement of the −25 °C pattern was also obtained by a combination of \( \text{P}4\text{mm} \) and \( \text{R}3\text{m} \) phases. The refinement converged at an \( R_p \) value of 4.9% with 5 wt. % \( \text{P}4\text{mm} \) and 95 wt. % \( \text{R}3\text{m} \) phase fractions. Due to the small fraction of \( \text{P}4\text{mm} \) phase, the lattice and profile parameters were the only parameters of this phase that were refined. Refinement with a pure \( \text{R}3\text{m} \) phase converged to an \( R_p \) value of 6.8% with a significantly poorer visual fit that did not account for the asymmetry of the (h00)\(_\text{pc} \) reflections. Selected reflections from both refinements at −25 °C are shown in Fig. 5.

The pattern at −100 °C was modeled by a single phase in the \( \text{R}3\text{m} \) space group. Possible indications of peaks in addition to the \( \text{R}3\text{m} \) peaks were observed as peak asymmetries or subtle shoulders on the high-angle (222)\(_\text{pc} \) and...
(133)_pc reflections, and refinement within the monoclinic Cm space group was, therefore, also attempted. However, the extra reflections allowed by symmetry lowering did not account for these possible profile deviations or otherwise improve the quality of the fit.

Final refined values at each temperature are listed in Table I. Additional refined values (atomic positions and isotropic displacement parameters) are listed in Table SI (supplementary information^18). All of the final refinements converged to Rp values of 6% or less. Fig. 6 shows some trends of the refined values as a function of temperature. Specifically, the rhombohedral and tetragonal spontaneous lattice strains appear to decrease with temperature while the average unit cell volume increases. These changes are expected because spontaneous ferroelastic lattice strains typically decrease with temperature, and the coefficient of thermal expansion implies a unit cell volume increase. The phase sequence described in Fig. 6 is in good correlation with the gradual peak shape changes in the diffractograms (Fig. 3) and supports prior observations of a rhombohedral and tetragonal co-existence in the 50BZT-50BCT composition near room temperature.\(^2,3\) The present work indicates that the two-phase coexistence region extends to temperatures down to 50°C below room temperature or at least to \(-25°C\).

The property measurements from Damjanovic et al.\(^7\) that are re-drawn in Fig. 1(b) indicate three dominant phase transitions at approximately 90°C, 34°C, and \(-60°C\). The phase transition at \(-60°C\) was observed in Ref. 7 as both an inflection in the dielectric loss and a change in the Raman spectra that indicated a phase transition. In the present work, this transition is attributed as a change between single-phase \(R3m\) at lower temperatures to mixed-phase \(R3m + P4mm\) at higher temperatures. Similarly, the transition around 34°C in Ref. 7 is assigned from results in the present work as a transition from mixed-phase \(R3m + P4mm\) at lower temperatures to single-phase \(P4mm\) at higher temperatures. Finally, the transition at 90°C in Ref. 7 is assigned from results in the present work as a transition from \(P4mm\) to \(Pm\_3m\). The inflections in the dielectric and elastic properties around 8°C, however cannot be attributed to a measurable phase transition from high-resolution X-ray diffraction. In the

**Fig. 6.** Thermal trends in refined parameters of 50BZT-50BCT. (a) Refined values for the rhombohedral angle \(\alpha\) and tetragonality \((c/a)\), (b) refined unit cell volumes. The error bars are smaller than the symbol size. Grey areas indicate approximate phase transition temperatures.
present work, the diffraction patterns measured at temperatures both below $-25^\circ C$ and above $20^\circ C$ show differences that are best explained by changes in phase fractions, not by changes in the symmetry of the respective phases. It was observed that the phase fraction of $R3m$ in this two-phase mixture changes from 95 wt. % at $-25^\circ C$ to somewhere between 23 wt. % to 58 wt. % at $20^\circ C$. Most significantly, there were no observed superlattice reflections at either temperature that might be attributed to long-range octahedral tilting or other superstructure effects, and other phase combinations or phases of lower symmetry were not found to better describe the diffraction patterns. If a significant structural change exists in this temperature range, its signature in the diffraction pattern is small.

One remaining explanation that could describe the origin of the elastic and dielectric property inflections at $8^\circ C$ is that of domain wall motion. Domain wall motion can lead to the temperature dependent phase changes suggest interphase this property inflection and/or their coordinated effects, and domain wall motion of either phase may be contributing to the range results further define the existence of this region in at least tence near room temperature for 50BZT-50BCT. The present

IV. CONCLUSION

A phase sequence has been established for 50BZT-50BCT from $-100^\circ C$ to $150^\circ C$ by crystallographic refinement using the Rietveld method. High-resolution X-ray diffraction patterns allowed for a delineation of 50BZT-50BCT into cubic, tetragonal, tetragonal + rhombohedral, and rhombohedral regions upon cooling. In the mixed-phase region, the phase fractions were quantified to 23–58 wt. % $R3m$ at $20^\circ C$ and 95 wt. % $R3m$ at $-25^\circ C$. This work agrees with the previously reported room temperature two-phase region and expands its range in temperature to well below room temperature. Contributions from domain wall scattering and/or microstructural strain dependent on thermal history are evident in the diffractograms.
