1100 V AlGaN/GaN MOSHEMTs With Integrated Tri-Anode Freewheeling Diodes

Taifang Wang, Jun Ma, and Elison Matioli, Member, IEEE

Abstract—In this letter, we present high-performance reverse-conduction GaN-on-Si metal–oxide–semiconductor high-electron-mobility transistors (RC-MOSHEMTs) with integrated tri-anode freewheeling diodes. Tri-anode Schottky diodes presenting small turn-ON voltage (V\text{ON}), ultra-low reverse leakage current, and high breakdown voltage (V\text{BR}) was incorporated at portions of the drift region of AlGaN/GaN MOSHEMTs as freewheeling diodes. The tri-anode RC-MOSHEMTs exhibited outstanding reverse-conduction performance with a small V\text{ON} of 0.55 V, along with a high V\text{BR} of 1150 V, state-of-the-art low ON-resistance (R\text{ON}) of 8.83 Ω·mm, and high-power figure-of-merit (FOM = V\text{BR}^2/R\text{ON,SP}) of 1.32 GW/cm^2. These results reveal the potential of the tri-gate/tri-anode technology for future integrated power electronic devices.

Index Terms—GaN, HEMT, reverse conduction, freewheeling diode, Schottky diode, tri-gate, tri-anode, breakdown, leakage current.

I. INTRODUCTION

GaN-on-Si HEMTs are ideal candidates for the next generation of power electronic devices. Low R\text{ON} and high V\text{BR} can be achieved due to the exceptional properties of GaN, such as large band-gap, and two-dimensional electron gas (2DEG) with high electron mobility and carrier density. Considering its application for power conversion, especially in topologies in which transistors are connected to inductive elements, a reverse conduction path for the current is required to release the stored inductor energy at switching events [1]. In traditional Si- and SiC-based vertical power devices, built-in body diodes can be designed using the doped layers to offer a freewheeling path when the transistor is switched off [1]–[3]. However, such body diodes cannot be formed in lateral GaN HEMTs, due to their unipolar nature and absence of doped layers. In addition, the reverse current of a HEMT, which is dependent on the gate voltage (V\text{G}), is insufficient to offer freewheeling capability [1]. One way to achieve the freewheeling path is by connecting an anti-parallel diode between the source and drain, which provides a path, independent from V\text{G}, for current to flow under reverse drain bias (V\text{D}) [4]. However, using discrete anti-parallel diodes [5] results in extra device area, larger specific on-resistance (R\text{ON,SP}), and generates additional parasitic components [6]. A compact solution to this issue is to form a SBD on the backside of the GaN-on-Si substrate, which leverages the small V\text{ON} of Si SBDs [7]. Nevertheless, this method requires complex Si deep etching process, and the small V\text{BR} of Si SBDs hinders the advantage of GaN transistors. Monolithic integration of anti-parallel planar SBDs between drain and gate of HEMT is another area-efficient approach that offers low reverse conduction loss and does not sacrifice the forward performance [8], [9]. But even so, the major limitation of such method is the large reverse leakage current of planar SBDs, which can be a few orders of magnitude higher than the transistors’ OFF-state leakage current (I\text{OFF}) [8]–[12]. The high reverse leakage current issue was addressed in [6] with an unconventional double channel heterostructure requiring relatively complex etching processes to demonstrate RC-MOSHEMTs.

Alternatively, we have recently shown the outstanding potential of tri-anode SBDs [13] with small V\text{ON}, high V\text{BR} and ultra-low leakage current for high-performance and high-voltage GaN power SBDs [14], [15] and reverse-blocking
transistors [16]. In this work, we demonstrate RC-MOSHEMT with integrated tri-anode SBDs as freewheeling diodes using a relatively simple process. The tri-anode RC-MOSHEMTs presented excellent reverse-conduction capability ($V_{ON} = 0.55 \text{ V}$), strong voltage-blocking ability ($I_{OFF} = 25 \text{ mA/mm}$ at 200 V and $V_{BR} = 1150 \text{ V}$ at $1 \mu A/mm$ with floating substrate), and a record small forward-conduction $R_{ON} (8.83 \Omega \cdot \text{mm})$.

II. DEVICE STRUCTURE AND FABRICATION

Figures 1(a) and (b) show the schematic and top-view scanning electron microscopy (SEM) image of the tri-anode RC-MOSHEMT. The epitaxy in this work consisted of 5 µm of buffer, 0.3 µm of un-doped GaN channel, 23.9 nm of AlGaN barrier, and 1.8 nm of GaN cap layers. The device fabrication started with e-beam lithography to define the fins in the tri-gate and tri-anode regions. Device isolation was done by inductively coupled plasma (ICP) mesa etching, with a depth of $180 \text{ nm}$. The fin width in the tri-gate and tri-anode regions were 200 nm and 620 nm, along with a spacing of 200 nm and 110 nm, respectively, which were designed based on our previous studies to balance of ON- and OFF-state performances of the device [13], [17]. Source and drain ohmic contacts were formed by alloying Ti/Al/Ti/Ni/Au. A 17 nm thick SiO$_2$ was deposited by atomic layer deposition (ALD) as the gate dielectric, which was then selectively removed by CHF$_3$/SF$_6$-based ICP in the Schottky contact region of tri-anode SBDs (Fig. 1(c)). The anode and gate were formed by Ni/Au (Fig. 1(d)), followed by the deposition of 50 nm-thick ALD SiO$_2$ interlayer dielectric (ILD) and the second Ni/Au metal layer (M2) as the source-to-anode connection.

The tri-anode RC-MOSHEMTs consisted of a tri-gate MOSHEMT and hybrid tri-anode SBDs integrated in its access region between the gate and drain. To equilibrate the forward and reverse current, 33% of the channel width was occupied by the SBDs, which defines a filling factor (FF) as the width of SBDs divided by the width of device footprint, which will be discussed later. All measurement results in this work were normalized by the width of the device footprint, which was $60 \text{ µm}$. Most of results used the dimensions shown in Fig. 1 (a), unless otherwise specified.

III. RESULTS AND DISCUSSION

As shown in Fig. 2(a), the integrated tri-anode SBDs enhanced significantly the reverse conduction performance of the transistors (Fig. 2(a)). The tri-anode RC-MOSHEMTs presented a $V_{ON}$ as small as 0.55 V (at $I_D = 1 \text{ mA/mm}$), along with a small reverse forward voltage ($V_F$) of 1.5 V (at $I_D = 50 \text{ mA/mm}$) at $V_G = -7 \text{ V}$. In contrast, the $V_{ON}$ and $V_F$ of the reference MOSHEMT consisting of a tri-gate structure with $L_{GD}$ of 15 µm were 2.70 V and 4.15 V at the same $V_G$, respectively. The small $V_{ON}$ is due to the direct contact of the metal to the 2DEG in the tri-anode SBDs [13], [18]. In forward-conduction mode, the tri-anode RC-MOSHEMTs presented a small $R_{ON}$ of 8.83 $\Omega \cdot \text{mm}$, which is comparable to the reference device ($7.69 \Omega \cdot \text{mm}$), and yields the smallest $R_{ON}$ among reverse-conduction GaN transistors reported in literature. The RC-MOSHEMTs also presented small $I_{OFF}$ and high ON/OFF ratio, which were identical to the reference devices (Fig. 2(b)), due to the small reverse leakage current of the hybrid tri-anode SBDs [13], [15], [19].

The small $R_{ON}$ achieved in the tri-anode RC-MOSHEMTs is mainly attributed to the optimized FF, as it determines the percentage of the channel width used for forward and reverse current conduction. Figure 3(a) plots the $I_D$ in reverse-conduction mode of the tri-anode RC-MOSHEMTs ($L_{GD} = 21 \mu m$, at $V_D = -5 \text{ V}$) as a function of their FFs. When $V_G$ is higher than $V_{TH}$, the reverse $I_D$ is independent of the FF as the transistor is in ON-state. When $V_G$ is below $V_{TH}$, FF = 33% is already large enough to nearly saturate the reverse $I_D$. This indicates that a small FF value is already enough for tri-anode SBDs to extract most of electrons injected from drain side. In forward-conduction mode, the $I_D$ decreases while the $R_{ON}$ increases with increasing FF (Fig. 3(b)), which is caused by the smaller effective channel width and higher spreading resistance. Based on these results, a FF of 33% was selected, which provided high freewheeling current with small degradation in the forward performance, resulting in a record small $R_{ON}$, which is highly desirable for efficient power conversion.

The tri-anode RC-MOSHEMT presented good reverse-conduction performance at high temperature. From 25 C to 150 °C, the $V_{ON}$ increased to 0.63 V, and the reverse current reduced to 213 mA/mm (at $V_D = -5 \text{ V}$) (Fig. 4(a)). In forward bias, the $R_{ON}$ was 20.69 $\Omega \cdot \text{mm}$ at 150 °C, which is comparable to other integrated devices [6], [16], revealing the great potential for high temperature applications (Fig. 4(b)).
Figure 5 shows the breakdown characteristics of the tri-anode RC-MOSHEMT and reference devices. The $V_{BR}$ of tri-anode RC-MOSHEMT was 1040 V, which is close to that of the reference MOSHEMT (tri-gate MOSHEMT with $L_{GD} = 15 \mu m$) and significantly improved as compared to the planar RC-MOSHEMT (planar MOSHEMT with planar SBDs, and $L_{GD}$ of 20 $\mu m$). Such enhancement in $V_{BR}$ is attributed to the better leakage control capability of integrated tri-anode SBDs [15], [19]–[21]. In addition, a very small $I_{OFF}$ of 0.6 $\mu A/mm$ at 650 V was observed for the tri-anode RC-MOSHEMTs, which is due to the reduced voltage drop at the Schottky junction in the hybrid tri-anode SBDs [15], [19]. With floating substrate, the $V_{BR}$ of the RC-MOSHEMTs was as high as 1150 V at 1 $\mu A/mm$, and the hard breakdown (HBD) did not occur until 1800 V due to better-distributed electric field of tri-gate MOSHEMTs [14], [15].

The RC-MOSHEMTs with integrated tri-anode SBDs were compared with other literature results of reverse-conduction GaN transistors in Table I, presenting small $R_{ON}$, $V_{ON}$, and $I_{OFF}$, along with the highest $V_{BR}$ of 1040 V. We further benchmarked the tri-anode RC-MOSHEMTs against state-of-the-art discrete lateral GaN-on-Si MOSHEMTs and lateral SBDs. The $V_{BR}$ was defined at 1 $\mu A/mm$ and a 15 $\mu m$ transfer length of source/drain was considered for the calculation of $R_{ON,SP}$. Only $V_{BR}$ larger than 500 V have been considered in this benchmark.

**IV. CONCLUSION**

In this work we presented reverse-conduction GaN-on-Si MOSHEMTs with state-of-the-art performance, by integrating tri-anode freewheeling SBDs. The devices exhibited excellent reverse performance, along with a record small $R_{ON}$, which can be promising for the next-generation of efficient power converters.
