Supporting Information

ABSTRACT: Three new lanthanide heterocyclic $\beta$-diketonate complexes [Dy(PPI)$_3$(EtOH)$_2$] (1), [Dy(PPI)$_3$(DPEPO)] (2), and [Tb(PPI)$_3$(DPEPO)] (3) [where HPPi = 3-phenyl-4-propanoyl-5-isoxazolonate and DPEPO = bis(2-(diphenylphosphino)phenyl)ether oxide] have been synthesized and fully characterized. Single-crystal X-ray diffraction analyses reveal that these complexes are mononuclear and that the central Ln\textsuperscript{III} ion is coordinated to eight oxygen atoms that are provided by three bidentate $\beta$-diketonate ligands and ethanol or bidentate DPEPO in a distorted square antiprismic geometry. These complexes have high molar absorption coefficients (up to $3 \times 10^4$ M\textsuperscript{−1} cm\textsuperscript{−1} at 285 nm) and display strong visible and, for Dy\textsuperscript{III}, NIR luminescence upon irradiation at the ligand-centered band in the range 250–350 nm. The emission quantum yields and the luminescence lifetimes at room temperature are $3 \pm 0.5\%$ and 15 ± 1 $\mu$s for 1, 12 ± 2\% and 33 ± 1 $\mu$s for 2, and 42 ± 6\% and 795 ± 1 $\mu$s for 3. Moreover, the crystals of 2 and 3 exhibit brilliant triboluminescence, visible in daylight.

INTRODUCTION

Ln\textsuperscript{III}-based functional molecular materials are stimulating more and more research because of their potential applications in fluoroimmunoassays,\textsuperscript{1} spectroscopic structural probes in biological systems,\textsuperscript{2} laser systems,\textsuperscript{3} optical amplification,\textsuperscript{4} organic light-emitting diodes,\textsuperscript{5} single-molecule magnets,\textsuperscript{6} and pressure/damage sensors.\textsuperscript{6} Among the Ln\textsuperscript{III} ions, Dy\textsuperscript{III} with its 4f\textsuperscript{9} electronic configuration exhibits two dominant emission bands in the visible region, one blue at $\sim$470 nm due to the $^4F_{9/2} \rightarrow ^4H_{15/2}$ transition and the other in yellow-orange at $\sim$575 nm arising from the $^4F_{9/2} \rightarrow ^4H_{13/2}$ transition. It is possible to achieve near-white light emission by adjusting the yellow-to-white light-emitting diodes,\textsuperscript{4} single-molecule magnets,\textsuperscript{5} and pressure/damage sensors.\textsuperscript{6} Among the Ln\textsuperscript{III} ions, Dy\textsuperscript{III} with its 4f\textsuperscript{9} electronic configuration exhibits two dominant emission bands in the visible region, one blue at $\sim$470 nm due to the $^4F_{9/2} \rightarrow ^4H_{15/2}$ transition and the other in yellow-orange at $\sim$575 nm arising from the $^4F_{9/2} \rightarrow ^4H_{13/2}$ transition. It is possible to achieve near-white light emission by adjusting the yellow-to-blue light-emission ratio.\textsuperscript{7} Consequently, Dy\textsuperscript{III}-activated luminescent materials are attracting much attention in view of their potential applications as single-phase white phosphors.\textsuperscript{8} Dy\textsuperscript{III} also emits several bands in the infrared spectral range, that is, between 0.75 and 1.5 $\mu$m, with one transition at around 1.3 $\mu$m ($^4H_{8/2}$ $\rightarrow ^4H_{13/2}$) that is considered a potential transition for fiber amplifiers,\textsuperscript{9} and it emits in the MIR range at 3 $\mu$m ($^4H_{11/2}$ $\rightarrow ^4H_{15/2}$) and 4.2 $\mu$m ($^4H_{11/2}$ $\rightarrow ^4H_{13/2}$). Like any other Ln\textsuperscript{III} ion, the low absorption coefficient of Dy\textsuperscript{III} ($\epsilon \leq 2.5$ M$^{-1}$ cm$^{-1}$ for the aqua ion) limits its practical applications, which require high emission intensities. This deficiency can be overcome by complexing it with an organic chromophore (antenna)\textsuperscript{10} that absorbs efficiently in the UV-visible spectral range and transfers its energy to the central Dy\textsuperscript{III} ion. $\beta$-Diketonates are known for efficiently transferring energy onto Ln\textsuperscript{III} ions, especially Eu\textsuperscript{III}.\textsuperscript{11} However, most $\beta$-diketonates are not efficient sensitizers for Tb\textsuperscript{III} and Dy\textsuperscript{III}, possibly because their triplet states lie at energies close to those of the emitting $^5D_{4}$ (20 400 cm$^{-1}$) and $^4F_{9/2}$ (20 800 cm$^{-1}$) levels of Tb\textsuperscript{III} and Dy\textsuperscript{III}, respectively.\textsuperscript{11b} It is known that an optimal ligand-to-metal energy transfer process for Ln\textsuperscript{III} needs $\Delta E($Ln$^{3+}$−$\pi\pi^*$) = 2500–5000 cm$^{-1}$,\textsuperscript{12} but there is no specific set of experimental data for discussing the ideal energy gap for the Dy\textsuperscript{III} ion. It has been noticed though that acylpyrazolones are efficient sensitizers for both Tb\textsuperscript{III}\textsuperscript{13} and Dy\textsuperscript{III}.\textsuperscript{14} In a previous study,

we designed two novel molecules based on isoxazoline, namely, 3-phenyl-4-propanoyl-5-isoxazoline (HPPI) and 4-isobutyryl-3-phenyl-5-isoxazoline (HIBPI), that proved to be highly efficient sensitizers for TbIII luminescence (overall quantum yields = 59–72%) because of the adequate energy of their triplet levels with respect to Tb(5D4)15.

One of the main causes of nonradiative deactivation of the LnIII ion is vibronic coupling with coordinated solvent (water) molecules, which dissipate energy nonradiatively in overtones of O–H vibrations.16 This drawback can be addressed by replacing the coordinated solvent molecules with neutral ligands capable of forming stable complexes with lanthanide ions and, additionally, allowing tuning of the photophysical properties. Thus, a large number of EuIII-tris-β-diketonates with several neutral donor ligands, like aromatic amines, sulfoxides, and phosphate oxides, saturating the coordination sphere have been reported. By contrast, systematic studies on the enhancement of the luminescent properties of TbIII or DyIII ions and, additionally, allowing tuning of the photophysical properties. Thus, a large number of EuIII-tris-β-diketonates with several neutral donor ligands, like aromatic amines, sulfoxides, and phosphate oxides, saturating the coordination sphere have been reported. were placed in calculated positions by means of the “riding” model. The crystal structures of 1 and 2 show, at the end of the refinement cycles, relatively high electron density (2.629 e/Å³ for 1 and 2.046 e/Å³ for 2), which are very close to Dy atoms. PLATON calculates higher values (because it uses a different algorithm than SHELXL97) for these peaks (obtained by difference Fourier synthesis), and it indicates that this may be due to unaccounted-for twinning or the wrong atomic assignment. These reasons are not valid here because no sign of twinning has been found, and the atomic assignment has been carefully checked. Our explanation relies on an absorption correction that has not been applied on these two samples because the software used (automar) has no option for it. Nevertheless, the absorption is not very important (see the absorption coefficient for both crystal structures), and the peaks obtained by PLATON are overestimated. CCDC-933593, and 732130 contain supplementary crystallographic data for complexes 1, 2·2MeCN, and 3·1.5MeCN, respectively. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 2EZ, U.K.; fax, (Internet) +44-1223/336033; e-mail, deposit@ccdc.cam.ac.uk].

RESULTS AND DISCUSSION
Spectroscopic Characterization of Complexes 1−3. The molecular structure of the ligands and LnIII complexes 1−3 are presented in Figure 1. Microanalysis and high-resolution mass spectral data for 1−3 demonstrate that the Ln/PPI mole ratio is 1:3 and that one molecule of DPEPO is coordinated to the metal ions in 2 and 3. The IR carbonyl stretching frequency of HPPI (1704 cm⁻¹) is shifted toward lower wavenumbers in the complexes (1648 cm⁻¹ in 1 and 1649 cm⁻¹ in 2 and 3), indicating the coordination of the carbonyl oxygen to the LnIII cation in each case. Furthermore, the red shifts observed in the P=O stretching frequency of DPEPO (1197 cm⁻¹) in complexes 2 and 3 (down to 1180−1181 cm⁻¹) confirm the coordination of DPEPO to each of the LnIII ions. Thermogravimetric analysis under a nitrogen atmosphere (Figure S1, Supporting Information) shows that the decomposition temperatures (Td) of complexes 2 and 3 (250 °C) are higher than 1 (100 °C). Subsequent continuous thermal decomposition of complex 1 takes place in the range 100−600 °C, leaving a residue representing approximately 21% of the initial mass and corresponding to the formation of Dy₂O₃. On the other hand, complexes 2 and 3 are stable until about 250 °C and do not decompose completely even up to 900 °C. This indicates that the replacement of coordinated ethanol molecules in 1 by the chelating phosphate oxide ligand considerably enhances the thermal stability of the ternary complexes with DPEPO.

Solid-State Structure. Slow evaporation of saturated solutions of 1 in EtOH/CH₂Cl₂ (1:1) and 2 and 3 in MeCN results in the formation of single crystals of the LnIII complexes containing four (2) or three (3) MeCN molecules per unit cell. Hence these solvates can be represented as 2·2MeCN and 3·1.5MeCN. The single-crystal X-ray diffraction analyses of 1, 2·2MeCN, and 3·1.5MeCN reveal that the complexes crystallize in the monoclinic space groups P2₁/c (1) and Cc (2 and 3). The asymmetric units of 1 and 2·2MeCN, along with a partial numbering scheme, are displayed in Figures 2 and 3, and those of 3·1.5MeCN are in Figure S2 (Supporting Information). Important experimental parameters for the structure determinations are listed in Table S1 (Supporting Information), and selected bond lengths (Å) and angles (deg) in Table 1. The ionic radii obtained for DyIII (1.053 Å in 1 and 1.044 Å in 2·2MeCN) and TbIII (1.050 Å) in 3·1.5MeCN are in good agreement with the accepted values for these complexes.
octacoordinated LnIII ions. Indeed, the LnIII ions are surrounded by eight oxygen atoms, out of which six are provided by three bidentate β-diketone ligands and two ethanol molecules in 1 or one bidentate DPEPO ligand in 2·2MeCN and 3·1.5MeCN. In the latter complexes, the two Ln−O bonds involving the DPEPO ligand are shorter than the six Ln−O bonds to the PPI ligands. A similar trend of bond distances has been observed in tris(3-phenyl-4-benzoyl-5-isooxazololento)terbium(III)-bis(2-diphenylphosphino)phenyl)ether oxide, where the Tb−O bond distances are 2.880(3)−2.905(3) Å for the DPEPO ligand and 2.499(3)−2.664(3) Å for the β-diketone.22 Bond-valence calculations29 confirm the tendency: parameters for the two kinds of bound oxygen atoms in 1 are the same, within experimental errors, at 0.38 and 0.37 for PPI and EtOH, respectively, whereas they amount to 0.36 and 0.44 in 2 for PPI and DPEPO, respectively.

The most common eight-coordination polyhedra are the square antiprism (SAP, D4d), the trigonal dodecahedron (DOD, D3d), and the bicapped trigonal prism (Cpv). Because the energy differences between these coordination geometries are very small, we have employed the shape measure S proposed by Raymond and coworkers30 to assess which coordination polyhedron best fits the observed structures:

\[ S = \min \left( \frac{1}{m} \sum_{i=1}^{m} (\delta_i - \bar{\theta})^2 \right) \]

Analysis of the data shows that in all studied crystal structures, the coordination polyhedron around the lanthanide atom deviates substantially from an ideal polyhedron for a bicapped trigonal prism and shows smaller deviations for a square antiprism and a trigonal dodecahedron (Table 2). The minimum value for S is obtained for D4d; thus the coordination polyhedra around the LnIII ions can best be described as distorted square antiprisms. The square faces formed by the oxygen atoms of the SAP are separated by distances of 2.585, 2.494, and 2.511 Å and are tilted by 1.98, 1.64, and 2.22° in 1, 2, and 3, respectively, whereas the dihedral angles are found to be 87.29, 86.76, and 88.89°, respectively.

**Electronic Spectroscopy.** Room temperature absorption spectra of the free ligands HPPI and DPEPO and of complexes 1–3 are measured as 2 × 10−5 M solutions in MeCN and are displayed in Figure S3 (Supporting Information). All of the compounds absorb only in the UV range due to their singlet−singlet (1ππ*−ππ*) electronic transitions. The absorption bands centered at 292 nm for HPPI and at around 288 nm in complexes 1–3 are due to 1ππ* enol absorption of β-diketone ligand.15 Compared to that of the ligand HPPI (λmax = 292), the absorption maxima are slightly blue-shifted to 288 nm in all the complexes. The determined molar absorption coefficient values of complex 1 (2.3 × 104 M−1 cm−1) at 288 nm is three times higher than that of HPPI (7 × 103 M−1 cm−1 at 292 nm). Such a relationship obviously highlights the presence of three β-diketone ligands in the corresponding complexes. Furthermore, the molar absorption coefficients of complexes 2 and 3 at 288 nm (3.1 × 104 M−1 cm−1) are approximately equal to the sum of the molar absorption coefficients of complex 1 (2.3 × 104 M−1 cm−1) and DPEPO (9 × 103 M−1 cm−1) at 288 nm. The absorption spectra of complexes 1–3 in solid state were also recorded (Figure S4, Supporting Information); they display similar shapes and absorption maxima compared to those in solution except for the spectra for 2 and 3, which display a more intense shoulder at ~235 nm.

**Photophysical Properties.** The excitation spectrum (Figure 4) of 1 exhibits a broad band between 250 and 350 nm (λmax = 320 nm), which is attributable to the 1ππ*−ππ* transition of the heterocyclic β-diketone ligand. On the other hand, the excitation maxima of 2 and 3 are blue-shifted to 260–280 nm (due to 2ππ*−ππ* transition of DPEPO), along with having humps at 310–330 nm. A series of sharp lines that are assignable to f−f transitions are also observed in the excitation spectra of the complexes. The latter transitions are weaker than the bands due to the organic ligands, pointing to an efficient energy transfer process.16 Furthermore, there is a large overlap between the absorption spectra of the ligands and the excitation spectra of 1–3. This is an indication for the sensitization of

LnIII ions by the organic ligands and, therefore, confirms that the LnIII ions in 1–3 are coordinated to the organic ligands.31 The room temperature emission spectra of DyIII complexes 1 and 2 in the visible region that were recorded by exciting the samples at the ligand-centered band at 320 nm are depicted in Figure 5. Both emission spectra display characteristic sharp peaks associated with the 4f → 4f transitions. The main emission band occurs at 576 nm (yellow emission) and is due to the 4F9/2 → 6H13/2 transition. The blue emission at 482 nm (4F9/2 → 6H15/2) is less intense, whereas the two other transitions originating from the 4F9/2 level at 660 and 750 nm are fainter. We have not been able to detect the transition to 6H17/2 (∼835 nm) due to lack of sensitivity of the photomultiplier. Finally, it is worth noting that a rare and very weak band is seen at 455 nm; according to a study of DyIII levels in LaAlGe2O7:Dy, it can be assigned to a transition originating from a group of very closely spaced levels (∼26 000 cm−1 and terminating onto the 6H13/2 level.32

The integral intensity ratio of the hypersensitive yellow emission 4F9/2 → 6H13/2 (ΔL = 2 and ΔJ = 2) to the blue emission is equal to 3.9 for 1 and 4.5 for 2. Such high values are expected for systems without an inversion center33 and are responsible for the intense yellow-green emission color of these DyIII complexes.7 The CIE coordinates computed for 1 (x = 0.210, y = 0.525) and 2 (x = 0.205, y = 0.519) are very similar and indeed lie in the yellow-green region of the visible spectrum.

Apart from the above-discussed transitions in the visible region, the DyIII ion has several transitions in the infrared. Although these transitions have mainly been reported for DyIII in inorganic systems,34 few studies deal with the NIR luminescence of DyIII in organic complexes.35 The NIR luminescence spectra of complexes 1 and 2 that were recorded under ligand excitation at 320 nm are shown in Figure 6. They are dominated by two intense bands corresponding to transitions from the 4F9/2 excited level to 6F7/2 (1006 nm) and 6F5/2 (1178 nm); less intense features are tentatively assigned to transitions from the same excited level to 6H5/2 (953 nm), 6F3/2 (1270 nm), and 6F1/2 (1386 nm); in view of the intricate electronic structure of DyIII, other transitions may also be involved. It is evident from Figures 5 and 6 that the displacement of the EtOH molecules from the first coordination sphere of 1 by DPEPO in 2 considerably enhances the luminescent properties of the latter with respect to both visible and NIR emission.

On the other hand, the luminescence intensity of TbIII complex 3 is comparable to the one exhibited by the hydrated precursor [Tb(PPI)3(H2O)2]15 (Figure 7). Both TbIII complexes have similar emission colors (x = 0.185, y = 0.512 for 3 and x = 0.189, y = 0.543 for [Tb(PPI)3(H2O)2]) and band features, originating from the transitions from the 5D4 state to the 7F6−0 states, with peaks at 488, 545, 584, 620, 650, 669, and...

\(^{1}\)In CDCl\(_3\) (concentration = 10^{-3} \text{ M}) at 77 K. \(^{2}\)355 nm for 1 and 2 and 320 nm for 3.

679 nm, respectively. For most Tb\(^{III}\) complexes, the \(^{3}D_4 \rightarrow \ ^{3}F_4\) transitions show moderate sensitivity to the ligand environment, and the \(^{3}D_4 \rightarrow \ ^{7}F_2\) transition is usually the most intense and is considered an internal standard to account for the differences in branching ratios induced by the ligands.\(^{15,36}\) The electric dipole transition \(^{3}D_4 \rightarrow \ ^{7}F_2\) is relatively more sensitive to the chemical environment and symmetry of the coordination polyhedron. For [Tb(PPI)\(_3\)]\(_2\)\(_3\)(H\(_2\)O)\(_2\)\(_3\)], the \(I(\ ^{3}D_4 \rightarrow \ ^{7}F_2)/I(\ ^{3}D_4 \rightarrow \ ^{7}F_2)\) ratio is 0.35,\(^{15}\) and it increases to 0.42 in 3. Thus, the presence of DPEPO increases the relative luminescent intensity of the \(^{3}D_4 \rightarrow \ ^{7}F_2\) transition, probably because the ligand induces more orbital mixing than water. In order to prove the efficiency of energy transfer between ligand and central Ln\(^{III}\) ions, we have recorded the emission spectra of the complexes by exciting through the \(f\rightarrow f\) transitions \(^{4}M_{15/2} \leftrightarrow \ ^{6}H_{15/2}\), \(^{4}H_{15/2} \leftrightarrow \ ^{6}H_{15/2}\), and \(^{4}F_{9/2} \leftrightarrow \ ^{6}H_{15/2}\) for Dy\(^{III}\) complexes 1 and 2 and through the \(^{3}D_4 \rightarrow \ ^{7}F_6\) and \(^{3}D_4 \rightarrow \ ^{7}F_4\) transitions for Tb\(^{III}\) complex 3 (Figures S5–S7, Supporting Information). The resulting emission spectra are less intense than the ones obtained by exciting through the antenna and contain residual emission from the organic moieties in the region 400–550 nm, proving that the antenna mechanism is more efficient than direct excitation in these complexes.

The overall quantum yield of the Ln\(^{III}\) sensitized emission (\(\Phi_{overal}\)), which is the ratio between the number of photons absorbed by the antenna to the number of photons emitted by the Ln\(^{III}\) ion, is regulated by the sensitization efficiency of the antenna molecule (\(\Phi_{\text{ant}}\)) and the intrinsic luminescence quantum yield of the Ln\(^{III}\) ion (\(\Phi_{\text{Ln}}\)): \(\Phi_{\text{overal}} = \Phi_{\text{ant}}\Phi_{\text{Ln}}\). Data for \(\Phi_{\text{overal}}\) for solid-state samples of 1–3 have been determined at room temperature by an absolute method and are listed in Table 3. In the case of Dy\(^{III}\), only transitions between 450 and 800 nm have been taken into consideration. The Dy\(^{III}\)\((^{9}F_{9/2})\) lifetime of complexes 1 and 2 at 298 K \(t_{\text{exc}}\) have been investigated by exciting the samples using a 355 nm laser line and monitoring the NIR transitions \(^{4}F_{9/2} \rightarrow \ ^{4}F_{7/2}\) and \(^{6}F_{5/2}\) at ~1006 and 1178 nm, respectively. All the decay curves could be fitted with single exponential functions, which is consistent with the presence of a single major luminescent species in the complexes. Average values are given in Table 3. and typical decay profiles are shown in Figure 8. For Tb\(^{III}\) complex 3, the \(^{3}D_4 \rightarrow \ ^{7}F_2\) transition at 545 nm was monitored under excitations in the ligand levels at 275 and 320 nm and \(f\rightarrow f\) levels at 377 \(^{3}D_4\) and 488 nm \(^{3}D_4\) at both 298 and 77 K. Substitution of EtOH in Dy\(^{III}\) complex 1 by DPEPO leads to a 4-fold increase in the absolute quantum yield and a 2-fold increase in the \(^{4}F_{9/2}\) lifetime at room temperature. The latter is diagnostic for minimization of the nonradiative decay channels upon removal of the high-frequency O–H oscillators. In addition, DPEPO may participate in the overall energy transfer mechanism so that the improvement in quantum yield is larger. As far as our knowledge is concerned, the overall quantum yield of 12 ± 2% and \(^{4}F_{9/2}\) lifetime of 33 ± 1 μs obtained for Dy\(^{III}\) ligand system can be considered one among the most efficient antenna chromophore system for Dy\(^{III}\) luminescence, along with the bis-tetrazolate-pyridine (\(\Phi_{\text{overal}} = 6.6 ± 3\% \text{ and } \tau = 70 ± 1\) μs),\(^{27}\) oxidacetaet/1,10-phenanthroline (\(\Phi_{\text{overal}} = 19\% \text{ and } \tau = 7.30–7.36\) μs),\(^{38}\) and 2,2′- (2,2′-oxybis(ethane-2,1-diyl)-bis(oxo))bis(N-benzylbenzamide) (\(\Phi_{\text{overal}} = 5.05\% \text{ and } \tau = 50\) μs)\(^{39}\) ligand systems.

A sizable value of emission quantum yield (42 ± 6%) is recorded for Tb\(^{III}\) complex 3. However, this value is only 70% of the value reported for the hydrate [Tb(PPI)\(_3\)](H\(_2\)O)\(_3\)] (\(\Phi_{\text{overal}} = 59 ± 6\%).\(^{15}\) The loss in emission quantum yield in the presence of ancillary ligands in Tb\(^{III}\) complexes is known, and the reason is explained in our previous reports.\(^{22,36}\) On the other hand, a slight increase in luminescence lifetime is noted, 795 ± 1 μs for 3 compared to 785 ± 1 μs for [Tb(PPI)](H\(_2\)O)\(_3\)] and might be due to minimization of concentration quenching. Indeed, the shortest Tb–Tb distance

\(^{a}\)PM = 1-phenyl-3-methyl-4-isobutyl-5-pyrazolone; DPVM = 1,3-di-tert-butyl-β-propanedione; DMAP = p-dimethylaminopyridine; acac = acetylaceton. \(^{b}\)Φ_{overal} measured in DMF. \(^{c}\)Biexponential decay (% of emitting species).
in the crystal lattice of [Tb(PPI)_3(H_2O)_2] is 5.992 Å,\(^1\) which increases to 11.637 Å in 3 because of the presence of the bulkier DPEPO.

**Ligand-to-Ln\(^{III}\) Energy Transfer Mechanism.** According to Crosby and Whan,\(^2\) the mechanism of sensitization in luminescent lanthanide complexes consists of three major steps: (i) absorption of ultraviolet/blue light that excites the ligand (antenna) to the excited singlet state (\(^1\)\(\pi\pi^*\)), (ii) energy migration via intersystem crossing from the singlet state to a triplet state (\(^3\)\(\pi\pi^*\)), and (iii) nonradiative energy transfer from the lowest triplet state to a resonant state of a coordinated Ln\(^{III}\) ion, resulting a multiphonon relaxation and emission. Of these three steps, the final one plays the most crucial role in determining the luminescent properties of the Ln\(^{III}\) complexes.\(^3\) Although direct transfer of energy from the excited singlet state to the energy levels of lanthanide ions is known for Tb\(^{III}\),\(^4\) Nd\(^{III}\),\(^5\) and Eu\(^{III}\),\(^6\) for instance, this process is usually less important in view of the shorter lifetime of the excited singlet state. In the present study, the \(\Delta E(3\pi\pi^*-\pi\pi^*)\) energy gaps for DPEPO (6620 cm\(^{-1}\)) and HPPI (7610 cm\(^{-1}\)) are sufficient for an efficient intersystem crossing process,\(^7\) and their triplet energy levels (HPPI, \(3\pi\pi^* = 23 640\) cm\(^{-1}\);\(^8\) DPEPO, \(3\pi\pi^* = 25 640\) cm\(^{-1}\))\(^9\) are higher than the emissive levels of Tb\(^{III}\) (\(5D_4: 20 400\) cm\(^{-1}\)) and Dy\(^{III}\) (\(4F_{9/2}: 20 800\) cm\(^{-1}\)); hence, they can populate the excited states of both ions. Furthermore, the singlet states of PPT and DPEPO can transfer energy directly to some of the several higher-excited states of Dy\(^{III}\) lying in the range 25 000–30 000 cm\(^{-1}\), for example, \(M_4\), \(6P_{7/2}\), \(4I_4\), and \(K_{11/2}\) (Figure S8, Supporting Information), and this process is most likely responsible for the observation of the faint transition at 455 nm in 1 and 2. All possible energy transfer pathways in complexes 1–3 are summarized in Figure 9. In comparison with [Dy-

![Figure 9. Schematic representation of the energy transfer mechanism in complexes 2 and 3.](image)

\((PM)_3(TPPO)_2\)\(^{14}\) \((\phi_{overall} = 3.5\%)\), complex 2 shows approximately three times higher overall quantum yield and five times higher lifetime values. This can be attributed to a much more adequate energy gap between the triplet levels and \(4F_{9/2}\) of HPPI and DPEPO \([\Delta E(3\pi\pi^*-4F_{9/2}) = +2810\) cm\(^{-1}\) for PPT and +4810 cm\(^{-1}\) for DPEPO\)] compared to those of PM and TPPO \([\Delta E(3\pi\pi^*-4F_{9/2}) = +630\) cm\(^{-1}\) for PM and –830 cm\(^{-1}\) for TPPO\]. In the latter case, the quasi-resonance between the ligand and Dy\(^{III}\) levels induces back energy transfer, translating into reduced sensitization and a shorter lifetime.

**Triboluminescence.** The word triboluminescence comes from the Greek tribein (“to rub”) and the Latin lumen (“light”). It is the phenomenon where the fracture of a material gives rise to the emission of light. A number of triboluminescent Eu\(^{III}\)\(^4\),\(^7\) and Tb\(^{III}\)\(^4\),\(^7\),\(^8\) complexes are described in the literature; on the other hand, triboluminescent Dy\(^{III}\) complexes are scarcer.\(^4\)\(^6\) Figure 10 shows the room temperature

![Figure 10. Triboluminescence (TL) spectra (uncorrected) of crystals of 2 and 3 recorded at 298 K. Vertical scale: arbitrary units.](image)

triboluminescence spectra for complexes 2 and 3. Both spectra match the overall pattern of the photoluminescence spectra, indicating that triboluminescence involves the same Ln\(^{III}\) excited states (\(5D_4\) and \(4F_{9/2}\)). TL is commonly displayed by piezoelectric materials without an inversion center like 2 and 3.\(^4\)\(^8\) However centrosymmetric crystals with triboluminescence properties have also been reported.\(^4\)\(^7\)\(^b\) The TL of complexes 2 and 3 is quite intense, as demonstrated by the short dropping heights (see the Experimental Section) and by the fact it is detectable to the naked eye in daylight (see video in Supporting Information), allowing detection using inexpensive, compact detectors. Given their large thermal stability (up to 250 °C), these complexes are potentially well-suited as smart optical sensors.

**CONCLUSION**

The present investigation points to HPPI and DPEPO being highly efficient sensitizers of Dy\(^{III}\) and Tb\(^{III}\) luminescence, as ascertained by the large quantum yields and long excited-state lifetimes reported. This may be attributed to the triplet energy levels of the ligands lying 3200–5200 cm\(^{-1}\) above the Ln\(^{III}\) emissive levels. The room temperature lifetime and overall quantum yield obtained for Dy\(^{III}\) complex 2 are found to be the highest values reported so far for Dy\(^{III}\)-tris-\(\beta\)-diketonates. Furthermore, this complex exhibits substantial NIR luminescence and singlet-state excitation from the ligand. Finally, the crystals of both Tb\(^{III}\) and Dy\(^{III}\) complexes show efficient triboluminescence. Because their thermal stability is large, this could be exploited in applications for damage detection of civil, aerospace, and military structures or biomedical materials as well as for impact sensors.\(^6\),\(^4\),\(^4\)\(^9\)
