Abstract

Immunotherapy can harness the power of the host immune system to fight cancer. In the last few decades, tremendous progress has been made in this field, with remarkable clinical successes achieved consisting of a durable response in a fraction of patients. However, there are enormous challenges to extending this therapy to the majority of cancer patients while retaining minimal adverse effects. Local immunotherapy is a promising approach for concentrating immunomodulation *in situ* without systemic exposure, therefore minimizing systemic toxicities. More importantly, local immunomodulation can still lead to systemic effects that confer overall anticancer immunity to eradicate disseminated diseases. To facilitate these local immunotherapies, a wide range of biomaterials have been developed as delivery systems to protect the locally injected immune-related therapeutics and extend their retention. Surgery-free injectable macroscale biomaterials are one of the most promising classes of biomaterials developed to date, as they are suitable for minimally invasive injection with needles or catheters and form a biocompatible three-dimensional matrix *in situ* as a drug-depot for controlled local delivery. In this mini-review, we provide an overview of the recent advancements in applying injectable macroscale biomaterials in local cancer immunotherapy by highlighting some recent examples. We compare various injectable biomaterials with different gelation mechanisms and discuss their applications in the delivery of immunomodulators, immune cells, and cancer vaccines. We also discuss current challenges and provide a perspective for the future development of injectable macroscale biomaterials in cancer immunotherapy.

Keywords: immunoengineering; injectable macroscale biomaterials; surgery-free; hydrogel; scaffold; depot; cancer immunotherapy; immunomodulator delivery; immune cell delivery; cancer vaccine delivery.

1. Introduction

Cancer immunotherapy, a treatment that harnesses the patient's own immune system to fight cancer, has recently shown dramatic clinical success.¹ For example, checkpoint blockade therapies have been widely used to treat a variety of malignancies leading to unprecedented durable responses in a fraction of treated patients.² Adoptive T-cell therapy, such as chimeric antigen receptor (CAR) T-cell therapy, has been effective in eradicating some hematopoietic cancers in the clinic.³ However, the percentage of cancer patients benefiting from immunotherapy remain modest. To realize its full clinical potential, strategies are being actively explored to further enhance anti-cancer immunity through combination therapies or using potent immunostimulant agents. However, balancing anti-cancer immunity and the concurrent immune-related toxicities remains a major challenge.⁴

Local immunotherapy concentrates the immunomodulatory activity *in situ* while eliminating systemic exposure, therefore minimizing the adverse systemic effects.⁵ This local treatment could also lead to systemic immunity that eradicates disseminated diseases, a phenomenon called the “abscopal effect”.^{6,7} To facilitate local immunotherapies, a wide range of biomaterials have been developed as delivery systems to protect the locally injected therapeutics and extend their retention.^{8–13} Among others, surgery-free injectable macroscale biomaterials are of particular interest, as these materials are suitable for injection with needles or catheters and form a biocompatible three-dimensional matrix *in situ* as a drug-depot for local therapeutic delivery (Figure 1). This easy and minimally invasive administration without the need for surgical implantation is clinically applicable^{14,15} and thus particularly promising in the delivery of immunotherapies.

Injectable macroscale biomaterials typically possess certain physical properties, such as a liquid form, a shear-thinning property or a high compression strain, which enable the injectability.^{16,17} A great number of these biomaterials have been developed with diverse physicochemical properties, including physically crosslinked hydrogels, chemically crosslinked hydrogels, cryogels, inorganic scaffolds, etc.^{18–21} Therapeutics with diverse physicochemical properties (e.g., positive charge, negative charge, hydrophilicity, hydrophobicity) can be loaded into those injectable macroscale biomaterials with a high encapsulation efficiency in defined doses. Biomaterials loaded with mono or combination therapies serve as reservoirs for controlled and sustained local release of encapsulated therapeutics upon injection, resulting in a concentrated local activity that minimizes systemic dissemination.

Other depot-forming macroscale biomaterials, such as implantable biomaterials, which are not injectable but require a surgery for implantation, can also be applied in immunotherapeutic delivery^{22,23} and have been reviewed previously.^{24,25} Nano- or micro-sized biomaterials that are injected locally without forming a macroscale matrix are not included in the discussion. In this mini-review, we give an overview of the recent developments in applications of injectable macroscale biomaterials in cancer immunotherapy delivery, including soluble immunomodulator delivery, immune cell delivery, and cancer vaccine delivery (Figure 1). The features and applications of various injectable macroscale biomaterials are discussed by highlighting some recent advances in the field (Table 1). We also share our perspectives on the future directions

for the development of these biomaterials for cancer immunotherapy.

2. Injectable Macroscale Biomaterials

Many different types of injectable macroscale biomaterials have been developed to date. In general, these biomaterials can be categorized into i) physically crosslinked injectable hydrogels, ii) chemically crosslinked injectable hydrogels, iii) injectable cryogels, and iv) injectable inorganic scaffolds, the features of which are summarized in Table 2. In fact, injectable biomaterials have been widely applied in the clinic for various applications, such as cosmetic surgery²⁶, post-operation anti-adhesion²⁷, and tissue repairing²⁸. Many are available in the market including hyaluronic acid-based hydrogel for post-operation anti-adhesion (e.g., Adcon®, SprayShield®)^{29,30} and osteoarthritis treatment (e.g., Gel-One® and Euflexxa®)³¹. Recently, a collagen-based injectable scaffold (AUGMENT®)²⁸ received the approval from USA-Food and Drug Administration (FDA) for bone regeneration, which is the first alternative to autograft in hindfoot and ankle arthrodesis.

Physically crosslinked hydrogels are typically fabricated based on noncovalent interactions, such as hydrophobic interactions, hydrogen bonding, etc. They either remain non-crosslinked (as a solution) before injection or possess a shear-thinning property that enables their injectability. Among them, supramolecular hydrogels and thermosensitive hydrogels are two extensively studied systems. The former has a three-dimensional network that is stabilized by noncovalent interactions, such as hydrogen bond, π - π interactions, host-guest interactions, etc.³² As noncovalent interactions are reversible and weaker than covalent bonds under normal conditions, supramolecular hydrogels are intrinsically self-healing and can easily be injected into the target site via needle. These hydrogels can be made from diverse materials, including proteins, nucleic acids, polysaccharides, oligo- or poly-peptides, or synthetic polymers with pendant host and guest chemical groups (e.g., β -cyclodextrin and adamantane).^{33,34} This imparts huge structural and functional diversities to the supramolecular hydrogel system, which are beneficial for designing a custom-tailored delivery system for specific therapeutics. Particularly, programmable supramolecular hydrogels have attracted much attention recently as they can respond to complex biochemical stimuli orthogonally for precisely controlled release pattern of multiple cargos.^{35,36}

Thermosensitive hydrogels are a special type of physical hydrogel whose gelation process is induced by temperature variation.^{37,38} It remains a solution before injection and quickly transforms into a gel at physiological temperatures. Basically, the building blocks of thermosensitive hydrogels feature an amphiphilic structure with segregated hydrophilic and hydrophobic domains. The temperature-induced gelation is usually driven by increased hydrophobic interactions upon elevated temperature that facilitate the formation of physical junctions of the three-dimensional network. Due to the nature of the physical crosslinking, temperature-induced gelation is reversible. Also, the gelation temperature can be controlled by fine-tuning the hydrophilic/hydrophobic domain ratio.³⁹ To date, various types of thermosensitive hydrogels have been developed, including polyethylene glycol (PEG)/polyester block copolymers, PEG/polypeptide block copolymers, amphiphilic poly(N-isopropylacrylamide)

(PNIPAAm) copolymers, amphiphilic polyphosphazenes, chitosan derivatives, etc.^{37,38} Notably, various recent studies focused on the biomedical applications of PEG/polypeptide block copolymers due to their inherent biocompatibility and tunable secondary structure that well mimics the extracellular matrix microenvironment.^{40,41} Generally, the encapsulation conditions for thermosensitive hydrogels are typically mild, especially suitable for some environmentally sensitive drugs, such as proteins, because loading can be done in an aqueous system at room temperature or even at refrigerated temperatures. Additionally, the temperature-induced physical gelling process largely maintains drug bioactivity as compared to chemically crosslinked injectable hydrogels that rely on chemical reactions for hydrogel network formation.^{42,43} hydrogels have received increasing attention

Chemically crosslinked injectable hydrogels exploit covalent bonds to form the three-dimensional network. Compared to traditional chemically crosslinked hydrogels, these injectable crosslinking reactions occur at the target site *in vivo* surrounded by tissues,²¹ requiring the reactions being biocompatible without generating by-products toxic to normal tissues. Also, the reactions should be efficient to avoid excess reactive functional groups. To fulfill these requirements, some mild though highly efficient reactions can be used (e.g., click chemistry, disulfide formation, Michael additions, Schiff's base reaction, enzymatic reactions, and redox/photo-initiated polymerization).⁴⁴ Chemically crosslinked injectable hydrogels typically have a higher mechanical strength and network stability than their physically crosslinked counterparts. These features are important in supporting cell/tissue ingrowth and fabricating defined or gradient functionalized patterns inside hydrogels or on hydrogel surfaces.⁴⁵⁻⁴⁷ Also, stimulus-responsive chemical bonds or enzymatically degradable moieties can be introduced into the hydrogel network to achieve responsive release of cargos or programmable degradation behaviors.^{48,49}

Cryogel is a sponge-like network with interconnected micropores surrounded by a polymer wall. Generally, the microporous network is generated by freeze-thawing, and the matrix structure across the cryogel can be either chemically or physically crosslinked. Also, both natural or synthetic polymer can be used to construct cryogel.⁵⁰ Due to the microporous structure and good interconnectivity, cryogel has advantages of quick diffusion of soluble factors and better cellular infiltration/ingrowth as compared to hydrogels without microporous structure.⁵¹ Although cryogel is a solid and usually possesses a high mechanical strength, it can be injectable if the cryogel is molded into a shape designed for passing through a needle. In recent years, nanocomposite-encapsulated injectable cryogels have emerged as an advanced technique for multi-functionality and improved performances in the delivery of therapeutics.^{52,53}

Injectable inorganic scaffolds are a new form of macroscale biomaterial that use high-aspect-ratio inorganic microrods to generate the scaffold network. Different from physically or chemically crosslinked injectable hydrogels, these rely on the physical stacking of the microrod to form a three-dimensional network structure and are injectable because of the microscale size of the building blocks that can pass through the needle. One unique characteristic of this system is that it has a highly rigid backbone made from microrod while retaining a micropore structure for cell/tissue ingrowth. It

provides an alternative platform for the delivery of cell-based therapeutics or the recruitment of host cells *in vivo*.

3. Injectable Macroscale Biomaterials for Immunomodulator Delivery

Immunomodulators refer to any soluble factors that can directly control the immune response,⁵⁴ such as cytokines, checkpoint blockade antibodies, co-stimulatory agonists, and chemical inhibitors. In cancer immunotherapy, immunomodulators stimulate the anti-tumor immune response. Systemic administration of those immunomodulators may lead to undesired immune stimulation and sometimes even lethal toxicity, especially in combination therapies.^{55,56} Therefore, a number of biomaterial-based strategies have been developed to improve immunomodulator targeting in tumor tissues to minimize this non-specific activation.⁵⁷ Among different biomaterials, injectable macroscale biomaterials are a highly promising platform that can form a concentrated depot to confine the activity of immunomodulators to the target site without systemic dissemination. Here, we review the applications of injectable macroscale biomaterials in immunomodulator delivery by highlighting some recent examples.

3.1. Physically Crosslinked Injectable Hydrogels

3.1.1. Peptide- or DNA-derived Supramolecular Hydrogels

In recent years, oligopeptide- and nucleic acid-based supramolecular hydrogels have gained much attention in the fabrication of delivery systems for immunomodulators due to their ease of synthesis and defined self-assembly structures.^{58–61} An interesting system called “STINGel” developed by Leach et al. is one elegant example made from an oligopeptide ($K_2(SL)_6K_2$) that can self-assemble into an anti-parallel β -sheet-based nanofiber in solution.⁵⁹ Interestingly, the immunomodulator, a synthetic cyclic dinucleotide (CDN), served as the crosslinker in the “STINGel” system via the electrostatic interactions between the negative thiophosphate groups on CDN and the positive lysine residues on the oligopeptide. Compared to CDN-encapsulated collagen hydrogels, the “STINGel” could achieve an eight-fold slower *in vitro* CDN release rate. This released CDN induced an anti-tumor response via the stimulation of the stimulator of interferon genes (STING) pathway, which involves the downstream activation of innate immune cells. It was demonstrated that after one peritumoral injection, six out of ten “STINGel”-treated mice displayed complete eradication of tumor growth, while only one out of ten mice treated with CDN-encapsulated collagen hydrogel showed the same. Thus, the local and extended release of the STING agonist greatly enhanced the treatment efficacy. Another possible reason for the enhanced efficacy is that the positive charges in the hydrogel network may increase the cellular uptake of CDN, which exhibits poor membrane permeability due to its overall negative charge. In principle, this supramolecular hydrogel system based on electrostatic interactions has great potential for the delivery of other immunomodulators with negative charge (e.g., unmethylated cytosine-phosphate-guanine oligodeoxynucleotides [CpG]). It could also be generalized to deliver positively charged immunomodulators by exchanging the

terminal lysine residues on the oligopeptide with other negatively charged amino acids, such as glutamic acid.

DNA-based supramolecular hydrogels are also of great interest in immunomodulator delivery as they enable the precise network structure design and can intrinsically deliver DNA-based drugs, such as the toll-like receptor 9 agonist CpG,^{60,61} which was developed as a hydrogel in 2011 by Nishikawa et al.⁶² At that time, however, this system showed only marginal anti-tumor efficacy even in combination with a chemical anti-tumor drug doxorubicin. Recently, the same research group further combined the CpG-incorporated DNA-based hydrogel with photothermal therapy to enhance the immunostimulatory functions of CpG.⁶¹ In this system, a CpG-containing hexapod-like DNA structure was designed to crosslink the gold nanorod (AuNR), which functioned as a photosensitizer for photothermal therapy, modified with complementary oligo-DNAs on its surface. After mixing, they could form a shear-thinning hydrogel (designated as AuNR-CpG hydrogel) that could be injected by needle. Remarkably, the intratumoral injection of the AuNR-CpG hydrogel significantly inhibited the tumor growth in mice when combined with laser-induced photothermal therapy. Likely the hydrogel formulation plays an important role in generating robust immune responses via controlled immunomodulator release. As CpG is a commonly used adjuvant in vaccine studies,^{63,64} this system also has great potential in generating an effective cancer vaccine. In fact, some work has been done on this topic, and the details are discussed in the section “Injectable Macroscale Biomaterials for Cancer Vaccine Delivery”.

3.1.2. Thermosensitive Hydrogels

Recently, thermosensitive hydrogels have attracted much attention as immunomodulator delivery systems for their mild encapsulation and gelation conditions that preserve therapeutic bioactivities. For instance, these hydrogels have been used to deliver growth factors and preserve their bioactivities for tissue repairing.^{65,66} At present, the majority of the systems used for immune-modulator delivery are focused on PEG/polypeptide block copolymers.^{67–70} One of the representative works is a recent study that chemically incorporated an indoleamine-pyrrrole 2,3-dioxygenase (IDO) inhibitor dextro-1-methyl tryptophan (D-1MT) into the polypeptide block of the amphiphilic copolymer-based thermosensitive hydrogel system (Figure 2).⁶⁷ The copolymer was synthesized by the ring-opening polymerization of D-1MT N-carboxyanhydride (NCA) and L-methionine NCA using amine-terminated PEG as an initiator. The L-methionine on the backbone imparted a reactive oxygen species (ROS)-responsive property to the hydrogel system that could be activated through the oxidation of the hydrophobic methylthiol group into the hydrophilic methyl sulfoxide/sulfone group. As a result, the hydrogel system exhibited an accelerated *in vitro* degradation kinetic and cargo release profile in the presence of ROS, which are upregulated in the tumor microenvironment. In a mouse model with B16F10 melanoma, a single intratumoral injection of the D-1MT-incorporated thermosensitive hydrogel system coloaded with anti-PD-L1 could significantly delay tumor growth and extend mouse survival when compared with free D-1MT plus anti-PD-L1 (Figure 2), suggesting that the hydrogel depot was crucial for the enhanced anti-

tumor efficacy. However, as the *in vivo* experiment lacked a blank thermosensitive hydrogel loaded with anti-PD-L1, it is unclear whether the enhanced anti-tumor efficacy was mainly attributed to a sustained release of anti-PD-L1 or an enhanced synergistic effect from the sustained release of D-1MT. Also concerning, this system might not release single molecules, but those in the form of oligo-D-1MT that has impaired IDO inhibitory activity. Nevertheless, this concept may be useful for delivering immunomodulators that function properly or even better in a polymer form, such as polyinosinic:polycytidylic acid (poly[I:C]).

Another interesting thermosensitive hydrogel system is a composite consisting of a cationic polyamine-PEG-polyamine triblock copolymer with ROS-responsive side chains (nitroxide radical) and a anionic homopolymer poly(acrylic acid) for the sustained release of interleukin-12 (IL-12).⁶⁸ Interestingly, the *in vitro* release patterns were similar among various protein cargos with different molecular weights and isoelectric points (e.g., bovine serum albumin, insulin, glucose oxidase, avidin, and neutravidin). Thus, it may provide a universal platform for the synchronized and sustained release of multiple protein cargos in one formulation. However, as the hydrogel-formulated IL-12 displayed only slightly increased anti-tumor efficacy, the release kinetic needs to be further optimized for maximum effect in the follow-up studies. Nevertheless, the application of this polyion-complex-based hydrogel system can potentially be extended for the delivery of various positively or negatively charged immunomodulators, as it has the potential to achieve high loading efficiency and controlled cargo release via electrostatic interaction between the hydrogel network and immunomodulators.

3.2. Chemically Crosslinked Injectable Hydrogels

Despite the advantages of chemically crosslinked injectable hydrogels (e.g., persistent network structure for stable release kinetics), few studies to date have reported using them for immunomodulator delivery.^{71,72} One recent example is a ROS-responsive system developed by the Gu group for the co-delivery of a checkpoint inhibitor and a chemical anti-tumor drug gemcitabine (GEM) (Figure 3).⁷² The hydrogel system was made of poly(vinylalcohol) (PVA) and *N*¹-(4-boronobenzyl)-*N*³-(4-boronophenyl)-*N*¹, *N*¹, *N*³, *N*³-tetramethylpropane-1, 3-diaminium (TSPBA). In this system, the TSPBA crosslinked the diols on PVA by complexing them with its two phenylboronic acid groups. The TSPBA could also be oxidized and scavenged upon elevated ROS levels, a key feature in the tumor microenvironment, to achieve tumor-site-specific release. As the crosslinking reaction occurs quickly, the PVA and TSPBA need to be loaded into a dual syringe separately before injection and mixed together only when they pass through the needle. Although this method ensures the injectability of the hydrogel system, it is worth noting that this method may generate heterogeneous regions with various physicochemical properties inside hydrogel, as the mixing process in the needle may not be sufficient. In *in vivo* studies, the peritumoral injection of the GEM and anti-PD-L1-encapsulated hydrogel system significantly inhibited tumor growth and prolonged survival in both B16F10 (Figure 3) and low immunogenic 4T1 carcinoma models. Particularly in the B16F10 tumor model, the hydrogel system induced a

systemic immune response that delayed the growth of distant tumor, as well, indicating that the hydrogel depot could also potentiate the efficacy of a chemo- and immuno-combination therapy. Interestingly, loss of tumor-promoting M2-like macrophage was observed in mice treated only with the blank hydrogel, implying that the ROS-scavenging property of the hydrogel system could remodel the tumor microenvironment for better anti-tumor efficacy. Therefore, the ROS scavenging moiety may be beneficial when designing injectable macroscale biomaterials for delivering macrophage-dependent immunomodulators. Finally, despite the injection method, this hydrogel system shows potential for clinical application, as it involves only two simple components: a small molecule crosslinker and PVA, which has been used as a drug additive in many clinical therapeutics.

3.3. Injectable Cryogels

Compared to physically or chemically crosslinked injectable hydrogels, injectable cryogel possesses a unique micropore structure that enables cell entrance, meaning it can concentrate target cells in the depot for a more efficient drug action kinetic. The pioneering work in the delivery of immunomodulators using injectable cryogel was done by the Mooney group⁷³ wherein methacrylated gelatin (GelMA) was used to form the cryogel polymer network via redox-initiated radical polymerization. The cryogel was preformed into a cylindrical shape (5 mm diameter, 2 mm thickness) for injection via needle. Interestingly, the cylindrical cryogel could pass through a 16G needle (inner diameter ~1.2 mm) and recover its original shape after injection due to its high compression strain and elasticity. The immunomodulator granulocyte-macrophage colony-stimulating factor (GM-CSF) that attracts and stimulates immune cells (e.g., dendritic cells [DCs] and macrophages) could be loaded into the cryogel before crosslinking. After subcutaneous injection of the GM-CSF-loaded cryogel, it exhibited 20-fold higher live-cell recruitment into the matrix when compared to blank cryogel, which is of great interest in generating a local immunization depot. However, the *in vitro* release of GM-CSF from the cryogel showed a large initial burst of around 50%, so there is still room for improvement in prolonged cargo release for the sustained recruitment of the host immune cells.

4. Injectable Macroscale Biomaterials for Immune Cell Delivery

In cancer immunotherapy, the ultimate anti-tumor responses are typically exerted by effector immune cells, such as cytotoxic CD8⁺ T cells, effector CD4⁺ T cells, and NK cells. Adoptive cell therapy has been developed into clinical applications including two CAR T-cell products recently approved by the FDA (Kymriah[®] and Yescarta[®]).^{74,75} Despite the exciting clinical results in the treatment of liquid cancers, the efficacy of adoptive cell immunotherapy in solid tumors remain modest due to the impaired infiltration of immune cells into solid tumors and the immuno-suppressive tumor microenvironment.^{76,77} Those cell-based immunotherapies could also induce serious or even fatal side effects.^{78–80}

To address these challenges, biomaterial-based strategies have been explored for the local delivery of therapeutic immune cells because they can enrich the immune cells inside tumor tissues, reverse the immune-suppressive tumor microenvironment, and alleviate systemic toxicities, such as cytokine release syndrome⁸¹. Injectable macroscale biomaterials provide significant advantages in this particular application as they permit the simple mixing of therapeutic immune cells and injectable biomaterials *ex vivo* followed by the minimally invasive injection without surgery. In recent years, injectable hydrogel systems have been extensively investigated for the delivery of immune cells. For example, injectable alginate hydrogels were explored in a pioneer study by the Irvine group for the co-delivery of antigen-pulsed DC cells with supporting immunomodulators (e.g., CCL19, CCL21, and IL-15SA) for cancer immunotherapy.^{82,83} The DCs and immunomodulator-encapsulated hydrogel system outperformed free DCs plus immunomodulators in tumor growth inhibition and prolonging animal survival. Other examples are highlighted and discussed in this section.

4.1. Chemically Crosslinked Injectable Hydrogels

Chemically crosslinked injectable hydrogels are favored for generating a stable depot with a defined mechanical strength and network structure for desired cell growth/differentiation. For example, several of these systems have been designed to deliver chondrocytes for cartilage tissue engineering.^{84–86} Recently, some have also been used to encapsulate immune cells for enhanced cancer immunotherapy.^{87,88} One example of this is a hydroxyphenyl propionic-acid-conjugated gelatin (GHPA)-based hydrogel for the co-delivery of DCs and oncolytic adenovirus (oAd) that could co-express IL-12 and GM-CSF in tumor tissue.⁸⁸ The *in situ* crosslinking of the hydrogel was initiated using the horseradish peroxidase (HRP) and H₂O₂ enzymatic reaction, which is highly efficient and biocompatible with living tissues, to generate multiple phenolic radicals on one single polymer chain that couple together to form a crosslinked network. Interestingly, the *in vitro* release of DCs from the hydrogel system was dependent on the stiffness, with a faster release rate coming from hydrogels with a lower stiffness. This phenomenon may be partly attributed to the lower crosslinking density of a hydrogel system with a lower stiffness, and it provides a possibility to control the DC-release kinetic for optimal immune responses. The hydrogel system could also help the accumulation of DCs and oAd in both tumor tissue and draining lymph nodes for a prolonged period of time. Importantly, a single intratumoral injection of a DC- and oAd-loaded hydrogel would facilitate greater infiltration of CD8⁺ T cells and induce a more potent antitumoral effect compared to that of free DCs plus oAd. Thus, the prolonged release of the immune cells has a positive impact on the outcome of immune-cell-based cancer treatment.

Chemically crosslinked injectable hydrogels have also been used to deliver macrophages to tumor sites for enhanced cancer immunotherapy using a hydrogel system consisting of thiolated poly(ethylene glycol)-grafted gelatin (Gel-PEG-Cys) and poly(ethylene glycol) diacrylate (PEGdA).⁸⁷ When mixing the two components, a gentle crosslinking occurred via the Michael's addition reaction between the thiol group

on Gel-PEG-Cys and the acrylic groups on PEGdA. The encapsulated M1-like macrophages retained their phenotype and displayed a similar cytokine-release profile to that of M1-like macrophages cultured in normal medium. The peritumoral injection of the M1-macrophage-encapsulated hydrogel significantly delayed the tumor growth in a xenograft model compared to a blank hydrogel group. It is worth noting that a treatment group with M1 macrophage alone was absent in the *in vivo* study, so it is unclear if the hydrogel system could promote the efficacy of macrophage-based cancer immunotherapy. In the tumor microenvironment, macrophages are polarized to an M2-like phenotype for tumor progression,⁸⁹⁻⁹¹ so for future studies it will be of great interest to see if the injectable hydrogel system protects the macrophages from this polarization in the tumor microenvironment. Also, this system has the potential to generate an injectable hydrogel that can reprogram the tumor-promoting M2-like macrophage into the tumor-inhibiting M1-like macrophage phenotype.

4.2. Thermosensitive Hydrogels

Thermosensitive hydrogels are a good candidate for immune-cell delivery as they can encapsulate cells in solution at a low temperature without cell damage. Additionally, no chemical additive is needed in the hydrogel system, so it has a better biocompatibility when compared with the chemically crosslinked hydrogel. These hydrogels have served as promising platforms for the delivery of stem cells and the control of their differentiation.^{92,93} In recent years, thermosensitive hydrogels have emerged as a potential platform for the delivery of immune cells in cancer immunotherapy.⁹⁴⁻⁹⁶ A representative work is a thermosensitive chitosan hydrogel for the delivery of tumor-infiltrating lymphocytes and activated CD8⁺ T cells (Figure 4).⁹⁶ Initially, the chitosan was premixed with a phosphate-based buffer to generate the thermogelling system. The gelation time and mechanical strength of the hydrogel system could be finely tuned by varying the concentration of sodium bicarbonate in the buffer, and this provided a good platform for designing suitable physical features for immune cell proliferation. In the *in vitro* T-cell expansion experiment, it was found that the hydrogel system with a larger pore size and higher stiffness promoted a higher cell viability and proliferation rate of the encapsulated T cells (Figure 4), which the authors suspected was due to the heightened gas diffusion and nutrient exchange inside the hydrogel. To corroborate this, some studies have shown that T cell behaviors are stiffness dependent,^{97,98} with a higher stiffness potentially contributing to better *in vitro* T cell expansion. Intriguingly, CD8⁺ T cells tended to grow faster than CD4⁺ T cells in the thermosensitive chitosan hydrogel system (Figure 4), but the related mechanism wasn't revealed in the article. It provides a hint that the type of immune response can be selectively controlled by using certain biomaterials. Finally, a primary Transwell T cell killing assay demonstrated that the encapsulated T cells could migrate from the thermosensitive chitosan hydrogel into the lower chamber seeded with tumor cells and perform normal, specific killing of these tumor cells. It suggested that the T cells delivered using thermosensitive chitosan hydrogels are likely to retain their potential for the specific killing of tumor cells *in vivo*.

Other thermosensitive hydrogels, such as PEG-grafted chitosan and PEG-*b*-

P(MEO2MA-*co*-OEGMA-*co*-NHSMA) copolymer, have also been explored for the encapsulation of T cells,^{94,95} though none of these thermosensitive hydrogel systems have been studied *in vivo* to determine their anti-tumor efficacy. In the future, the therapeutic effect of immune cell-encapsulated thermosensitive hydrogels needs to be demonstrated to better understand the *in vivo* behaviors of the encapsulated immune cells. It will be of great value in designing desirable thermosensitive hydrogel systems for the efficient delivery of immune cells and the precise modulation of anti-tumor immune responses.

5. Injectable Macroscale Biomaterials for Cancer Vaccine Delivery

Cancer vaccines activate the host immune system against tumor antigens, either for prophylactic or therapeutic purposes. To generate a potent cancer vaccine, different strategies have been developed, including antigen-pulsed DCs, a peptide subunit vaccine, antigen-encoding mRNA/DNA, and tumor cell lysates.⁹⁹ It remains challenging, however, to efficiently deliver tumor antigens to the desired immune organs or cells.¹⁰⁰ Subunit cancer vaccines, such as mRNA/DNA and peptide-based cancer vaccines, accumulate poorly in draining lymph nodes upon parental injections and rapidly disseminate into the systemic circulation.^{101,102} In recent years, a great deal of biomaterial-based cancer vaccine platforms, including injectable macroscale biomaterials, have emerged for improving the delivery efficiency and potency of cancer vaccines.^{103–106} Injectable macroscale biomaterials can serve as a depot for both antigens and adjuvants for slow release and extended retention in lymph nodes. Such a depot could also be designed as an artificial immune organ to recruit antigen-presenting cells (e.g., DCs) for enhanced antigen uptake and presentation. The application of those minimally invasive biomaterials in cancer vaccine delivery is reviewed here.

5.1. Physically Crosslinked Injectable Hydrogels

5.1.1. Peptide- or DNA-derived Supramolecular Hydrogels

In recent years, supramolecular hydrogels have attracted enormous interest in the delivery of cancer vaccines, with the majority of these hydrogels either oligo-peptide-based or nucleic-acid-based, as peptide antigens and some DNA-based adjuvants, such as CpG, can be inherently incorporated into the hydrogel network with a defined structure and composition.^{107–117} One of the representative works in this area is a DNA-derived supramolecular hydrogel-based cancer vaccine that incorporated the adjuvant CpG into the backbone of the DNA hydrogel network.¹⁰⁸ It used two sets of CpG-containing hexapod-like DNA with complementary ends to form the hydrogel network. Also, an ethylenediamine-conjugated ovalbumin (ED-OVA) with a positive net charge was developed to achieve the sustained release of the antigens via electrostatic interaction with the negatively charged DNA network. Intact OVA, even incorporated into the hydrogel, showed an initial burst release of up to 80 %, providing an elegant example of how to control the kinetic release via delicate chemical modification of the cargo. One intratumoral injection of ED-OVA-loaded DNA hydrogel could generate a

potent anti-tumor response and completely eradicate tumor growth in two out of eight mice compared with OVA-loaded DNA hydrogel, implying that the sustained release of the antigen could enhance the efficacy of cancer vaccine. Moreover, a cationic synthetic peptide antigen (R₈-FFRK-SIINF₈EKL) was tested for the fabrication of a subunit cancer vaccine. Remarkably, the R₈-FFRK-SIINF₈EKL-loaded DNA hydrogel led to complete regression of tumor growth in five out of six mice. In another study, a tandem dual-subunit peptide antigen MUC1-P30 was also delivered with a similar CpG-incorporated DNA supramolecular hydrogel, and the hydrogel formulation exhibited prominent anti-tumor effects compared to the free antigen plus CpG.¹¹³ Thus, this DNA supramolecular hydrogel may provide a universal platform for effective synthetic peptide-based subunit cancer vaccines. In addition to introducing positively charged moieties into peptide antigens, incorporating a positively charged polymer into the hydrogel system could achieve the prolonged release of the antigens with a negative net charge,¹¹⁰ which may be simpler and more practical as it does not require chemical modification of the antigens.

Peptide-based supramolecular hydrogels can form various self-assembled structures, such as nanofibers containing α -helixes or β -sheets, and self-assembling peptides could serve as adjuvants when conjugated with peptide or protein antigens.^{118–121} Various preclinical vaccines have been constructed based on these hydrogels against infectious diseases.^{122,123} Recently, some peptide-based supramolecular hydrogels have also been developed to elicit both effective humoral and cellular immune responses for cancer vaccines.^{109,111,114,116} A representative work is a system based on the naphthylacetic acid-modified tetra-peptide (Nap-GFFY; designated as L-gel),¹⁰⁹ which possesses shear-thinning properties that enabled the injection and loading of the antigens through gentle shaking (Figure 5). Intriguingly, the enantiomeric counterpart of the tetra-peptide (Nap-G^DF^DF^DY; designated as D-gel) induced stronger humoral and cellular immune responses than L-gel, possibly due to better stability of D-gel *in vivo*. Particularly, the OVA-loaded D-gel better inhibited tumor growth than the monophosphoryl lipid A + OVA bolus formulation. Moreover, the potential of D-gel for fabricating whole-cell cancer vaccines was also tested. X-ray-treated EG7 tumor cell (XTC)-loaded D-gel significantly inhibited tumor growth with decreased tumor volume over time (Figure 5). Interestingly, the XTC-loaded L-gel displayed a similar, marginal anti-tumor efficacy to that of XTC alone. This suggests that the chemical composition of the hydrogel system, including isomeric effects, plays a key role in triggering potent anti-tumoral immune responses and should be considered for developing effective cancer vaccines.

Another interesting peptide-based supramolecular hydrogel system is a self-assembling and tumor-penetrable peptide Fmoc-KCRGDK (FK) for the construction of whole-cell cancer vaccines.¹¹⁵ The tumor cells were loaded with a PD-L1 expression inhibitor and a photoabsorbent indocyanine green (ICG). In this system, the potent anti-tumor immune response could be temporally triggered with laser radiation, providing a promising approach for precisely controlling anti-tumor responses using an external trigger.

So far, none of the recent injectable peptide-based supramolecular hydrogels have been explored for the delivery of subunit peptide antigens, which will be of great interest in

the future for cancer vaccines. These peptide antigens can be chemically incorporated into the hydrogel network for prolonged presentation and precise control over the ratio between different peptide epitopes.

5.1.2. Thermosensitive Hydrogels

Thermosensitive hydrogels can be kept in a solution state before being injected into the body, providing the advantage that the antigen and adjuvant can be loaded into the hydrogel homogeneously without any further modification or reaction step. Also, as the antigen and adjuvant are formulated into the hydrogel system in advance before transportation, it can be directly used on the spot without any additional mixing step, which is beneficial for vaccinations of large-scale populations.

In recent years, the thermosensitive hydrogel systems for cancer vaccine fabrication have been almost entirely based on PEG/polyester block copolymers or chitosan.^{124–128} The amphiphilic PEG/polyester block copolymer is first assembled into micelles and then aggregated to form a hydrogel network upon increased temperature.^{19,39} As this hydrogel system intrinsically contains a large proportion of hydrophobic domains, it has an edge in the sustained release of hydrophobic drugs. In a recent study, the DC-recruiting factor GM-CSF was encapsulated in a methoxy-poly(ethylene glycol)-*b*-poly(lactic-*co*-glycolic acid) (mPEG-PLGA)-based thermosensitive hydrogel, and a sustained release kinetic of GM-CSF was achieved without a significant initial burst.¹²⁵ As a result, the GM-CSF-loaded mPEG-PLGA thermosensitive hydrogel effectively enriched for DCs and macrophages in the depot after subcutaneous injection. After two immunization doses of DC-targeted and OVA-encoded lentiviral vectors as the antigen and monophosphoryl lipid A as the adjuvant, this system significantly suppressed tumor growth as compared to the system lacking GM-CSF. This indicated that DC enrichment in the hydrogel depot is crucial for enhanced vaccination efficacy. Interestingly, the authors injected the antigen/adjuvant mixture separately after the injection of GM-CSF-loaded hydrogel for the immunization. If the separated administration of antigen and adjuvant improves the vaccination efficacy, it may provide a better administration strategy for injectable macroscale biomaterial-based cancer vaccines.

The chitosan thermosensitive hydrogel is usually obtained by adding polyol salts (e.g., glycerol 2-phosphate disodium hydrate [GPDH]) into a chitosan solution. In one representative study, a chitosan/methylcellulose/GPDH ternary thermosensitive hydrogel was used to fabricate a subunit peptide cancer vaccine.¹²⁷ The subcutaneous vaccination with TRP2 peptide^{180–188} (tyrosinase-related protein 2 residues 180–188; a B16 endogenous antigen) and Quil A (an adjuvant)-loaded chitosan thermosensitive hydrogel showed enhanced protection against tumor growth compared to TRP2 peptide^{180–188}-pulsed DCs. Using OVA as a model antigen, it was further demonstrated that chitosan thermosensitive hydrogel-assisted vaccination could elicit stronger antigen-specific cytotoxic and memory CD8⁺ T-cell responses than DC-based vaccinations, suggesting that the sustained release of antigen and adjuvant could achieve superior efficacy compared to the antigen-pulsed DC strategy. For future studies, it will be of great interest to investigate whether the enhanced vaccination efficacy is a result of local DC activation at the hydrogel depot or the enhanced accumulation of antigen and

adjuvant in draining lymph nodes.

5.2. Injectable Cryogels

Because cryogel intrinsically possesses a microporous structure and high network interconnectivity, it is ideal for generating a favorable artificial niche for the recruitment and activation of DCs. Recently, the Mooney group explored the feasibility of using injectable cryogels for fabricating whole-cell cancer vaccines.^{129,130} These vaccines typically use irradiated tumor cells to elicit a broad spectrum of immune responses to tumor-derived antigens, including tumor-associated antigens and neoantigens.¹³¹ In some clinical trials, genetically modified tumor cells expressing GM-CSF were used for vaccinations, but this method is costly and phase 3 trial results were disappointing, possibly due to the lack of efficient DC co-stimulation.¹³² Here, the cryogel is expected to provide a platform for the enrichment and durable stimulation of DCs. In Mooney's lab, a methacrylated alginate was used to fabricate the injectable cryogel sponge crosslinked via redox-initiated radical polymerization.¹³⁰ The DC-stimulator GM-CSF and a CpG adjuvant could be physically incorporated into the system before crosslinking while the irradiated tumor cells were seeded on the fabricated cryogel sponge to serve as an antigen source. Strikingly, in a highly aggressive B16F10 tumor model, the cryogel-based whole-cell vaccine completely eradicated the established tumor in 40 % of mice after subcutaneous immunization with only a second boosting. More recently, a similar methacrylated alginate-based injectable cryogel was also examined to generate a prophylactic whole-cell cancer vaccine, and its subcutaneous injection prevented tumor growth in up to 80 % of mice.¹²⁹

Thus, this injectable cryogel system is a promising universal platform for fabricating effective whole-cell vaccines. However, the common problem in the existing systems is that the encapsulated cytokine or adjuvant (e.g., GM-CSF and CpG) displays a huge initial burst release (>50%), which is not ideal for maintaining a cytokine concentration gradient and a sufficient dose of adjuvants for effective DC recruitment and activation. A possible solution to this is to incorporate the cytokine or adjuvant-encapsulated polymer microspheres (e.g., poly[lactic-co-glycolic acid] and alginate microspheres) into the cryogel for sustained release of the cytokine and adjuvant.

5.3. Injectable Inorganic Scaffolds

At present, the vast majority of injectable macroscale biomaterial platforms rely on organic compounds such as synthetic polymers, peptides, and DNA for constructing the biomaterial network. Very few studies have focused on developing injectable inorganic biomaterials for the delivery of cancer immunotherapy and cancer vaccines. Until recently, the Mooney group has pursued the pioneering work on developing these scaffolds for effective cancer vaccines for both tumor-associated antigens and neoantigens.^{133,134} The building block of their injectable inorganic scaffold was a mesoporous silica microrod (MSR) with a high aspect ratio that could spontaneously assemble into a 3D scaffold *in vivo* (Figure 6). This system has the advantage that a simple fabrication combines both a mesoporous structure for drug release and a

microporous structure for cell recruitment. Notably, cell recruitment into the MSR scaffold was highly dependent on the structural parameters of the MSR, with the high-aspect-ratio MSR recruiting more DCs than the one formed from a low-aspect-ratio MSR. Moreover, both the mesopores on the MSR and the micropores between the stacking MSR were crucial for efficient cell recruitment, indicating that the physical features are important in designing injectable macroscale biomaterials to generate an effective immunization depot. Interestingly, a single immunization with GM-CSF, CpG, and OVA-loaded MSR scaffold (designated as MSR vaccine) induced both strong Th1 and Th2 responses, while the bolus form containing the same dose of GM-CSF, CpG, and OVA elicited only a moderate Th1 response. Moreover, the MSR vaccine significantly delayed the onset of EG7-OVA tumor growth and extended the survival of the mice compared to the bolus vaccine (GM-CSF + CpG + OVA) (Figure 6).

The same group further improved the MSR scaffold-based vaccine system by coating the MSR with cationic polymer polyethyleneimine (PEI).¹³³ The PEI coating promoted the maturation and the antigen cross-presentation level of DCs, which may be due to enhanced lysosome rupture upon PEI uptake. Compared to the MSR vaccine in previous work, the GM-CSF, CpG, and OVA-loaded PEI-coated MSR scaffold (designated as MSR-PEI vaccine) stimulated stronger CD8⁺ cytotoxic T cell responses. Impressively, with a synthetic long peptide from the E7 oncoprotein of HPV as the antigen, one single intrascapular immunization with the MSR-PEI vaccine resulted in complete regression of tumor growth in 80% of mice with an E7-expressing TC-1 carcinoma. Additionally, all the tumor-free mice were protected from a re-challenging with E7-expressing TC-1 carcinoma, which indicated that a potent immunological memory was generated. Moreover, a pool of B16F10 or MT26 neoantigens could be simultaneously loaded into the MSR-PEI scaffold in one formulation, and this formulated vaccine effectively eradicated lung metastases and synergized with anti-CTLA4 antibodies to delay tumor growth in mice. Thus, this injectable inorganic scaffold may offer a simple and modular platform for the delivery of multiple antigens against different epitopes on a tumor cell surface.

6. Perspective

As illustrated by many examples, injectable macroscale biomaterials have exhibited great promise in promoting local cancer immunotherapy with enhanced efficacy and safety. Applications of such biomaterials have been focused to date on the delivery of various immunomodulators, immune cells, and cancer vaccines. Compared to other commonly used biomaterials (e.g., implantable biomaterials, nano-/micro-biomaterials), this class has some unique advantages, such as facile formulation, surgery-free administration, shape fitness to body cavities, ease of depot size control, sustained local release of cargos, and a reduced toxicity. Studies are currently being performed to better understand the interactions between the immune system and the injectable macroscale biomaterials to further improve the physicochemical properties, such as chemical composition, network density, porosity and stiffness, and degradation products, of those materials for cancer immunotherapy.

There are several key challenges to be addressed in the future application of this category of biomaterials for cancer immunotherapy in the clinic. First, intra-/peritumoral injection of the biomaterials to deep tumors is challenging, though imaging-guided injection techniques may provide solutions to this issue. Second, on-demand release of immune modulators/cells is highly desired for the exquisite manipulation of immune responses with improved spatiotemporal resolution. The injectable macroscale biomaterials developed to date have mainly depended on the passive release of the cargo via either diffusion- or degradation-dependent mechanisms. Controlled cargo release in response to intrinsic stimuli in the tumor microenvironment, such as low pH and matrix metalloproteinases, or extrinsic stimuli, such as light, magnetic fields, heat, and ultrasound, will be important for intelligent injectable biomaterials. Third, little is known about the *in vivo* expansion, migration, and functional status of encapsulated immune cells inside injectable macroscale biomaterials, which greatly hampers the application of these biomaterials in immune cell delivery. Finally, good biocompatibility is a prerequisite. Until now, few injectable biomaterials have been tested in the clinic for drug delivery applications (we performed a search in ClinicalTrials.gov). One example is a controlled release formulation of paclitaxel in a PEG-PLGA-based injectable thermosensitive hydrogel (OncoGel™), which has entered Phase II clinical trial for the treatment of recurrent glioma.¹³⁵ Polysaccharides (hyaluronic acid, alginate, chitosan, etc.), collagen, poly(ethylene oxide)-poly(propylene oxide) (PEO-PPO), and PEG-PLGA block copolymers so far constitute the majority of injectable macroscale biomaterials used in the clinic likely due to their excellent biocompatibility and biodegradability. Collaborations among bioengineers, immunologists, and cancer biologists will potentially address these issues and further advance the development of biomaterial-assisted cancer immunotherapy. We foresee that injectable macroscale biomaterials with sophisticated designs could provide a unique platform for the further development of local cancer immunotherapy, especially for combination therapies through the co-delivery of therapeutics with a synergistic effect.

Table 1. Representative examples of recent advances in injectable macroscale biomaterials for cancer immunotherapy delivery (From 2014 to 2018)

Biomaterial type	Composition	Cargo	Gelation Factor	Tumor Model	Ref.
1. Immunomodulator Delivery					
Supramolecular hydrogel	K ₂ (SL) ₆ K ₂ peptide	Synthetic STING agonist	Formation of β -sheet nanofiber	C57BL/6 mice with MOC2-E6E7 tumor	59
Supramolecular hydrogel	CpG-containing hexapod-like DNA	CpG	Formation of DNA double helix	C57BL/6J mice with EG7-OVA tumor	61
Supramolecular hydrogel	Alginate/Ca ²⁺	anti-PD-1/ celecoxib	Electrostatic interaction	C57BL/6 mice with B16F10 tumor or 4T1 lung metastases	136
Thermosensitive hydrogel	P(Me-D-1MT)-PEG-P(Me-D-1MT) triblock copolymer	anti-PD-L1	Micelle stacking via hydrophobic interaction	C57BL/6 mice with B16F10 tumor	67
Thermosensitive hydrogel	PMNT-PEG-PMNT and PAAc	IL-12	Micelle stacking through hydrophobic and electrostatic interaction	Balb/c mice with C26 tumor	68
Chemically crosslinked injectable hydrogel	PVA and TSPBA	anti-PD-L1/ gemcitabine	Covalent bond formation between diol and boronic acid	C57BL/6 mice with B16F10 or 4T1 tumor	72
Injectable cryogel	Methacrylated gelatin	GM-CSF	Polymerization of acylate groups	\	73
2. Immune cell delivery					
Chemically crosslinked injectable hydrogel	HP-modified gelatin/H ₂ O ₂ /HRP	DC- and oAd-expressing IL-12 and GM-CSF	Enzymatic coupling of phenolic groups	C57BL/6 mice with LLC	88
Chemically crosslinked injectable hydrogel	PEGdA/Gel-PEG-Cys	M1 macrophage	Michael addition between acrylate group and sulfide	BALB/c nu/nu mice with MHCC97L xenograft	87
Thermosensitive hydrogel	Chitosan/NaHCO ₃ /phosphate buffer	TIL or activated T cells	Hydrophobic and electrostatic interactions	\	96
3. Cancer vaccine delivery					
Supramolecular hydrogel	Fmoc-KCRGDK peptide	JQ1- and ICG-loaded 4T1 tumor cells	Formation of self-assembled nanofiber	BALB/c mice with 4T1 or EMT6 tumor xenograft	115
Supramolecular hydrogel	Nap-modified D-tetrapeptide	OVA or X-ray-treated EG7 tumor	Formation of β -sheet nanofiber	C57BL/6J mice with B16-OVA or EG7 tumor	109

		cell			
Supramolecular hydrogel	PEG-poly(L-valine) copolymer	TCL and poly(I:C)	Physical aggregation of nanoassemblies via β -sheet and α -helix formations	C57BL/6 mice with B16 tumor	117
Supramolecular hydrogel	CpG-containing hexapod-like DNA	ED-OVA or R ₈ FFRKSII NFEKL	Formation of DNA double helix	C57BL/6J mice with EG7-OVA tumor	108
Thermosensitive hydrogel	Chitosan/Methylcellulose/GPDH	OVA or TRP ₂₁₈₀₋₁₈₈ /Quil A	Hydrophobic and electrostatic interaction	C57BL/6J mice with B16-OVA or B16 tumor	126
Thermosensitive hydrogel	mPEG-PLGA diblock copolymer	DC-LV-OVA/GM-CSF/MPL	Micelle stacking through hydrophobic interaction	C57BL/6J mice with B16-OVA tumor	125
Injectable cryogel	Methacrylated-alginate	Irradiated DD cell/GM-CSF/CpG	Polymerization of acylate groups	BALB/cJ mice challenged by DD breast cancer	129
Injectable inorganic scaffold	PEI-coated mesoporous silica microrod	Peptide antigens/GM-CSF/CpG	Stacking of high-aspect-ratio microrods	C57BL/6 mice with E7-TC-1, B16F10 or CT26 tumor	133
Injectable inorganic scaffold	Mesoporous silica microrod	OVA/GM-CSF/CpG	Stacking of high-aspect-ratio microrods	C57BL/6J mice with EG7-OVA tumor	134

Abbreviations: \, not performed; Fmoc, fluorenylmethyloxycarbonyl; STING, stimulator of interferon genes; CDN, synthetic cyclic dinucleotide; CpG, unmethylated cytosine-phosphate-guanine oligodeoxynucleotides; anti-PD-1, anti-PD-1 antibody; DMSO, dimethyl sulfoxide; HSP70, heat shock protein 70; P(Me-D-1MT), poly(L-methionine-*co*-dextro-1-methyl tryptophan); anti-PD-L1, anti-PD-1 antibody; PEG, polyethylene glycol; PELG, poly- γ -ethyl-L-glutamate; DOX, doxorubicin; IL-2, interleukin-2; IFN- γ , interferon γ ; PMNT, poly[4-(2,2,6,6-tetramethylpiperidine-N-oxyl) aminomethylstyrene]; PAAc, poly(acrylic acid); IL-12, interleukin-12; PVA, poly(vinyl alcohol); TSPBA, *N*¹-(4-boronobenzyl)-*N*³-(4-boronophenyl)-*N*¹, *N*¹, *N*³, *N*³-tetramethylpropane-1, 3-diaminium; hIFN- α , human interferon α ; GM-CSF, granulocyte-macrophage colony-stimulating factor; ICG, indocyanine green; DC, dendritic cell; OVA, ovalbumin; TCL, tumor cell lysates; Nap, naphthylacetyl; NSAID, nonsteroidal anti-inflammatory drug; poly(I:C), polyinosinic:polycytidylic acid; GPDH, glycerol 2-phosphate disodium hydrate; ED-OVA, ethylenediamine-conjugated ovalbumin; PLGA-PEG-PLGA, poly(lactic-*co*-glycolic acid)-*b*-poly(ethylene glycol)-*b*-poly(lactic-*co*-glycolic acid); mPEG-PLGA, methoxy-poly(ethylene glycol)-*b*-poly(lactic-*co*-glycolic acid); DC-LV-OVA, DC-targeting lentivirus expressing ovalbumin; MPL, monophosphoryl lipid A; PEI, polyethyleneimine; HRP, horseradish peroxidase; HP, hydroxyphenyl propionic acid; oAd, oncolytic adenovirus; PEGdA, polyethylene glycol diacrylate; Gel-PEG-Cys, thiolated poly(ethylene glycol)-grafted gelatin; TIL, tumor infiltrated lymphocytes; OEGMA, oligo(ethylene glycol) methyl ether methacrylate; EGFR, epidermal growth factor receptor; CAR T, chimeric antigen receptor T cell.

Table 2. Representative features of different types of injectable macroscale biomaterials.

	Physically crosslinked injectable hydrogel	Chemically crosslinked injectable hydrogel	Injectable cryogel	Injectable inorganic scaffold
Size	1 mm ~	1 mm ~	1 mm ~ 10 mm	1 mm ~
Backbone	Polymer or self- assembled structure	Polymer chain	Polymer chain or self- assembled structure	Inorganic microrod
Crosslinking structure	Physical aggregate	Covalent linkage	Covalent linkage or physical aggregate	Physical stacking
Porous structure	No	No	Yes	Yes
Mechanical strength	Low	Moderate to high	High	Moderate

Figure 1. Schematic illustration of injectable biomaterials for the delivery of various cancer immunotherapies, including immunomodulators, cancer vaccines, and immune cells. Injectable biomaterials can be easily implanted into tissues via a simple injection and form a depot *in situ* for sustained and controlled therapeutic release. CpG, unmethylated cytosine-phosphate-guanine oligodeoxynucleotides; CDN, synthetic cyclic dinucleotide; IL-2, interleukin-2; GM-CSF, granulocyte-macrophage colony-stimulating factor; PD-1, programmed cell death protein 1; CTLA-4, cytotoxic T-lymphocyte-associated protein 4; DCs, dendritic cells; MPL, monophosphoryl lipid A.

Figure 2. (A) Structure of P(Me-D-1MT)-PEG-P(Me-D-1MT) and ROS-triggered polymeric hydrophobicity transition. (B) Schematic illustration of localized hydrogel formation and bio-stimuli-triggered drug release and synergistic immunotherapy. (C) Average tumor volumes ($n = 5$), and (D) survival curves ($n = 5$) after a single treatment with various therapeutics (G1, PBS; G2, blank P[Me-D-1MT]-PEG-P[Me-D-1MT] hydrogel; G3, free D-1MT; and aPD-L1; G4, aPD-L1-loaded P[Me-D-1MT]-PEG-P[Me-D-1MT]) when the tumor volumes reached $\sim 110 \text{ mm}^3$ on the seventh day (marked by red arrow). PEG, poly(ethylene glycol); D-1MT, dextro-1-methyl tryptophan; Me, L-methionine; P(Me-D-1MT), poly(L-methionine-co-dextro-1-methyl tryptophan); ROS, reactive oxygen species; DC, dendritic cell; aPD-L1, programmed death-ligand 1 antibody; IDO, indoleamine-pyrrole 2,3-dioxygenase; Treg, regulatory T cell. Adapted from ref. 67 with permission from Wiley-VCH.

Figure 3. (A) Schematic of combination chemoimmunotherapy using a ROS-degradable hydrogel scaffold to deliver GEM and aPD1 into the TME. (B and C) Local gel scaffold for inhibiting B16F10 melanoma growth *in vivo*. (B) Average tumor growth kinetics in control and treated groups (treatment started at day 0). Growth curves represent mean $\pm$ SEM; growth curves were stopped when the first animal of the corresponding group died. (C) Survival curves for the treated and control mice ($n = 7$ to 10). ROS, reactive oxygen species; PVA, poly(vinyl alcohol); TSPBA, *N*1-(4-boronobenzyl)-*N*3-(4-boronophenyl)-*N*1,*N*1,*N*3,*N*3-tetramethylpropane-1,3-diaminium; aPD1, programmed death-ligand 1 antibody; GEM, gemcitabine; ICB, immune-checkpoint blockade; UnTx, untreated. Adapted from ref. 72 with permission from American Association for the Advancement of Science.

Figure 4. (A) Method of cell encapsulation and culture into chitosan-based biocompatible thermogels (CTGels). (B) Logarithmic scale of average cell numbers obtained at different time points from the supernatant and from CTGels 1 or 2. The storage modulus of CTGels 1 and 2 were ~2.4 kPa and 3.5 kPa, respectively. (C) Graph of average percent of CD3⁺ cells that are also CD8⁺ or CD4⁺ was determined from cells collected from the media or those extracted from CTGel2 over a 15-day time course. Adapted from ref. 96 with permission from Elsevier.

Figure 5. (A) Chemical structure of short peptide-based hydrogelators. The hydrogels could be converted to viscous solutions by shaking or vortexing, allowing the incorporation of antigens by simple mixing. (B and C) D-gel enhances the immunogenicity and therapeutic efficacy of X-ray-treated whole-cell vaccines. (B) Tumor growth in C57BL/6J mice ($n = 6$ per group) vaccinated with PBS, XTC, L-gel, D-gel, L-gel-XTC, or D-gel-XTC, and then challenged with EG7 tumor cells. Mice were vaccinated and inoculated as described above, and the tumor volume was monitored every three days. (C) The survival time of mice vaccinated with PBS, XTC, L-gel, D-gel, L-gel-XTC, or D-gel-XTC, respectively ($n = 6$ per group). Day 0 on the survival curves represents the day of tumor challenge. Nap, naphthylacetic acid; G, L-glycine; F, L-phenylalanine; Y, L-tyrosine; G^D, D-glycine; F^D, D-phenylalanine; XTC, X-ray-treated whole tumor cell; L-gel, hydrogel self-assembled from Nap-GFFY; D-gel, hydrogel self-assembled from Nap-G^DF^DF^DY. Adapted from ref. 109 with permission from Wiley-VCH.

Figure 6. (A) A schematic representation of the *in vivo* spontaneous assembly of MSRs and the recruitment of host cells for maturation. (B) Prophylactic cancer vaccine study using injectable MSRs. EG7-OVA tumor volume after the subcutaneous injection of various vaccine formulations ten days before tumor inoculation ($n = 10$). In (B), the tumor volumes were compared on days 21, 23, and 25 following the onset of tumor growth in the vaccine group. MSR, mesoporous silica microrod; OVA, ovalbumin. Adapted from ref. 134 with permission from Springer Nature.
