Abstract. Let $P$ be a finite point set in the plane. A $c$-ordinary triangle in $P$ is a subset of $P$ consisting of three non-collinear points such that each of the three lines determined by the three points contains at most $c$ points of $P$. Motivated by a question of Erdős, and answering a question of de Zeeuw, we prove that there exists a constant $c > 0$ such that $P$ contains a $c$-ordinary triangle, provided that $P$ is not contained in the union of two lines. Furthermore, the number of $c$-ordinary triangles in $P$ is $\Omega(|P|)$.

1. Introduction

In 1893, Sylvester [Syl93] asked whether, for any finite set of non-collinear points on the Euclidean plane, there exists a line incident with exactly two points. The positive answer to this question, now known as the Sylvester–Gallai theorem, was first obtained almost half a century later in 1941 by Melchior [Mel41] as a consequence of the positive answer to an analogous question in the projective dual. Erdős [EBW+43], unaware of these developments, posed the same problem in 1943, and it was solved by Gallai in 1944. For more on the history of this and related problems, see [GT13].

Given a finite set of points $P$ on the Euclidean plane, a line $\ell \subset \mathbb{R}^2$ is determined by $P$ if $\ell$ contains at least two points of $P$. We say that $\ell$ is an ordinary line, if $\ell$ contains exactly two points of $P$. Erdős [Erd84] considered the problem of finding an ordinary triangle, that is, three ordinary lines determined by three points of a finite planar point set. See [BM90] for details on the origin of this problem. Motivated by this problem, and with an application in studying ordinary conics [BVdZ16], de Zeeuw asked a related question at the 13th Gremon’s Workshop on Open Problems (GWOP 2015, Feldis, Switzerland), which we describe below.

Definition 1.1 ($c$-ordinary triangle). Let $c$ be a natural number and let $P$ be a point set in the plane. A $c$-ordinary triangle in $P$ is a subset of $P$ consisting of three non-collinear points such that each of the three lines determined by the three points contains at most $c$ points of $P$.

It is easy to see that in order to be able to find a $c$-ordinary triangle for large $n$, we have to assume that $P$ is not contained in the union of two lines. Under this restriction one might suspect that there is a 2-ordinary triangle in $P$. However, this is not true as shown by Böröczky’s construction [GT13, Figure 4.5.6]. The following simple example also shows this. Let $P_1$ be a set of points that are not all collinear and let $\ell$ be some line. For each line $\ell_1$ determined by the point set $P_1$, we add the point at the intersection of $\ell$ and $\ell_1$. Let us denote this new set of points by $P_2$. All points of $P_2$ are collinear, hence a 2-ordinary

Key words and phrases. Dirac–Motzkin Conjecture, incidences, ordinary lines, ordinary triangle, planar point set.
triangle must contain two points from $P_1$. However, by construction every line determined by $P_1$ contains a point of $P_2$. Hence there are no 2-ordinary triangles in this point set.

De Zeeuw asked whether a $c$-ordinary triangle can be found in $P$. The aim of this manuscript is to give a positive answer to this question.

**Theorem 1.2.** There is a natural number $c$ such that the following holds. Assume $P$ is a finite set of points on the Euclidean plane not contained in the union of two lines. Then $P$ contains a $c$-ordinary triangle, that is three non-collinear points such that each of the three lines determined by these three points contains at most $c$ points of $P$. Moreover, the number of $c$-ordinary triangles in $P$ is $\Omega(|P|)$.

**Remark 1.3.** The constant in the theorem above can be chosen as $c = 1200$.

We see no reason to believe that this is the best constant. Moreover, it remains open if the number of $c$-ordinary triangles in $P$ is superlinear (possibly even quadratic) in $|P|$.

2. Tools

To prove Theorem 1.2 we need the following lemmas. The first one is a corollary of the Szemerédi-Trotter Theorem.

**Lemma 2.1.** [ST83] [PRT06] Let $k, n \geq 2$ be natural numbers, $P$ a set of $n$ points in the plane, and let $f(k)$ denote the number of lines in the plane containing at least $k$ points of $P$. Then

$$f(k) \leq \begin{cases} c'n^2, & \text{if } k \leq \sqrt{n}, \\ c'n_k^2, & \text{if } k > \sqrt{n} \end{cases}$$

for a universal constant $c' > 0$. In fact, we may take $c' = 125$.

**Proof.** Clearly, the claimed bound holds for $k = 2, 3$, since $f(2) \leq \binom{n}{2}$ and $f(3) \leq \binom{n}{2}/3$. To prove the statement for $k > 3$, we rely on the following result by Pach, Radoičić, Tardos and Tóth [PRT06, Corollary 5.1]: for any given $n$ points and $m$ lines on the Euclidean plane, the number of incidences between them is at most $2.5m^{2/3}n^{2/3} + m + n$. Let $m = f(k)$ denote the number of lines containing at least $k$ points of $P$. Observe that the number of point-line incidences are thus at least $mk$. Hence, $mk \leq 2.5m^{2/3}n^{2/3} + m + n$.

First, consider the case $m > n$. Observe that for $k > 3$, we have $mk/2 \leq m(k - 2) \leq 2.5m^{2/3}n^{2/3}$. It follows that $m \leq 125n_k^2$, and specifically, $m \leq 125\frac{n}{k}$ if $k > \sqrt{n}$.

Next, consider the case $m < n$. We have $mk \leq 2.5m^{2/3}n^{2/3} + m + n \leq 2.5m^{2/3}n^{2/3} + 2.5n$, and therefore $mk \leq \max\{5m^{2/3}n^{2/3}, 5n\}$. Hence, $m \leq \max\{125\frac{n^2}{k^2}, 5\frac{n}{k}\}$. For $k \leq 5\sqrt{n}$, the maximum is attained at the first term, whereas for $k > \sqrt{n}$, we trivially have $\frac{n^2}{k^2} < \frac{n}{k}$, establishing the claim for $c' = 125$. □

The following Turán-type lemma (related to Mantel’s theorem) from extremal graph theory provides a lower bound for the number of triangles (subgraphs isomorphic to $K_3$) in a graph. It can be found with a proof as Problem 10.33 in [Lov07].

**Lemma 2.2.** Consider a graph $G = (V(G), E(G))$ with $|V(G)| = n$ and $|E(G)| = m$. Let $t_3(G)$ denote the number of triangles in $G$. Then we have

$$t_3(G) \geq \frac{m}{3n^2}(4m - n^2).$$
3. Proof of Theorem 1.2

In this section, we prove Theorem 1.2. Our proof is closely related to the standard proof of Beck’s Theorem, where the number of pairs of points on medium-rich lines is bounded using the Szemerédi-Trotter theorem, and then it is concluded that either there is a very rich line, or there are many pairs of points on poor lines, see the proof of Theorem 18.8 in [Juk11].

The constant \( c \) will be chosen at the end of the proof. Assume \( P \) is a set of \( n \geq c \) points in the plane and let \( \mathcal{L} = \{ L_1, L_2, \ldots, L_m \} \) denote the set of lines determined by \( P \). Define \( l_i = |L_i \cap P| \), for \( i = 1, 2, \ldots, m \).

Set \( \alpha = \frac{4}{c+1} \). We split the proof into two cases:

(i) There is a line \( L_i \in \mathcal{L} \) such that \( l_i > \alpha n \);

(ii) For all \( i = 1, 2, \ldots, m \) we have \( l_i \leq \alpha n \).

Consider the first case. Since the point set \( P \setminus L_i \) is non-collinear by the assumption, by applying the Sylvester-Gallai theorem, we can find an ordinary line \( L \in \mathcal{L} \) for \( P \setminus L_i \), i.e. \( L \) contains exactly two points \( q, r \in P \setminus L_i \). Note that \( L \) may contain at most one point of \( P \cap L_i \). Next, we show that there are many points on \( L_i \) which together with \( q, r \) form \( c \)-ordinary triangles. For this, we define the set \( P_q \subset P \) as

\[
P_q = \{ p \in L_i \cap P : |pq| \cap P| > c \},
\]

where \( pq \) denotes the line passing through \( p, q \). We define \( P_r \) in a similar way. Note that for any point \( p \in P_q \), the line \( pq \) contains at least \( c - 1 \) points of \( P \setminus (L_i \cup \{ q \}) \), moreover, these sets of \( c - 1 \) points are disjoint for different \( p \in P_q \). So we get

\[
(c - 1) \cdot |P_q| \leq n - l_i
\]

which implies that

\[
|P_q| \leq \frac{n - l_i}{c - 1} < \frac{l_i/\alpha - l_i}{c - 1} = \frac{(c + 1)/4 - 1}{c - 1} \cdot l_i < \frac{l_i}{4}.
\]

Similarly, \( |P_r| < \frac{l_i}{4} \). So there are at least \( \frac{l_i}{2} \) points \( s \in P \cap L_i \) such that \( s \notin P_q \cup P_r \). Furthermore, \( s, q, r \) are non-collinear. This implies that the lines \( sq, sr \) contain at most \( c \) points of \( P \). Therefore every triangle determined by \( s, q, r \), where \( s \notin P_q \cup P_r \), is a \( c \)-ordinary triangle for \( P \). The number of these triangles is at least \( \frac{l_i}{2} > \frac{\alpha n}{2} = \frac{2n}{c+1} \), completing the proof of case (i). Note that, so far, \( c \) may be chosen as any integer greater than 2.

Next, we consider case (ii). So we assume that no line of \( \mathcal{L} \) contains more than \( \alpha n \) points of \( P \). First we bound \( \sum_{c < l_i \leq \alpha n} \binom{l_i}{2} \) from above. With the notation of Lemma 2.4 we have

\[
\sum_{i : c < l_i \leq \sqrt{n}} \binom{l_i}{2} \leq \frac{\log \sqrt{n}}{j = \lfloor \log (c+1) \rfloor} \sum_{i : 2j \leq l_i \leq 2j+1} \binom{l_i}{2} \leq \frac{\log \sqrt{n}}{j = \lfloor \log (c+1) \rfloor} f(2^j) \binom{2^j+1}{2}
\]

\[
\leq c' \frac{n^2}{2^{2j-1}} \binom{2^j+1}{2} \leq \frac{\log \sqrt{n}}{j = \lfloor \log (c+1) \rfloor} c' \frac{n^2}{2^{2j-1}} \leq 8c' \frac{n^2}{c+1},
\]
where logarithms are base 2, and the inequality with star follows from Lemma 2.1.

On the other hand, by the same lemma, we have

\[
\sum_{i : \sqrt{n} < l_i \leq \alpha n} \left( \frac{l_i}{2} \right) = \sum_{j=0}^{[\log(\alpha \sqrt{n})] - 1} \sum_{2^j \sqrt{n} < l_i \leq 2^{j+1} \sqrt{n}} \left( \frac{l_i}{2} \right) \leq \sum_{j=0}^{[\log(\alpha \sqrt{n})] - 1} f(2^j \sqrt{n}) \binom{2^{j+1} \sqrt{n}}{2} \\
\leq \sum_{j=0}^{[\log(\alpha \sqrt{n})] - 1} c' \frac{n}{2^j \sqrt{n}} \binom{2^{j+1} \sqrt{n}}{2} \\
\leq \sum_{j=0}^{[\log(\alpha \sqrt{n})] - 1} c' n^{3/2} 2^{j+1} \leq 4c' n^{3/2} \cdot \alpha \sqrt{n} = \frac{16c'n^2}{c+1}.
\]

As a result, we obtain

\[
\sum_{i : c < l_i \leq \alpha n} \left( \frac{l_i}{2} \right) = \sum_{i : \sqrt{n} < l_i \leq \sqrt{n}} \left( \frac{l_i}{2} \right) + \sum_{i : \sqrt{n} < l_i \leq \alpha n} \left( \frac{l_i}{2} \right) \leq \frac{24c'n^2}{c+1}.
\]

Let \( G \) be the graph with vertex set \( V(G) = P \), such that two points \( p, p' \in P \) are adjacent in \( G \) if the line \( pp' \) spanned by \( p, p' \) satisfies \( |pp' \cap P| \leq c \).

By the following identity

\[
\sum_{i : 2 \leq l_i \leq c} \left( \frac{l_i}{2} \right) = \binom{n}{2},
\]

we obtain for the number of edges of \( G \),

\[
|E(G)| = \sum_{i : 2 \leq l_i \leq c} \left( \frac{l_i}{2} \right) \geq \binom{n}{2} - \frac{24c'n^2}{c+1}.
\]

Now we choose \( c \) large enough such that

\[
4 \left( \binom{n}{2} - \frac{24c'n^2}{c+1} \right) - n^2 = \Omega(n^2).
\]

Combining it with (1) yields

\[
4|E(G)| - n^2 = 4 \left( \sum_{i : 2 \leq l_i \leq c} \left( \frac{l_i}{2} \right) \right) - n^2 = \Omega(n^2).
\]

Therefore, by Lemma 2.2 we have

\[
t_3(G) \geq \frac{|E(G)|}{3n} \left( 4|E(G)| - n^2 \right) = \frac{\Omega(n^2)}{n} \cdot \Omega(n^2) = \Omega(n^3).
\]

This implies that \( G \) has \( \Omega(n^3) \) triangles. Let \( T \) be the set of those triangles in \( G \) whose three vertices are non-collinear. It is easy to see that these triangles correspond to \( c \)-ordinary triangles in \( P \).

Note that the number of triangles with collinear vertices is at most

\[
\sum_{i : 2 \leq l_i \leq c} \left( \frac{l_i}{3} \right) \leq \sum_{i : 2 \leq l_i \leq c} \binom{c}{3} \leq \binom{n}{2} \cdot \binom{c}{3} = O(n^2).
\]
So we get
\[ |T| = \Omega(n^3) - O(n^2) = \Omega(n^3). \]
As a result, \( P \) has \( \Omega(n^3) \) \( c \)-ordinary triangles, provided that \( c \) satisfies (2).

**Proof of Remark 7.3** Equation (2) yields that we may choose \( c = 96c' \), where \( c' \) is from Lemma 2.1. \( \square \)
