The selective adsorption of CO₂ is one of the proposed methods for carbon capture that should result in the mitigation of greenhouse gases in the atmosphere. Developments in the field suggest that porous materials such as zeolites and metal–organic frameworks (MOFs) are promising materials for carbon capture due to their large capacity to selectively absorb CO₂. In particular, MOFs with open metal sites such as Mg₂(dobdc) (dobdc⁺⁻ = 2,5-dioxido-1,4-benzenedicarboxylate; Mg-MOF-74) possess strong CO₂-binding sites leading to large experimental CO₂ uptake values. Recently, a number of research papers devoted specifically to this structure and its variants have been reported. Most of the past research on open-metal-site structures, however, has focused on the equilibrium properties of the CO₂ adsorption rather than its dynamics. The dynamics of CO₂ molecules within these structures is an important topic that can lead to better designs for open-metal-site MOFs, while exposing possible diffusion limitations.

A recent study presented ¹³C NMR spectra and relaxation times for CO₂ adsorbed inside Mg-MOF-74. The observed CO₂ chemical shift anisotropy (CSA) patterns “flipped” at temperatures above 150 K, yielding CSA patterns consistent with simple uniaxial rotation of the O=C=O molecule about a fixed rotational angle. At a CO₂ loading of 0.3 CO₂/Mg site, a second motion-averaged powder pattern was observed at temperatures above 350 K. The uniaxial rotational model, when applied to the “flipped” CSA patterns, yielded a rotational angle that varied from 59° (0.5 CO₂/Mg site, 300 K) to 69° (0.3 CO₂/Mg site, 210 K). Carbon-13 spin-lattice relaxation times for Mg-MOF-74 with a loading of 0.5 CO₂/Mg site in the temperature range of 12 K–200 K were fit to a Bloembergen–Purcell–Pound (BPP)-type relaxation mechanism governed by two different exponentially activated motions. The authors did not provide any details as to why such processes would be occurring within the Mg-MOF-74 framework. In a further study, visual inspection of molecular dynamics trajectories was made to conclude that the high binding strength between CO₂ and open metal sites, as well as the presence of the rotational motion, reduce the transversal mobility of CO₂ along the channels and thereby reduce diffusivity.

From a structural and thermodynamic point of view, the presence of uniaxial rotation of CO₂ in Mg-MOF-74 is not intuitive. Both density functional theory (DFT) and neutron powder diffraction data at 20 K indicate that the angle θ, shown in Figure 1a, between the minimum-energy CO₂ configuration and the Mg–O(CO₂) vector is in a range of 50–60°, consistent with the angle extracted from the experimental CSA pattern fit to uniaxial rotation. It seems clear, though, that the chemical environment near a metal site is not perfectly symmetric with respect to the Mg–O(CO₂) vector, implying that the CO₂ is unlikely to possess a uniform free energy surface (that is, the “cone” for uniaxial rotation is not of constant free energy). More vexing is the fact that fitting the CSA patterns to a simple uniaxial rotation yields a decreasing CO₂ rotational angle with increasing temperature. At higher temperatures, one would expect CO₂ to explore a larger portion of phase space, which would correspond to an increase in the rotational angle. However, the experiments were interpreted as a decrease in the angle, suggesting a counterintuitive reduction in entropy.

In light of these observations, we utilized molecular simulations to arrive at a different explanation for the experimental results. Canonical Monte Carlo simulations were carried out at various loadings (infinite dilution, 0.3 CO₂/Mg site, and 0.5 CO₂/Mg site) to probe the free energy landscape of CO₂ molecules in Mg-MOF-74 at temperatures ranging from 100 K to 375 K. In these simulations, both dispersive and electrostatic energies were included to model the guest–framework and the guest–guest interactions. Similar to previous studies, we assumed the framework to be rigid and used the DFT optimized structure for our calculations. The Lennard-Jones potential was adopted to describe the dispersion interaction, in which we used the universal force field (UFF) for the framework atoms and the TraPPE model for the CO₂ molecule. The
atomic partial charges of the framework atoms were computed using the REPEAT algorithm.\cite{13}

In carrying out the Monte Carlo simulations, we are probing equilibrium configurations. In order to make meaningful comparisons with the NMR experiments, these equilibrium configurations must be carefully interpreted in the context of CO$_2$ dynamics. In our simulations, we observe (see Section 4 in the Supporting Information) two types of motion: 1) fluctuation of the CO$_2$ molecule near the minimum-energy configuration (illustrated in Figure 1b) and 2) hops of the CO$_2$ molecules between different metal sites (Figure 1c). Accordingly, in our analysis we compute the CSA patterns\cite{14} for these two different cases (see Section 1-VI in the Supporting Information for details).

At sufficiently low temperatures, we expect CO$_2$ to be localized near a single metal site with minimal motion. With the onset of motion, localized fluctuations and nonlocalized hops are expected to contribute differently to the motion-averaged NMR CSA pattern. Comparison of the NMR data and our simulation at $T = 100$ K shows that the simulated pattern corresponding to the localized fluctuations (Figure 2a, dashed red line) agrees with the experimental spectrum (Figure 2b), while the simulated pattern including hopping between metal sites (Figure 2a, blue lines) has a qualitatively different CSA pattern. The slight asymmetry of the CSA pattern calculated with the localized fluctuations (Figure 2a, dashed red line) reflects the asymmetry of the motion (see Figures SI6–8 in the Supporting Information: the 2D projected plots demonstrate the asymmetric free energy surface near a metal site). This small asymmetry is not apparent in the experimental data owing to dipolar broadening from nearby linker protons.\cite{4} At higher temperatures, the experimental patterns, which show uniaxial rotational motions, clearly deviate from the simulated patterns based on the fluctuation motions (Figure 2a, dashed red line).

To properly account for the experimental NMR data at higher temperatures, we consider hopping motions of CO$_2$ between different metal sites in the $x$, $y$ plane (Figure 1c). It is important to realize that the NMR experiment only measures the relative orientation of the CO$_2$ molecule with respect to the applied magnetic field. Figure 1c shows the six minimum-energy CO$_2$ configurations obtained from DFT calculations.\cite{10} If a CO$_2$ molecule hops between these configurations, the observed NMR signal is equivalent to a uniaxial rotation. This is best imagined by defining a common origin at the oxygen atom of the CO$_2$ molecule that is bound to the metal.
site. Because of the symmetry of the crystal, these minimum-energy configurations are related through a uniaxial rotation of 80° (see Section 3 in the Supporting Information), a fixed angle, which we define as the “equivalent rotational angle” (see Figure 1d). Hence, from an NMR point of view, hopping between these sites creates a CSA pattern that is identical to that predicted from uniaxial rotation about this equivalent angle. With the hopping motions, the simulated pattern at 100 K has an equivalent rotation angle of 71°. However, the temperature is too low here to observe hopping, which becomes possible above 200 K.

At $T > 200$ K, the experimental NMR lineshape is consistent with uniaxial rotation at an angle of approximately 60°,[4] which is the equivalent rotational angle we calculate by including hopping between sites. Moreover, our simulations show that the equivalent rotational angle decreases with increasing temperature, with values of 61° and 57° at 200 K and 300 K, respectively. The apparent decrease in the equivalent rotational angle with increasing temperature is seen as a manifestation of thermally activated motion along the z-direction (see Section 4 in the Supporting Information; the changes of the C(CO2) position along the z-direction are shown in Figures S17 and S8 in the Supporting Information). Enhanced motion along the z-direction results in a larger tilt angle of the CO2 molecules with respect to the $x$,$y$ plane, which is the effect that decreases the equivalent rotational angle.

The experimental CSA pattern at 150 K (Figure 2b) reveals a transition behavior that mixes both the localized and the nonlocalized CO2 movements. We expect that this temperature is just high enough to allow the CO2 molecules to hop between the different metal sites, but at the same time low enough to categorize hopping as a rare event. This transition temperature is an exquisite probe of the energetics of CO2 hopping.

Figure 2c shows the effect of changing the CO2 loading on the simulated CSA pattern. The results indicate that there is a shift in the pattern for larger loading values, which leads to smaller equivalent rotation angles (i.e., 60° and 59° at the loadings of 0.3 CO2/Mg site and 0.5 CO2/Mg site, respectively). This shift to smaller rotational angles is also what is observed experimentally. As the number of CO2 molecules inside the structure increases, the repulsive forces between CO2 molecules cause them to stay apart along the channel ($z$-direction) from each other, enlarging the angle of CO2 adsorbed at open metal sites with respect to the $x$,$y$ plane.

We can use the knowledge gained from this study to make a prediction regarding the CSA pattern of CO2 in a similar structure: Mg$_8$(dobpdc) (dobpdc$^{t^-}$ = 4,4’-dioxidio-3,3’-biphenyldicarboxylate), which is an expanded MOF-74 structure owing to an extended organic linker.[15] In this structure, the smallest Mg–Mg separations within a channel are 10.82 Å in the $xy$ plane, while the corresponding separations in Mg-MOF-74 are 8.22 Å (see Figures S1 and 2 for visualizing the structures). The local dynamics of adsorbed CO2 in the expanded MOF is expected to be similar to those for Mg-MOF-74. The difference between these two structures is that the longer ligand might make it more difficult for the CO2 molecule to hop between metal sites. Figure 3 illustrates the CO2 free energy map[16] within a cylinder-like channel for these two structures at 200 K. The angular channel opening and the position along the direction of the channel (i.e., $z$-direction) were utilized to map the entire channel profile. These maps show that a CO2 molecule can hop to the two neighboring sites in the $xy$ plane and along the Mg–O–Mg backbone in the $z$-direction. It is important to note that hops along the $z$-direction do not change the orientation of the molecules. Although these hops are important for diffusion, they are not probed by the NMR methods reported previously.[12] The maps show that the free energy barrier for hopping between two adjacent sites along the $xy$ plane in the expanded structure is two times larger than what is computed for Mg-MOF-74. Given that the uniaxial rotation-like CSA pattern originates from CO2 hops between different metal sites, the jumps should occur less frequently within the pores of the expanded structure. As a result, we predict a higher transition temperature for the expanded Mg-MOF-74 structure in which the purely localized motions become mixed with the hopping motions. Figure 4 further shows the experimental CSA pattern obtained for Mg$_8$(dobpdc). Comparison of NMR lineshapes between Mg-MOF-74 (Figure 2b) and the expanded structure (Figure 4) indicates that the pattern that has the signature of the hopping motions indeed shifts to

![Figure 3. Free energy map of a cylinder-like channel in a) Mg-MOF-74 and in b) Mg$_8$(dobpdc) at 200 K is shown as a function of the angular angle $\varphi$ of the channel opening and the position of the channel along the $z$-direction. The minimum free energy binding site near an open metal site was set to be zero $k_B T$ in this illustration.](image)
CO2 dynamics is important and this work illustrates that the emphasis that obtaining detailed information regarding the hopping motions between different metal sites. We re-

a uniaxial rotation at the open metal site, but a signature of higher temperatures, \( T = 150–200 \text{ K in Mg-MOF-74 and } T \approx 250 \text{ K in Mg}_{2}(dobpdc). \) It would be interesting to investigate how this change in the dynamics depends on the length of the linkers.\(^{[17]}\)

In summary, we have proposed a dynamic mechanism that provides an alternative explanation for the experimental CSA pattern than the one put forward previously.\(^{[3]}\) We argue that the more proper interpretation of the NMR signal is not a uniaxial rotation at the open metal site, but a signature of the hopping motions between different metal sites. We re-emphasize that obtaining detailed information regarding the CO2 dynamics is much richer than initially expected.
