11 Abstract

12 The elastic strain energy release rate and seismic waves emitted during earthquakes are

13 controlled by the on-fault temporal evolution of the shear stress during rupture propagation.

14 High velocity friction experiments highlighted that shear stress on the fault surface evolves

15 rapidly during seismic slip pulses. This temporal evolution of shear stress is controlled by both

16 fault weakening at seismic slip initiation and re-strengthening rate towards the end of slip.

17 While numerous studies focused on fault weakening, less attention was given to co-seismic re-

18 strengthening processes. Here we performed 53 friction experiments (normal stress $\leq$30 MPa,

19 slip-rate $\leq$6.5 m s^{-1}) imposing constant slip acceleration and deceleration (7.8 m s^{-2}), on

20 cohesive Carrara marble (99% calcite) and micro-gabbro (silicate-built rock) under dry, vacuum

21 and water pressurized conditions. Microstructural observations showed that micro-gabbro

22 accommodated seismic slip by bulk melting of the sliding surfaces, whereas Carrara marble by

23 coupled decarbonation and grain-size dependent crystal plastic processes. Under room humidity

24 conditions and low imposed power density (i.e., product of normal stress per slip rate), re-

25 strengthening rate during the deceleration stage was up to ~ 17 times faster in marble than in

26 micrograbbro. In the latter, the re-strengthening rate increased slightly with the power density.

27 The presence of water enhanced further this trend. On the contrary, in marbles the re-

28 strengthening rate decreased drastically with power density and in the presence of water. Our

29 experimental observations highlighted the first order importance of the mineralogy and

30 rheology of the slip zone materials and, to a second order, of the presence of water in controlling

31 co-seismic re-strengthening of faults during seismic slip deceleration.

32

33 Keywords: Earthquake, Friction, Re-strengthening, Ground motions, Water effect.

34

35   1) <u>Introduction:</u>

36   Earthquakes are the result of sudden slip along faults, which releases the elastic strain

37 and gravitational energy stored in the wall rocks [Reid, 1910; Scholz, 2002]. Damage associated

38 with earthquakes is due to the radiation of elastic waves during seismic rupture propagation

39 [Stein and Wysession, 2009, Marty et al., 2019] and to dynamic stress concentration at the

40 rupture front [e.g., Andrews, 2005]. The intensity and the frequency of seismic waves (ground

41 motions) are controlled by the rupture length and by the abrupt variations in rupture and slip

42 velocities along fault during earthquakes [Brune, 1970; Madariaga, 1976]. Seismic rupture (~

43 km/s) and slip velocities (~ m/s) depend in particular on the temporal evolution of the shear

44 stress along the fault during sliding (i.e., fault strength weakening and re-strengthening) [Ida,

45 1972; Ruina, 1983]. Friction experiments, performed with rotary shear machines designed to

46 impose on rock specimens slip and slip rates typical of natural earthquakes, proved that

47 experimental faults weakened due to several rock-type and environmental-dependent thermally

48 activated weakening mechanisms, including melt lubrication, grain-size dependent processes,

49 thermal and thermomechanical pressurization of pore fluids, etc. [Tsutsumi and Shimamoto,

50 1997; Di Toro et al., 2004; Han et al., 2010; Rice, 2006; Ferri et al., 2010; Di Toro 2011; Green

et al., 2015; De Paola et al., 2015; Spagnuolo et al., 2015; Violay et al., 2015]. Field studies of exhumed natural seismogenic faults support the evidence of rapid weakening and fault lubrication during earthquakes [Sibson, 1975; Di Toro et al., 2006]. The rheology of the fault is related to the physical state (e.g., liquid vs. solid) of the slipping zone [Rice, 2006], the slip rate and slip acceleration [Di Toro et al., 2004; Niemeijer et al., 2011; Chang et al., 2012], the rock composition [Di Toro et al., 2011; Goldsby and Tullis, 2011; Green et al., 2015], the presence of water [Violay et al., 2013; 2014], the ambient and local temperature [Lockner et al., 1986, Verberne et al., 2015], and in presence of non-cohesive rocks, on the gouge grain size [De Paola et al., 2015]. Indeed, in cohesive rocks, slip is highly localized from the very initiation of sliding and the rise of the temperature in the slipping zone increases with slip rate, effective normal stress and square root of the duration of sliding [e.g., Rice, 2006, Aubry et al., 2018]. In cohesive rocks, the abrupt increase in temperature favors "flash" heating and weakening mechanisms [Goldsby and Tullis, 2011] which may eventually evolve, for some silicate-built cohesive rocks, in bulk melting [Hirose et al., 2005; Niemeijer et al., 2011; Violay et al., 2013; Aubry et al., 2018]. On the contrary, in the presence of gouges, some slip is required before strain localization is achieved [Beeler et al., 1996; Marone 1990; Smith et al., 2015; Rempe et al., 2017; Pozzi et al., 2018]. As a consequence, heat production is more distributed in the slipping zone and other processes including thermal (if fluids are already present in the pores of the slipping zone) and thermomechanical (if fluids like CO_2 and H_2O are released by the breakdown of the minerals of the slipping zone) pressurization might be favored before bulk melting of the slipping zone occurs [e.g., Rice, 2006; Segall and Rice, 2006; Brantut et al., 2008; Ferri et al., 2010; Acosta et al., 2018].

While the physical parameters controlling fault weakening have been extensively studied, little attention has been dedicated on the processes associated to frictional re-strengthening observed during slip deceleration in seismic velocity pulses [Del Gaudio et al.,

76 2009; Chang et al., 2012; Liao et al., 2015; Proctor et al., 2014; Sone and Shimamoto, 2009].

77 However, fault strength evolution, i.e both strength weakening and re-strengthening, coupled

78 with electrodynamic rupture propagation contributes actively to the slip rate evolution during

79 seismic faulting and to the release of seismic waves [Sone and Shimamoto, 2009]. In addition,

80 co-seismic re-strengthening processes controls the energy budget of earthquakes, as well as the

81 transition from crack-like to pulse-like rupture, which implies a strong fault re-strengthening

82 after the passage of the rupture front [Beeler and Tullis, 1998]. Few mechanisms of fault re-

83 strengthening have been proposed so far: (1) temporal variation of stress conditions on the

84 rupture interface during the passage of the rupture front (e.g., punctual pore fluid pressurization)

85 [Lykotrafitis et al., 2006], (2) spatial variation of the initial stress field (barrier model) [Peyrat

86 et al., 2001, Latour et al., 2011], (3) high dependence of friction to sliding velocity, i.e., "self-

87 healing" behavior during sliding velocity deceleration [Beeler and Tullis, 1998; Sone and

88 Shimamoto, 2009; Proctor et al., 2014; Perrin et al., 1995; Zheng and Rice, 1998]. Here, we

89 present friction experiments that, by reproducing seismic slip conditions, aim at understanding

90 the effect of rock composition and water content on fault re-strengthening during slip

91 deceleration. In particular, we focused on cohesive rocks (calcitic marble and micrograbbro)

92 where strain is localized from slip initiation to the final re-strengthening stage and the

93 temperature evolution in the slipping zone is simpler than in case for non-cohesive rocks

94 (gouges). Moreover, the analysis of the data reported here exploit the achievement of the so-

95 called "steady-state" shear stress conditions in the experiments. This achievement requires slips

96 of several centimeters to tens of centimeters depending on the applied effective normal stress

97 [Di Toro et al., 2011]. Consequently, the results presented here should be valid for moderate to

98 large in magnitude earthquakes, though steady-state conditions might not ever be achieved in

99 nature [Liao et al., 2015]. The experimental evidences suggest that rock composition and

100   environmental conditions play a pivotal role in fault re-strengthening during seismic faulting,

101   with dramatic consequences in the radiation pattern of the emitted seismic waves.

102

103   2) <u>Methods</u>

104   We performed 53 high speed friction experiments on hollow cylinders (30/50 mm

105   internal/external diameter) of carbonate-built rock (Carrara marble, 99% calcite) and silicate-

106   bearing rock (micro-gabbro) (for sample preparation, see Nielsen et al., 2013). Carbonate-built

107   rocks and gabbros often host earthquakes sequences in nature, as attested by geological

108   evidence [Sibson, 1975]. The experiments were performed with SHIVA, a rotary shear machine

109   installed at the HP-HT INGV laboratories in Rome (see sup.mat.Table 1). SHIVA was equipped

110   with two brushless engines (max power 300 kW) and an air actuator (2000 kg amplified to 5000

111   kg thanks to a lever) in a rotary shear configuration to slid the two contacting hollow rock

112   cylinders under the desired conditions (Di Toro et al., 2010). Experiments were performed

113   either in the presence of pressurized liquid water, room humidity or under vacuum (10^{-4} mbar).

114   In the experiments with liquid water, SHIVA was equipped with a pressurizing system which

115   consisted of (1) a fluid pressure vessel (i.e., the samples were fully immersed in water), (2) a

116   membrane pump with a 30 cm^3 fluid capacity, (3) a pressure multiplier that imposes up to 15

117   MPa of fluid pressure (P_f), (4) a pressure regulator and, (5) valves and pipes [Violay et al.,

118   2013]. Normal stress (σ_n) and pore pressure (P_f) (drained conditions) were kept constant during

119   experiments to target values ranging between 10 and 40 MPa and 0 (nominally dry) and 15

120   MPa, respectively. To mimic the sliding velocity at a given point of the fault during propagation

121   and arrest of seismic slip, we imposed a trapezoidal slip velocity function by imposing constant

122   acceleration and deceleration (7.8 m s^{-2}) and target slip velocities ranging from 1 m s^{-1} to 6.5 m

123   s^{-1}. Total slip ranged from 0.83 m to 18.37 m.

124   Mechanical data (axial load, torque, axial displacement, and angular rotation) were

125   acquired at a frequency up to 25 kHz (for description of the installed instrumentation, their

126   calibration and acquisition rates, see Niemeijer et al., 2011). Normal stress, shear stress (τ) and

127   slip velocity (V) were computed from experimental measurements following Tsutsumi and

128   Shimamoto [1997] and Di Toro et al. [2010].

129

130   3) <u>Results</u>

131   In all the experiments, once the slip velocity function was applied, the apparatus and the

132   sample initially deformed elastically until the static friction coefficient μ_p ($\mu = \tau/\sigma_n^{eff}$ with

133    $\sigma_n^{eff} = \sigma_n - P_f$) was overcome and slip initiated (Fig. 1). Then, the friction coefficient decreased

134   exponentially with slip over a weakening distance D_w down to a so-called steady-state friction

135   coefficient μ_{ss}. Towards the end of the experiment, during slip velocity deceleration, the friction

136   coefficient recovered with time and slip to a final value μ_r at the offset of slip (Figs.1a-b). The

137   effects of rock composition and environmental conditions on fault weakening and μ_p, μ_{ss} and

138   D_w were discussed in Violay et al. [2013 and 2014]. As well as for initial fault weakening [Di

139   Toro et al., 2011], the recovery of the friction coefficient during the deceleration stage of the

140   velocity pulse is a function of the sliding velocity (Figs.1c-d) [Goldsby and Tullis, 2011;

141   Passelègue et al., 2014; Proctor et al., 2014]. The value of μ_r ranged from 0.08 to 0.63 for

142   Carrara marble and 0.11 to 0.37 for micro-gabbro, respectively, and independently of (1) the

143   environmental conditions, (2) the final slip and (3) of the initial power ($\sigma_n^{eff} V$) imposed on the

144   fault (Figs. 2 and 3). To investigate the physics of the re-strengthening processes, we computed,

145   for each experiment, the friction re-strengthening rate $\dot{\mu} = (\mu_r - \mu_{ss})/(t_r - t_{ss})$, where $(t_r - t_{ss})$ is the

146   deceleration duration from end of the steady-state to the end of slip (Figs. 1a-b). At constant

147   acceleration and deceleration rate, in the experiments conducted at low initial power density

148   (σ_n^{eff} V < 20 MW m^{-2}) and under both room humidity and vacuum conditions, the re-

149   strengthening rate was ~ 17 times faster in Carrara marble (from 2.00 to 3.68 s^{-1}) than in micro-

150   grabbro (from 0.02 to 0.16 s^{-1}) (Fig 4). In both rock types, re-strengthening rate was inital power

151   density-dependent and work density independent (i.e., slip independent) (Fig.4). In Carrara

152   marble, independently of the environmental conditions, the friction re-strengthening rate

153   decreased with increasing power density (Figs. 3-4). This trend was amplified in pressurized

154   water conditions, and at the largest power densities tested, re-strengthening rate became almost

155   negligible (Fig. 4a). The opposite behavior was observed in micro-gabbro. The re-strengthening

156   rate slightly increased with the power density, and this effect was amplified in presence of

157   pressurized water (Fig. 4b). Moreover, in Carrara marble the re-strengthening rate was about

158   two times (at low power density) slower in the presence of pressurized liquid water than under

159   room and vacuum conditions (Fig 4). Instead, in micro-gabbro, the frictional re-strengthening

160   rate was about three times faster in the presence of pressurized liquid water than under room

161   humidity and vacuum conditions (Fig 4). Therefore, pressurized liquid water had an opposite

162   effect on the frictional re-strengthening rate of Carrara marble with respect to the one of micro-

163   gabbro.

164   Regarding the microstructures, mineralogy and geochemistry of the slipping zones and

165   slip surfaces recovered after the experiments, we refer to previous studies performed (1) on

166   several samples from the experiments presented here [Violay et al., 2013; 2014] and (2) on

167   slipping zone produced in experiments conducted on similar rocks (e.g., gabbro, basalts and

168   Carrara marbles) under very similar deformation conditions [Han et al., 2010; Di Toro et al.,

169   2011]. In the case of micro-gabbro, the slipping zone consisted of a continuous ca. 200 μm thick

170   layer of a quenched melt (see composition in Table 2), independently of the presence or absence

171   of liquid water (Fig. 5a) [Violay et al., 2014; 2015; Nielsen et al., 2008; 2010; Niemeijer et al.,

172   2011; Giacomel et al., 2018]. In the case of the Carrara marble, the slipping zone after

173 experiments conducted under vacuum and room humidity consisted of a 50 to 100 μm thick

174 layer of nano- to micro-grained, poorly cohesive material made of calcite and, to a minor extent,

175 lime (Violay et al., 2013; Spagnuolo et al., 2015) (Fig. 5b). Unfortunately, due to the poorly

176 cohesive nature of the nano- to micro-grained deformed layer, most of the slipping zone was

177 flushed away during sample recovery in the experiments performed in the presence of liquid

178 water. However, the few micro-fault patches recovered from the slip surface showed the

179 presence of nano- to micro-grained slipping zones [Violay et al., 2013; 2015] and evidence of

180 calcite decabonatation attested by the presence of vacuoles within the grains. Violay et al.,

181 [2013] also showed evidence of CO_2 increase in the fluids recovered after high-speed friction

182 experiments performed on carbonate bearing rocks. We infer that also in the case of the

183 experiments performed with Carrara marble, the slipping had the same microstructure

184 independently of the presence or absence of liquid water.

185

186   4) <u>Discussion</u>

187 *4.1) Effect of water on friction re-strengthening rate*

188   The different effect of the presence of pressurized liquid water on the frictional re-

189 strengthening rate of micro-gabbro and Carrara marble suggested that different micro-physical

190 processes operated during the deceleration phase of the slip pulse, as clearly supported by

191 microstructural evidence (Fig. 5). It is well-known that fault surfaces of micro-gabbro melt with

192 seismic slip under room humidity and vacuum conditions [Tsutsumi and Shimamoto, 1997;

193 Hirose and Shimamoto, 2005; Nielsen et al., 2008; Niemeijer et al., 2011], but also in the

194 presence of liquid water [Violay 2014a; 2014b]. On the contrary, slipping zones of Carrara

195 marble did not record microstructural evidence of frictional melting. Instead, the slipping zones

196 were made of sub-micrometer to nanometer in size grains [Spagnuolo et al., 2015]. These

197 microstructures can be associated to grain-size dependent crystal plastic processes [Green et al.,

2015; De Paola et al., 2015; Spagnuolo et al., 2015]. Similarly to what occurred during the initial weakening stage, was the rheology of the materials building the slipping zone that controlled the final frictional re-strengthening. In our experiments, the rheology of the slipping zone depended on the physical state of the sheared materials (melt vs. nano-grains), on the slip and strain rate, on the normal stress, as well as on the environmental conditions and, for Carrara marble, on grain size.

In the case of micro-gabbro, the viscosity and thickness of the melt layer and its extrusion rate from the slipping zone controlled the viscous strength of the experimental fault [Nielsen et al., 2008]. Violay et al., [2014a] showed that the initial fault weakening by frictional melts was delayed by the presence of liquid water that cools the asperity contacts. Here, we hypothesize that frictional re-strengthening might be enhanced by an increase of the viscous strength of the melt layer due to water-cooling. To test this hypothesis, we implemented a Finite Element Methods numerical model which included the rock specimens and the steel-made pressure vessel (Fig. 6 a, b, c). The slipping zone was modeled as a 200 µm-thick layer (red in color in Fig. 6, a), consistently with the typical thickness of the solidified melt layers recovered at the end of the experiments [Nielsen et al., 2008], made by melt plus water or melt plus air with a constant volume ratio (ϕ) ranging from 0.5 to 0.9 in agreement with microstructural observations [Brown and Fialko, 2002, Violay et al., 2014a; 2014b] (Fig. 5). The melt temperature during slip deceleration was computed using the mechanical data of the samples sheared under vacuum conditions as a reference. In fact, under vacuum conditions, most of the frictional work was dissipated into heat (the contribution to wear and rock fragmentation was negligible, see Niemeijer et al., 2011) and very limited heat was lost by radiation. Consequently, the heat flux Q was a function of shear stress and slip rate that evolved with time t (Fig. 1) and varied along the sample radius r:

$$Q(r,t) = 0.5 \cdot \tau(t) \cdot V(r,t) \qquad (Eq.1).$$

223   For experiments performed under room humidity conditions and in the presence of water, we

224   imposed that the melt layer was cooled by air or water (2D heat diffusion model), respectively.

225   Then, as representative of the entire slipping zone, we used the estimated temperature achieved

226   by the friction melt at 2/3 of the sample radius. The properties of the slipping zone (indicated

227   by the subscript $_{eff}$ for effective) were considered as a linear combination of the thermal

228   properties of the fluid (air or water) and those of the melt (Table 1). Therefore, the "effective"

229   thermal diffusivity in the slip zone was:

230    $$\alpha_{eff} = K_{eff} / (\rho\, C)_{eff} \qquad (Eq.2)$$

231   where

232    $$K_{eff} = (1 - \phi)\, K_R + \phi\, K_f \qquad (Eq.3)$$

233   and

234    $$(\rho\, C)_{eff} = (1 - \phi)\, \rho_R\, C_R + \phi\, \rho_f\, C_f \qquad (Eq.4)$$

235   with K, the thermal conductivity (W m^{-1} K^{-1}), C the specific heat capacity (J kg^{-1} K^{-1}), ρ the

236   density (kg m^{-3}) and ϕ the liquid fraction in the melt. Index R and f are related to the rock and

237   fluid properties, respectively. Then, the heat diffusion is:

238    $$\rho . C_{eff} . \frac{\partial T}{\partial t} = \nabla . \left(k_{eff,i} . T \right) \qquad (Eq.5)$$

239   where i represents the two different materials (water/air and rock) in the model of Fig. 6. Values

240   of thermal conductivity, specific heat capacity and density are reported in Table 1. The melt

241   viscosity (η) was computed with the viscosity simulator for silicate melts of Giordano et al.,

242   [2008] (we did not take into account the crystal fraction in the melt). The model predicts the

243   non-Arrhenius temperature dependence of viscosity for naturally-occurring silicate melts at

244   atmospheric pressure:

245    $$log(\eta) = A + \frac{B}{T(K) - C} \qquad (Eq.6)$$

246 where *A* is a constant independent of composition and *B* and *C* are adjustable parameters

247 depending on melt composition. The glass chemical composition was published by Violay et

248 al., [2014, sup mat item 4] and reported in Table 2. Numerical modelling results highlighted

249 that the melt viscosity, because of cooling of the melt, increases with decreasing sliding velocity

250 (Fig. 6), in agreement with the logarithmic increase of the "friction coefficient" during the

251 deceleration stage (Figs. 1 and 3). In addition, the increase of melt viscosity during slip

252 deceleration was significantly faster in experiments performed in the presence of pressurized

253 water than under room humidity conditions, suggesting that water-cooling was an efficient

254 mechanism of re-strengthening. Moreover, the efficiency of water-cooling was proportional to

255 the fluid-to-melt ratio in the slipping zone, and therefore of the temperature of the melt before

256 deceleration. Indeed, higher was the melt temperature at the steady-state, which was slightly

257 proportional to the imposed power density, faster was the increase of melt viscosity during slip

258 deceleration. Instead, given the same conditions, the observation that the re-strengthening rate

259 was independent of slip (Figs. 4d) was related to the large shortening rate of the rock specimens

260 during frictional melting (mm per meters of slip, Violay et al., 2014). At steady-state conditions,

261 the isotherms were almost fixed in space while the rock specimen passes through them and got

262 melted and extruded (see discussion in Nielsen et al., 2008). As a consequence, once steady-

263 state had been achieved (always the case for the experiments presented here), during

264 deceleration and melt cooling, the wall rocks were at similar temperatures independently of the

265 cumulated slip and the re-strengthening is independent of slip.

266   In the case of Carrara marble, the slower re-strengthening rate in the presence of water

267 than under room humidity conditions (Fig. 4a) cannot be explained by water cooling of the

268 slipping zone or by thermal fluid depressurization (i.e., fluid pressure decrease after a short

269 period of expansion caused by frictional heating). Indeed, neither melt was produced nor

270 pressurization was observed during these experiments where fluid pressure was kept constant

271 under drained conditions [Violay et al., 2015]. Moreover, both melt lubrication and thermal

272 pressurization would lead to a faster re-strengthening in presence of water than under room

273 humidity conditions. However, this is at odds with the experimental evidence: re-strengthening

274 rate is faster under vacuum conditions (Fig4). Note also that calcite decarbonation as potential

275 re-strengthening mechanism can be ruled out in our experiments. This mechanism would led to

276 faster re-strengthening at high power density (i.e., higher temperature), which it is just the

277 opposite of our experimental evidence.

278 We suggest that the slower recovery of the frictional strength in the presence of liquid water

279 during slip deceleration can be due to the strain rate sensitive, grain size dependent crystal

280 plasticity of calcite in the presence of water (e.g.. grain boundary sliding aided by diffusion

281 creep) [Rutter, 1974, Schmidt et al., 1980, 1987, Walker et al., 1990, Renner et al., 2002].

282 Decarbonation reaction can propably help this mechanism because it triggers the formation of

283 nanoparticles allowing the activation of grain size depend processes. Despite relevant

284 differences between our experimental protocol and those reported in the above-mentioned

285 studies (high pressure - high temperature triaxial tests performed at very low strain rates, 10^{-6}-

286 $10^{-4}\,s^{-1}$, compared to those achieved in our experiments, 10^2-$10^4\,s^{-1}$), a comparison with those

287 studies may help to understand better the mechanisms accommodating deformation in our

288 experiments. At high temperature ($> 400°C$), calcite strength is temperature and strain rate

289 dependent [Rutter, 1971, 1974], and governed by crystal-plastic and grain size-dependent

290 deformation mechanisms (intracrystalline plasticity and grain boundary sliding diffusion-

291 assisted plasticity). Similar deformation mechanisms were inferred to be operating at sub-

292 seismic and seismic slip rates in calcite [Verberne et al., 2015; De Paola et al., 2015; Spagnuolo

293 et al 2015]. Rutter [1972] showed that calcite strength is inversely proportional to water content

294 due to the reduction of the surface energy at calcite grain boundaries [Boozer et al., 1962] and

295 its strain rate sensitive behavior decreased with increasing water content. Rutter [1974] had also

296 shown that water effect is relatively small in Carrara marble. If crystal-plastic and grain-size

297 dependent processes were triggered during high velocity friction experiments, they would

298 therefore result in a negative dependence of strain-rate on residual flow stress, and may explain

299 the inhibition of the frictional re-strengthening in Carrara marbles especially at large power

300 densities. In fact, for larger power densities, higher temperatures should be achieved in both the

301 slipping zone and wall rocks. This should be the case especially once the so-called steady-

302 steady conditions were achieved (note that, because of the power-law decay in Carrara marble,

303 "steady-state" conditions remain an approximation, see Nielsen et al., 2016). In fact, because

304 of the absence or negligible shortening of the marble specimens, contrary to what happens in

305 micro-gabbro, heat diffused in the wall rocks. Hotter wall rocks and the different deformation

306 mechanism involved would result in slower cooling of the slipping zone, especially if compared

307 to the frictional melting case (compare Fig. 4a with 4b). In the presence of water, the efficiency

308 of grain size dependent and diffusion-controlled processes should be enhanced due to lower

309 activation energy in presence of water, explaining the lower re-strengthening rate. However,

310 the slipping zone was flushed away at the end of slip preventing sample recovery for micro-

311 analytical investigations [Violay et al., 2013, 2014]. To test this hypothesis, we performed a

312 one dimension-time dependent diffusion temperature model fully coupled with grain-size

313 diffusion creep flow law (Fig.7). Calcite thermal properties are reported on Table 1. The

314 slipping zone was modeled by a 100 μm- layer composed of 100 nm grain size calcite, in

315 agreement with microstructural observations [Violay et al., 2013, 2015] (Fig.5). The heat flux

316 and diffusion were computed following Eq.1 and 5. The predicted flow stress for diffusion

317 creep plasticity can be modelled by the constitutive flow law (Eq. 8, 9).

318
$$\frac{\partial T}{\partial t} = \frac{1}{2}\tau(t)V(t) + \frac{k}{C_p\rho}\frac{\partial^2 T}{\partial x^2} \quad \text{(eq.7)}$$

319
$$\tau(t) = \left(\frac{\dot{\gamma}}{\left(A \cdot D^{-b} e^{-\frac{H}{RT(t)}}\right)}\right)^{\frac{1}{n}} \quad \text{(eq.8)}$$

320
$$\dot{\gamma} = \frac{1}{l}\frac{\partial V}{\partial t} \quad (eq.9)$$

321 where $\dot{\gamma}$ is the shear strain rate, A the pre-exponential factor, H the apparent activation energy

322 for creep, R the gas constant, T the temperature, τ the shear stress at time step (t), n the stress

323 exponent, D the grain size with b the grain size exponent, l is the layer thickness, and V (t) is

324 the slip velocity function.

325 Following [De Paola et al., 2015], under room-humidity conditions, b= 2, n=1, H=217 kJ mol^{-}

326 ^{1}, A=9.55 *10^5 (s^{-1}. Bar^{-n})., R=8.314 J.K.mol^{-1}. In presence of water, we supposed a reduction

327 of the activation energy (H) of about 20% , with H=176 Kj kJ mol^{-1} (see discussion in Rutter

328 1972). Flow stress estimates based on Eqs.7,8,9 (Fig.7) showed that grain boundary sliding

329 aided by diffusion mechanism can explained both the strength weakening at the beginning of

330 the experiments, the steady state friction and the final re-strengthening. Moreover, a decrease

331 of the activation energy of only 20% under pore fluid conditions [Rutter, 1972] may justify the

332 faster re-strengthening observed under dry rather than under pore fluid conditions (Fig. 1c).

333

334 *4.2) Implications for natural earthquakes*

335 Our experiments demonstrated that the slip deceleration can result in rapid fault re-

336 strengthening, up to 10 to 90% of the initial peak stress, depending on the rheology of the

337 material building the slip zone which depends on lithology and environmental conditions (Fig.

338 1). Because the friction coefficient is strongly velocity-dependent [Sone and Shimamoto, 2009],

339 the magnitude of the re-strengthening depends mainly on the imposed deceleration rate [Del

340 Gaudio et al., 2009]. The extrapolation of these results to natural earthquakes can be gained by

341 (1) comparing the friction re-strengthening rate between experiments performed with different

342 rock types and under environmental conditions, and (2) using the dependency of the re-

343 strengthening rate with the power density.

344   Here below, we estimate the slip-velocity, acceleration and power density of natural

345   earthquakes and compare them to the imposed parameters during our experiments. Slip-

346   velocity functions during earthquake rupture propagation are obtained by inverting ground

347   motion waveforms. Slip acceleration and deceleration during earthquakes are ~1-10 m s^{-2} (and

348   larger, Tinti et al., 2005) and slip rates, on average, ~ 1 m s^{-1} [Heaton, 1990]. Therefore,

349   acceleration, deceleration as well as slip-velocity imposed in our experiments are somehow

350   comparable to those of natural earthquakes. The main differences between tests and

351   earthquakes are in the shape of the velocity function (trapezoidal in our case) and on the

352   normal stress imposed. Indeed, crustal earthquakes nucleate between 5 and 15 km depth,

353   possibly at effective normal stresses of ~100-200 MPa [Zoback and Harjes, 1997], and at

354   power densities perhaps up to ten times higher than those imposed in the experiments

355   discussed here. Extrapolation of our results to realistic stresses conditions suggest that in

356   cohesive carbonate-bearing rocks, frictional re-strengthening during slip-velocity deceleration

357   is probably almost negligible whereas in cohesive silicate bearing-rocks, re-strengthening

358   processes are highly deceleration-dependent, especially in the presence of water.

359   Indeed, our results demonstrate that, due to the large expected power densities during

360   natural earthquakes, small variations in the slip velocity could induce strong variations in

361   friction promoting further changes in the slip velocity history due to co-seismic re-

362   strengthening, especially in the case of calcite-built rocks. Moreover, the frequency content of

363   the radiated energy is affected by the abruptness of velocity changes (emission of higher

364   frequency waves is expected under abrupt decelerations) and thus, by the re-strengthening rate.

365   Based on our results, cohesive silicate-bearing faults that undergo to frictional melting, also in

366   the presence of liquid water [see natural case discussed by Brantut and Mitchell, 2018] will

367   have the largest re-strengthening rates at the highest power densities (5-15 km depth) and should

368   promote more intense high frequency radiation during slip deceleration. However, according to

369   Fig. 4, the re-strengthening rates in micro-gabbro are much smaller than those achieved in

370   calcitic-built cohesive rocks. In the latter rocks, if grain-size dependent processes are activated,

371   intense high frequency radiation should occur especially at low power densities (perhaps

372   corresponding to shallow depths, < 2 km) and dry conditions, when re-strengthening rates are

373   the highest (Fig. 4).

374

375   5) <u>Conclusions</u>

376   We performed a series of experiments simulating seismic slip under different

377   environmental conditions (vacuum, room humidity and pressurized water) on two common

378   cohesive crustal rocks (calcitic Carrara marble and micro-gabbro). In general, independently of

379   the environmental conditions, the fault re-strengthening rate at the end of slip is up to one order

380   of magnitude larger in Carrara marble than in micro-gabbro, especially at low power densities

381   (Fig. 4). This large difference in re-strengthening rates is due to the different on-fault

382   deformation processes operating during seismic slip: crystal plastic and grain-size dependent

383   for Carrara marble, melt lubrication for micro-gabbro. The two deformation mechanisms have

384   different constitutive equations and dependence with temperature. With increasing power

385   density, which may correspond to increasing crustal depths, the fault re-strengthening rate

386   becomes almost negligible for Carrara marble whereas it slightly increases for micro-gabbro.

387   We also found some intriguing second order differences in the magnitude of the re-

388   strengthening rate for the two rock types. These differences are due to the environmental

389   conditions which impact on the efficiency of the particular co-seismic deformation mechanism

390   of the rock. Under vacuum and room-humidity conditions, fault re-strengthening rate at the end

391   of simulated seismic slip in Carrara marble is significantly faster than in the presence of

392   pressurized water, especially at low power densities (Fig. 4). Instead, in micro-gabbro, fault re-

393 strengthening rate is faster in the presence of pressurized water than under room humidity and

394 vacuum conditions (Fig. 4). We interpreted these well-reproducible second order variations in

395 the re-strengthening rate as the consequence of the change in rate-dependent plasticity in the

396 presence of water for Carrara marble and water-cooling of the frictional interface for micro-

397 gabbro. Our results suggest that both rock composition and presence of water affect the elastic

398 strain energy release rate and the seismic waves radiation pattern during rupture propagation.

Figure 1. Evolution of the friction coefficient with time and slip rate for Carrara marble and micro-gabbro slid at seismic slip rates. (**a) and (b)** Evolution of the friction coefficient with time in Carrara marble and micro-gabbro. (**c) and (d)** Evolution of the friction coefficient measured during deceleration versus log of the sliding velocity. The experiments were conducted at target velocity $V_t = 3$ m s^{-1}, acceleration and deceleration = 7.8 m s^{-2}, and σ_n^{eff} = 20 MPa (effective normal stress = $\sigma_n - P_f$). Blue curves (S615 and S567): fluid pressure experiments σ_n = 25 MPa, P_f = 5 MPa; green curves (S307 and S555): room humidity experiments; red curves (S614 and S585): vacuum experiments were run at $P_{vacuum} = 10^{-4}$ mbar. Two examples of sliding velocity function are drawn in grey.
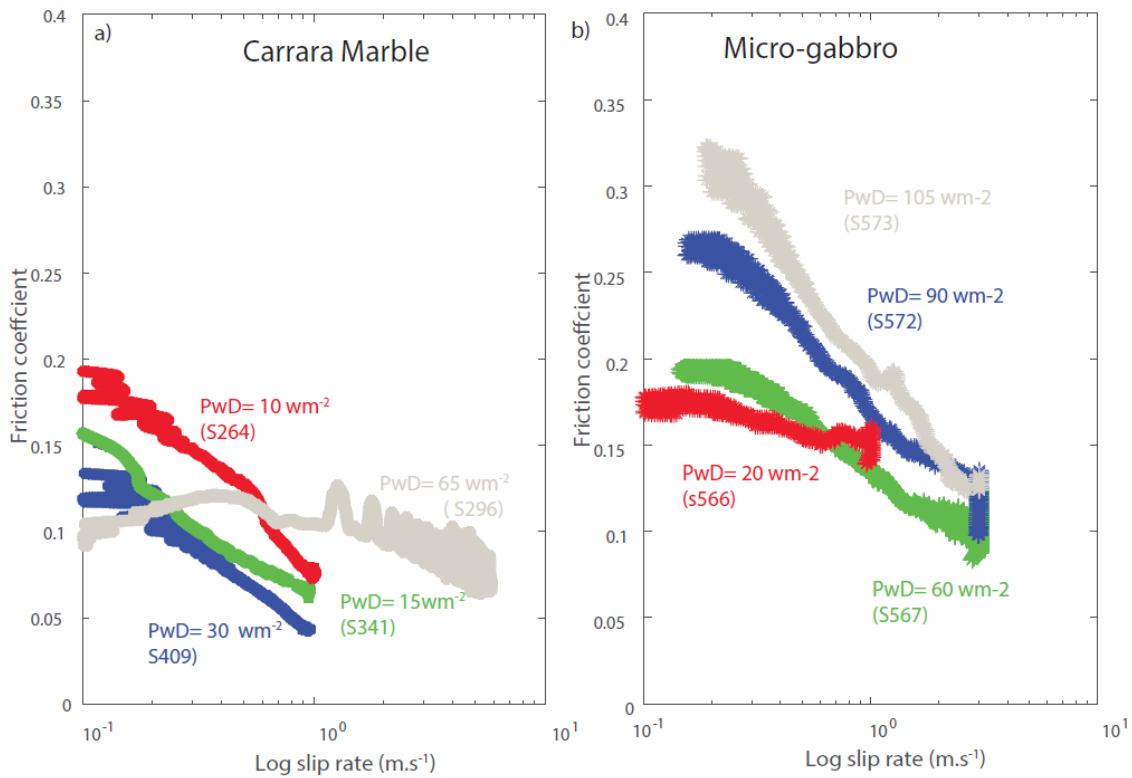

Figure 2. Influence of σ_n^{eff} on the re-strenghtening for **(a)** Carrara Marble and **(b)** micro-gabbro. Blue dots: fluid pressure experiments; green dots: room humidity experiments; red dots: vacuum experiments $P_{vacuum} = 10^{-4}$ mbar.
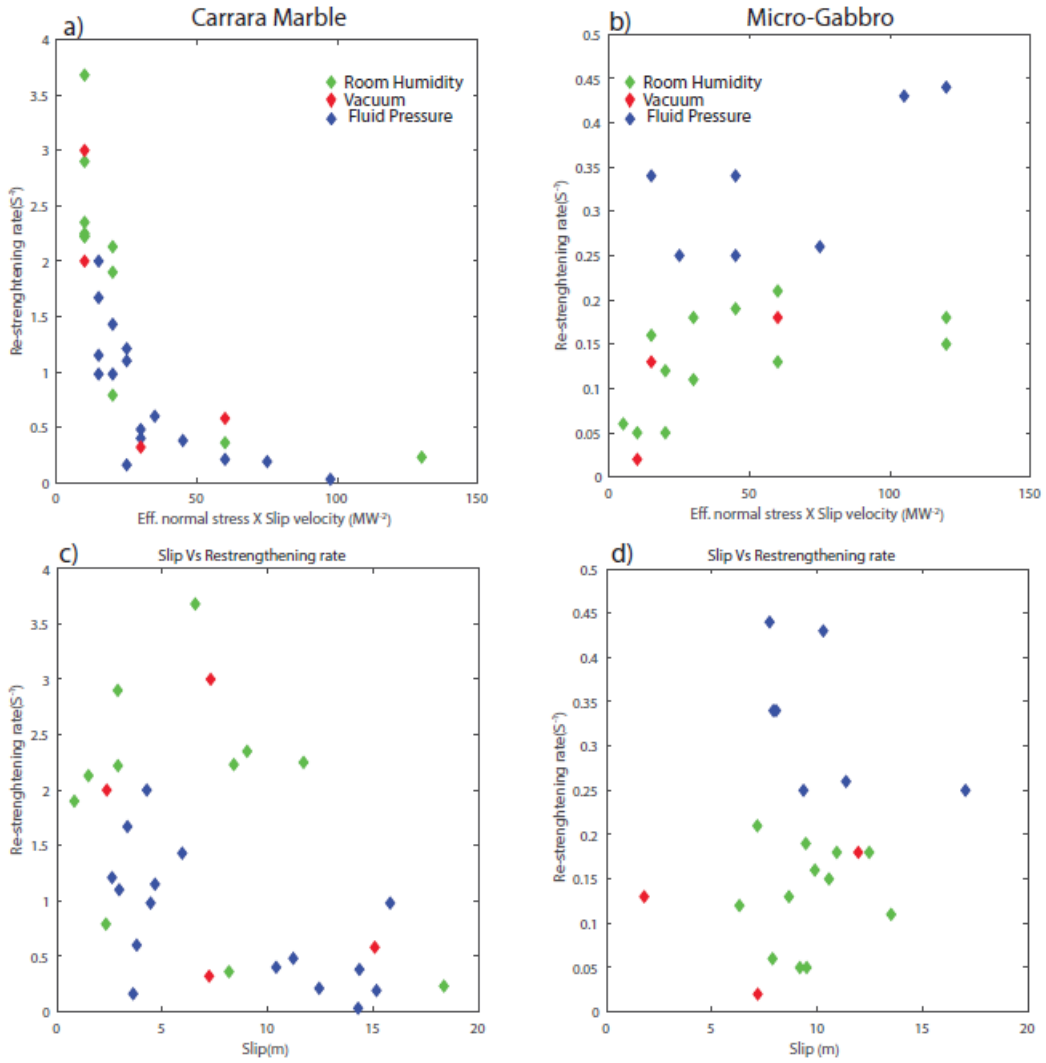

Figure 3. Evolution of the friction coefficient during slip deceleration versus log of the sliding velocity for **(a)** Carrara marble (S409, S341, S296, S264) and **(b)** micro-grabbro (S566, S567, S572 and S573). Experiments were conducted at different power density ($\sigma_n^{eff} \cdot Vt$). Target velocity (Vt) ranging from 1 and 6.5 m s^{-1}, acceleration and deceleration $= 7.8$ m s^{-2}, and σ_n^{eff} from 10 to 30 MPa (effective normal stress $= \sigma_n - P_f$). The experiments were all performed under fluid pressure conditions ($P_f = 5$ MPa).

601

Figure 4. Influence of power density **(a,b)** ($\sigma_n^{eff} \cdot Vt$) and slip **(c, d)** on the friction re-strengthening rate. Blue dots: fluid pressure experiments; green dots: room humidity experiments; red dots: vacuum experiments $P_{vacuum} = 10^{-4}$ mbar.

Figure 5. Microstructural observations of experimental slip surfaces and slipping zones after shearing. **(a)** Slipping zone after an experiment performed on micro-gabbro (s585, $V = 3$ m s^{-1}, $\sigma_n = 20$ MPa, Vacuum conditions see also Violay et al., 2014). The slipping zone is made by quenched melt (i.e., glass matrix, see composition in Table 2) which wraps grains of plagioclase and pyroxene that survived from frictional melting (Scanning Electron Microscope, back scatter electron image). **(b)** Slip surface after an experiment performed on calcitic Carrara marble (s614, $V = 3$ m s^{-1}, $\sigma_n = 20$ MPa, Vacuum conditions, see Violay et al., 2014). The slip surface is made by micro- to nano-grains of calcite and lime. Small decarbonation vacuoles decorate the recrystallized calcite grains (Scanning Electron Microscope, secondary electron image).

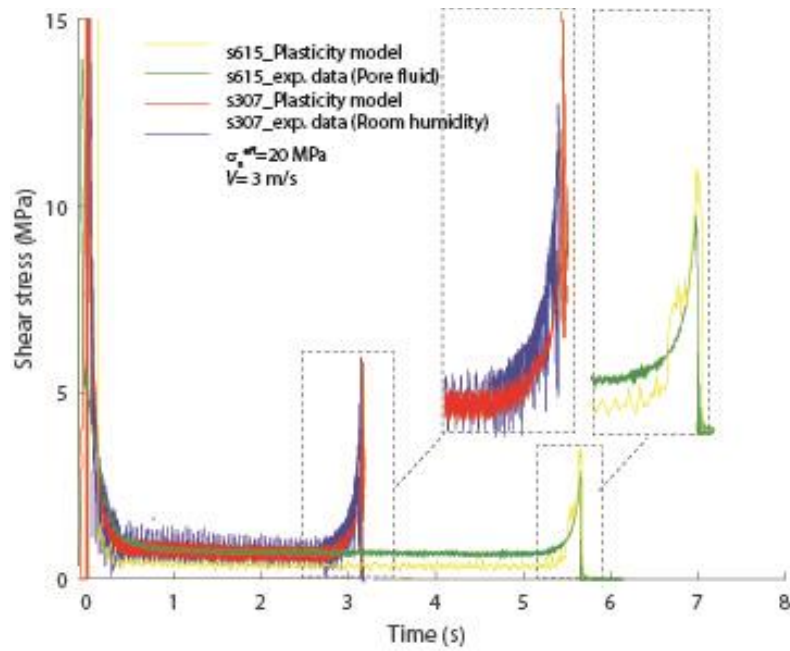

Figure 6. FEM 2D time dependent heat diffusion model. **(a,b)** Model geometry with description of the Boundary Conditions and mesh geometry. **(c)** The snapshot of the temperature distribution at the end of the experiment s585 conducted on gabbro. **(d)** Temperature evolution

621   of the slip zone during slip deceleration (t_r-t_{ss}). **(e)** Melt viscosity evolution during slip

622   deceleration.

626   **Figure 7.** Results of the 1D time dependent heat diffusion model fully coupled with diffusion

627   creep flow law for both room humidity (blue and red curves) and pore fluid (green and yellow

628   curves) conditions.

629

	Micro-Gabbro	Carrara Marble	Water	Air	Melt	Steel
K [10 ^-6 m2/s]	0.8	1.48	0.15	1.5	0.344	4.2
ρ [kg/m3]	2990	2700	1000	1.2	2591	2000
C [J/(kgK)]	949	700	4200	1000	1484	460

630   **Table 1.** Thermal properties of the fluid (air and water) and micro-gabbro used in the FEM

631   numerical model, as well as the thermal properties of Carrara marble used for the coupled

632 diffusion model and plasticity flow law. K = thermal conductivity, ρ = density, C = specific

633 heat. Φ the liquid fraction.

Sample	Micro-Gabbro	s585	
Phase	crystalline	glass	s.d.
#		7	
Al_2O_3	14.27	15.68	0.74
Na_2O	4.49	4.26	0.91
CaO	9.22	10.21	1.43
SiO_2	45.48	45.22	0.90
K_2O	2.71	2.71	0.57
MgO	7.15	6.88	0.57
P_2O_5	1.88	1.14	0.14
FeO	10.28	8.31	0.34
TiO_2	3.02	2.88	0.38
MnO	0.19	0.17	0.05
Total	98.69	97.46	

634 **Table 2.** Chemical composition of the micro-gabbro (XRD) and of the glass for experiment

635 S585 performed under vacuum conditions (Electron Microprobe Analysis). The analysis does

636 not close to about 100% because only Fe2+ was determined.
