*Although the road is never ending
take a step
and keep walking,
do not look fearfully into the distance...
On this path
let the heart be your guide
for the body is hesitant and full of fear*

– Rumi

Abstract

Mobility concerns most daily tasks (e.g., householding, shopping), affecting life quality. Gait speed, recognized as “*the sixth vital sign*”, is a key to characterize mobility. It is also a primary outcome of many clinical interventions. Monitoring gait in unsupervised free-living situations is crucial. It offers the possibility to assess purposeful gait (e.g., catching a bus) in contextual situations (e.g., socializing), multitasking conditions requiring attention, and where the activity is affected by environmental components (e.g., buildings, streets).

The Global Navigation Sattelite System (GNSS) measures real-world gait speed, but it suffers from high power consumption and is available only outdoors. Multiple Inertial Measurement Units (IMU, including accelerometer and gyroscope) worn on the body could be used to estimate speed accurately. However, it is challenging and cumbersome to wear them every day. Another alternative is to use a single IMU, where the wrist and the Lower Back (LB) are recognized as appropriate sensor locations for real-life conditions. The Wrist-mounted IMU could be integrated inside a watch, thus, increasing user satisfaction. The LB-worn IMU could capture robust gait patterns even for patients and could be used to extract gait parameters like asymmetry. The wrist-based algorithms are mostly validated in supervised situations. They significantly lose their performance in daily life. While many LB-based methods exist, they have not been fully compared to determine what algorithms and under what criteria (slow, normal, and fast walkers) lead to better performance.

This thesis primarily presents accurate wrist-worn IMU-based (with barometer) speed (including cadence and step length) estimation and gait bout detection algorithms using Machine Learning (ML). An online personalization was devised in which the GNSS was sporadically used to capture a few speed data of a person’s gait to tune the speed model gradually. Biomechanically-derived features were also extracted based on acceleration intensity, periodicity, noisiness, and wrist posture. The gait bout detection algorithm was validated against a multiple-IMU-based system for healthy people in unsupervised daily life. High sensitivity, specificity, accuracy were achieved (90, 97, 96 %). The personalized speed algorithm was also validated against GNSS for healthy subjects in real-world conditions, reaching an accuracy of 0.05 and 0.14 m/s for walking and running.

Furthermore, this thesis performs cross-validation on the LB-based algorithms to investigate the best algorithms for different speed ranges. Twenty-nine algorithms were organized in a conceptual framework, improved, and implemented. A novel combination technique was also proposed. The cross-validation against an instrumented mat and a multiple-IMU-based algorithm on both healthy and patient populations offered the combined approach as an accurate and robust solution with an error of 0.10 m/s. Finally, this thesis demonstrates the feasibility of using the proposed wrist-based algorithms for long-duration monitoring of gait in a large cohort study (around 2800 subjects). Results showed that the gait speed significantly improves frailty and handgrip strength estimations.

Overall, the proposed algorithms are independent of sensor orientation, thus, easy-to-use. A single IMU offers a high battery life and comfort, perfect for long-duration outdoors/indoors monitoring.

Keywords: Gait analysis, walking, running, wearable system, inertial sensors, IMU, wrist, lower-back, real-world, speed estimation, gait bout detection, cadence, step length, validation, cohort study, unsupervised monitoring.

Résumé

La mobilité fait partie intégrante des tâches quotidiennes (p. ex., ménage, shopping), et a un impact direct sur la qualité de vie. La vitesse de marche, reconnue comme « le sixième signe vital », est un paramètre clé d'évaluation de la mobilité et des performances physiques des patients après des interventions cliniques. Ainsi, la mesure de la marche dans les situations du quotidien est importante, car elle permet d'évaluer la marche de manière ciblée (p. ex., attraper un autobus), dans différents contextes (p. ex., activités sociales), dans des situations multitâches nécessitant une attention particulière, et lorsque l'activité est affectée par l'environnement (p. ex., bâtiments, rues).

Les systèmes de navigation par satellites (GNSS en anglais) peuvent mesurer la vitesse de marche dans la vie quotidienne, mais ceux-ci souffrent d'une consommation d'énergie élevée et d'un signal uniquement disponible à l'extérieur. Les centrales inertielles (IMU, incluant accéléromètres et gyroscopes) portées sur différentes parties du corps permettent d'estimer la vitesse de marche avec précision. Cependant, il est difficile et encombrant de les porter tous les jours. Une alternative est donc de réduire la configuration à un seul capteur. Le poignet et le bas du dos (LowBack/LB en anglais) sont reconnus comme des emplacements appropriés pour les mesures au quotidien et de longue-durée. De plus, un IMU au niveau du poignet pourrait être intégré à l'intérieur d'une montre, augmentant ainsi la satisfaction des utilisateurs. L'IMU portée sur LB permet d'évaluer de manière plus robuste les caractéristiques de la marche, même pour les patients, et peut ainsi être utilisé pour extraire des paramètres additionnels tel que l'asymétrie. La majorité des algorithmes basés sur le poignet ont été validés dans des environnements contrôlés (en laboratoire, par exemple). Or, il s'avère que leur performance décroît considérablement lorsqu'ils sont utilisés pour comme appareil de mesure dans la vie quotidienne. Bien qu'il existe de nombreuses méthodes basées sur LB, celle-ci n'ont pas été systématiquement validées pour déterminer lesquels de ces algorithmes présentent les meilleures performances selon les situations étudiées (marcheurs lents, normaux et rapides).

Cette thèse présente de nouveaux algorithmes d'apprentissage automatique (machine learning/ML) performants pour la détection des périodes de locomotion (marche, course) et l'estimation de la vitesse (y compris la cadence et la longueur des pas), en utilisant un dispositif basé sur un IMU (et baromètre) porté sur le poignet et intégré dans une

montre/bracelet. Une procédure de personnalisation en ligne a été conçue, pour laquelle un système GNSS a été utilisé *de manière occasionnelle* afin d'ajuster le modèle de vitesse. Les algorithmes(s) sont basés sur des caractéristiques biomécaniques des signaux IMU, telle que l'intensité d'accélération, la périodicité, le bruit, et l'orientation du poignet. L'algorithme de détection des périodes de locomotion a été validé pour des personnes saines, au quotidien et de manière non supervisée, en utilisant comme référence un système avec plusieurs IMUs. Des valeurs élevées de sensibilité, spécificité, et de précision (90, 97, 96 %, respectivement) ont été obtenues. L'algorithme personnalisé pour l'estimation de la vitesse a également été comparé à un système GNSS pour des sujets sains, dans des conditions réelles, obtenant une précision de 0,05 et 0,14 m/s pour la marche et la course, respectivement.

De plus, une validation étendue des algorithmes basés sur LB a été menée afin d'évaluer quels sont les meilleurs algorithmes selon les différentes gammes de vitesse. Au total, 29 algorithmes ont été catégorisés en fonction de leur approche méthodologique, puis ont été améliorés et implémentés. Une nouvelle technique a également été proposée. La validation en laboratoire avec un tapis instrumenté, et un système constitué de plusieurs IMUs, sur des populations saines et malades, a indiquée l'approche combinée comme une solution précise et robuste, avec une erreur d'environ 0,10 m/s. Enfin, le travail de cette thèse démontre la faisabilité de l'utilisation des algorithmes basés sur le poignet pour l'évaluation de longue durée de la marche en utilisant les données d'un grand nombre de participants (environ 2800 sujets). Les résultats ont montrés que la vitesse de marche améliore significativement la détection de la fragilité et l'estimation de la force au poignet.

Dans l'ensemble, les algorithmes proposés sont indépendants de l'orientation du capteur, donc, facile à utiliser. Un seul IMU offre une autonomie et un confort élevés, pour une surveillance à l'extérieur/intérieur de longue durée.

Mots clés: Analyse de la marche, marche, course, portable, capteurs inertiels, poignet, bas du dos, vitesse de marche au quotidien, périodes de locomotion, cadence, longueur du pas, validation, étude de cohorte, surveillance non supervisée.

Acknowledgment

It is my distinct pleasure to express my deep gratitude to Professor Kamiar Aminian for his excellent supervision and continuous support during my Ph.D. study at the Laboratory of Movement Analysis and Measurement (LMAM). I primarily appreciate his trust in me to join LMAM from Iran. His proficiency, unwavering guidance, creativity, and humor provided an enjoyable ambiance and a fertile ground for me to flourish my ideas and research. His insightful feedback pushed me to sharpen my thinking and brought my work to a higher level. Under his supervision, I had the valuable chance to go beyond books, libraries, and theories towards the real world and participate in fascinating projects targeting real-life challenges. I learned a lot from him in both professional and personal aspects of life.

I would also like to thank Dr. Anisoara Paraschiv-Ionescu (my co-director) and Dr. Hooman Dejnabadi (former scientist at LMAM), who were generous and reliable big brother and sister to me. They offered me the chance to taste the sweetness of learning and growing by their precious presence and continuous guidance. Working with them was a golden opportunity to learn and gain experience that I could have never found in any books or courses.

I also appreciate all the former and current members of the LMAM (especially Dr. Christopher Moufawad el Achkar, Dr. Benedikt Fasel, Dr. Matteo Mancuso, Dr. Mathieu Pascal Falbriard, Dr. Pritish Chakravarty, Dr. Lena Carcreff, Dr. Mina Baniasad, Dr. Wei Zhang, Mr. Arash Atrsaei, Mr. Mahdi Hamidi Rad, Mr. Salil Apte, Mrs. Gaëlle Prigent, Mrs. Yasaman Izadmehr, Mrs. Francine Eglese, and Mr. Pascal Morel), who provided a fantastic, supportive, friendly and fun atmosphere without which fulfilling this journey was never possible. We had many unforgettable moments, memories, and experiences together, and I am happy and grateful for finding such amazing friends.

In the first part of my Ph.D. study, I participated in the fascinating project ACTIWISE in close collaboration with the Electronics and Signal Processing Laboratory (ESPLAB) and a Swiss industrial partner. It provided me the opportunity to deal with practical and real-life challenges where I learned a lot about industrialized needs and procedures. I am gratified to give my special thanks to Professor Pierre-André Farine

Acknowledgment

(director of ESPLAB), Mr. Martin Savary, Mr. Joaquín Cabeza, Mrs. Sara Grassi, Mr. Flavien Bardyn, and all other partners who assisted me during this project.

During my doctoral education, I also had the chance to take part in a breathtaking cohort study called CoLaus (on more than 3000 people) in collaboration with the CHUV hospital in Lausanne, Switzerland. It granted me an exceptional possibility to regularly meet the most outstanding doctors in CHUV and become familiar with the real needs of clinical applications. They shared not only their valuable knowledge and experiences but also their extraordinary data and facilities with me, which significantly improved the quality of my research. I am delighted to express my gratitude to Professor Pedro Marques-Vidal, Professor Peter Vollenweider, Professor Bengt Kayser, Professor Bogdan Draganski, Dr. Nazanin Abolhassani, and all other people who assisted me during this project.

In the last step of my journey, I had an exceptional opportunity to participate in an ongoing European project called Mobilise-D. It was a great honor to collaborate with outstanding researchers from more than thirty academic and industrial partners during the Mobilise-D project. I am pleased to thank the Consortium members, especially members of the technical validation work package (WP2) led by Professor Claudia Mazza` from the University of Sheffield. I would also like to thank the funding parties, including the Innovative Medicines Initiative 2 Joint Undertaking (JU), receiving support from the European Union's Horizon 2020 research and innovation program, and EFPIA.

I also want to give my gratitude to medical centers, research institutions, universities, industrial partners, and study participants who generously took part in collecting data used in this thesis.

Finally, I would like to thank my family and friends in Switzerland and Iran for all their unconditional, generous, and continuous support and advice, without which none of this would have been possible. They have always been kindly beside me and generously volunteered to make the intense working periods more relaxed and comfortable. I am enormously grateful to them.

Lausanne, November 30, 2020

Part I – Introduction and Background

1 Introduction

1.1 Why does the mobility assessment matter?

Since the very first days of our lives, when we were too young even to understand “*who we are*” or “*what we need*”, all of us quickly realized that we need to move in order to survive. We stood up and fell again and again, but we insisted. We sensed that mobility is vital!

Mobility is a key to independence. It is between us and almost all daily tasks. Householding, shopping, and visiting friends are just a few examples of what mobility offers us. A painless independent walking to perform some basic self-care daily tasks might become the only dream of the aging population (from 524 million in 2010 to 1.5 billion in 2050) (WHO, 2010, 2015).

For centuries, many scientists have attempted to describe the movements of animals and human beings (Marey, 1868; Nussbaum, 1985; Pope, 2005). These days, in the 21st century, the incredible advances in science and technology have provided a fertile ground for the field of mobility assessment to flourish. Every day looking at the market, we find new attractive electronic gadgets capable of analyzing and providing feedback on a wide range of human physical activities (e.g., walking, running).

The mobility assessment has become a crucial topic in interdisciplinary and translational research. Clinicians have deployed tools designed by engineers to evaluate many diseases and age-related functional decline outcomes. The World Health Organization (WHO) has recently announced a definite association between physical activity (PA, such as walking, standing, sitting, lying) and muscular fitness, functional health, cognitive function, and risk of falling in aging societies. That is why, today, many fascinating research projects have emerged all over the world to use movement analysis as an objective and reliable tool for monitoring, assessment, and development of appropriate interventions. The target is a broad spectrum of diseases, from chronic non-communicable disorders like hypertension, obesity, cardiovascular diseases, depression, diabetes, and cancer (causing over 60 % of global deaths), to movement-

related pathologies such as Multiple Sclerosis (MS) and Parkinson’s Disease (PD) (Chodzko-Zajko et al., 2009; Pate et al., 1995; Tonino, 1989).

Gait, defined as “*the manner of walking or stepping*”¹, is a fundamental dimension of PA, directly connected to people’s health status, well-being, and quality of life (Cuomo et al., 2007). Amongst the various quantifiable gait parameters (later discussed in this chapter), Gait Speed (GS) has been recently emerged as an essential factor in characterizing people’s functional ability. The gait speed has been recognized as the sixth vital sign (Fritz and Lusardi, 2009; Middleton et al., 2015). Looking at the extraordinarily increasing trend of using the term “*gait speed*” in the scientific texts (Figure 1.1) provides another evidence on the growing prominence of the gait speed in scientific communities and research projects. This reliable and sensitive measure of mobility is a primary result of aging and is closely linked to the survival of elderly or diseased populations (Afilalo et al., 2016, 2018; Del Din et al., 2016a, 2016b; Elble et al., 1991; Karege et al., 2020; Liu et al., 2019; Wildes, 2019). Many studies have employed the gait speed for prevention, early detection, and assessment of impaired movement disorders and age-related functional declines (Castell et al., 2013; Fritz and Lusardi, 2009; Maki, 1997; Middleton et al., 2015; Perera et al., 2015; Quach et al., 2011; Rochat et al., 2010; Salarian et al., 2004; Studenski et al., 2011; Weiss et al., 2014).

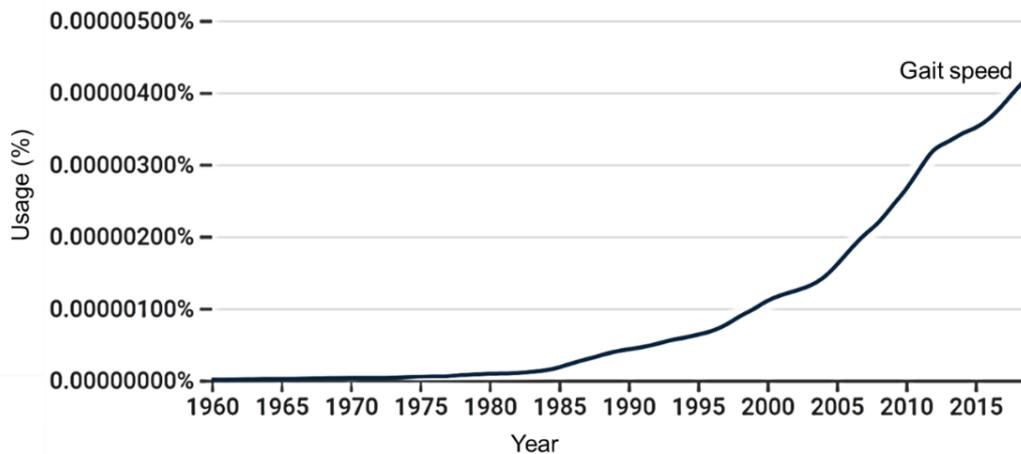

Figure 1.1 – The growing trend of using the term “gait speed” in recent scientific publications. The graph is generated by Google Book Ngram Viewer² on a selection of English-written books in the United States.

¹ Oxford English Dictionary

² <https://books.google.com/ngrams>

1.2 Significance of real-world analysis

Recent findings have demonstrated that PA, particularly the gait, measured in a supervised environment (e.g., a laboratory or clinical setting), does not fully represent the real functional ability of people, especially patients, in unsupervised everyday life context. The supervised gait assessment mainly reflects people's capacity (their best) than their expected performance in their free-living situations (Bonato, 2005; Brodie et al., 2016; Dobkin and Dorsch, 2011; Hillel et al., 2019; Kawai et al., 2020; Takayanagi et al., 2019; Warmerdam et al., 2020).

Daily-life gait is usually purposeful (e.g., catching a bus, walking to an office, shopping, moving in a house), and self-triggered. On the other hand, the gait in a clinical setting is typically initiated by instruction and performed in a controlled environment (Hutchinson et al., 2019; Van Ancum et al., 2019).

Furthermore, several psychological and psychological factors also contribute to the difference between daily-life and in-lab gaits. The white-coat and the inverse white-coat effects are two primary factors referring to changes of gait parameters (usually worsening and improving, respectively) due to being measured in a clinical setting (Warmerdam et al., 2020). Besides, people usually change their behavior when they realize that they are being monitored. This factor is known as the Hawthorne effect (Paradis and Sutkin, 2017; Robles-García et al., 2015). Other factors, such as alertness, fatigue, pain, and stress, could also significantly affect the in-lab gait parameters (Warmerdam et al., 2020). For instance, factors like pain could be managed better during short walking in a clinical setting than in long real-life activities.

Moreover, unsupervised gait is mostly in a multitasking context, which is rare in supervised settings. For instance, one could walk while texting by a cellphone, and/or on a crowded sidewalk, and/or accompanied by friends. Such a cognitive load could negatively influence gait parameters, especially speed. Eventually, the environment is typically standardized in clinical settings (e.g., walking in a quiet environment without distractions). However, the real-world environment includes many more unstable situations, such as various obstacles, different path types, lighting, and environment colors (Hillel et al., 2019; Jones et al., 2008; Patterson et al., 2014; Storm et al., 2016).

1.3 Gait analysis

1.3.1 Definition

Before diving into real-world gait speed estimation, it is worth presenting the basics of gait analysis. As an operational definition, human gait (also known as locomotion) refers to both walking and running in which one attempts to initiate and maintain a forward movement of the body Center of Mass (CoM) by the feet where the repetitive

and reciprocal movement of various segments of the body are engaged (Whittle, 2014). During walking, at least one foot is in contact with the ground. However, running has flight phases when both feet are off-ground in short periods (Novacheck, 1998; Whittle, 2014).

1.3.2 Analysis

In Biomechanics, the period between two same and consecutive events of one foot is called a gait cycle or stride, as the basic unit of gait analysis. However, it is preferred to consider an Initial Contact (IC, the moment when a foot contacts the ground) as the start of a gait cycle, as considered in Figure 1.2 and Figure 1.3. Accordingly, the step is the period between two same and successive events, but from different feet (e.g., from IC of a foot to another foot) (Novacheck, 1998; Whittle, 2014).

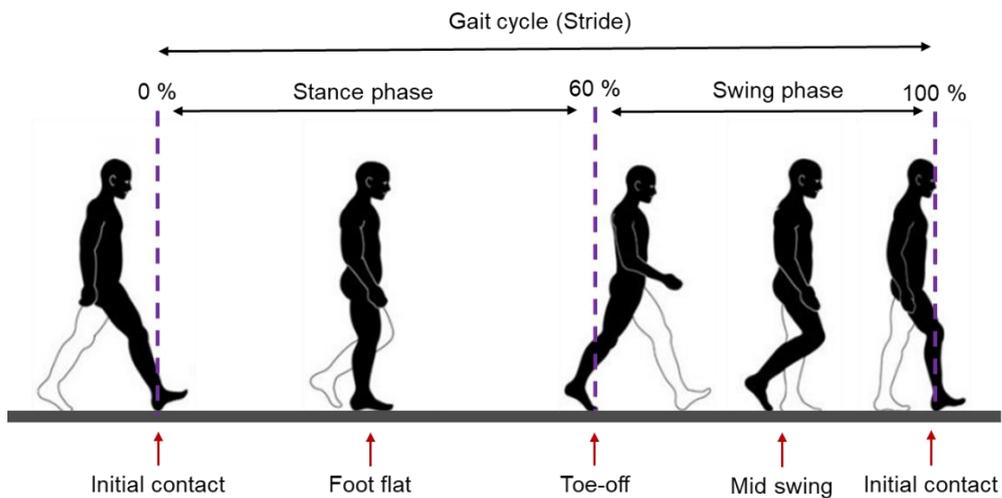

Figure 1.2 – Different events and phases of a typical gait cycle during walking.

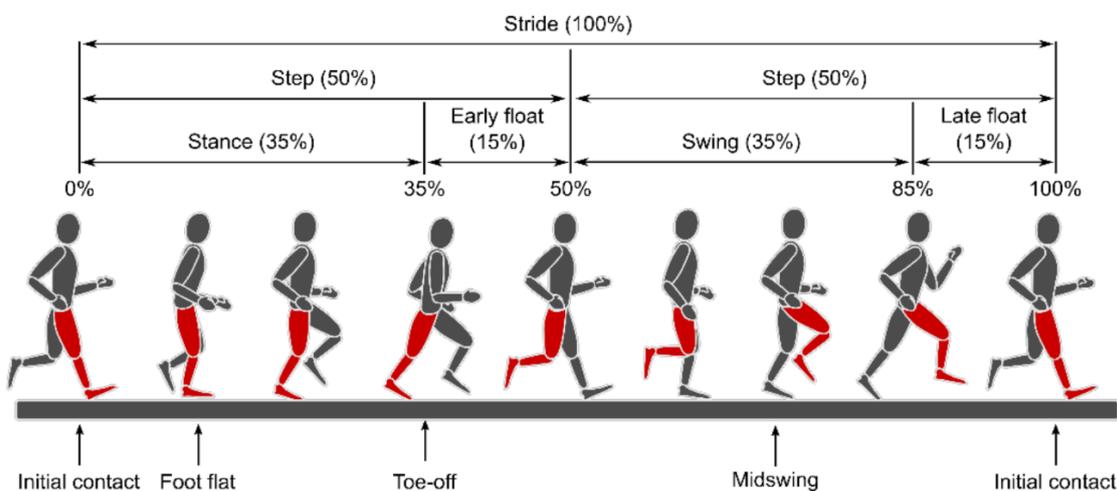

Figure 1.3 – Various events and phases of a normal gait cycle during running (Falbriard, 2020).

Figure 1.2 and Figure 1.3 represent the various events of gait during walking and running, respectively. The gait cycle has two main phases known as the stance phase (the period between the IC and the following toe-off of the same foot, including the foot flat) and the swing phase (the period between the toe-off and the following IC of the same foot including mid-swing). During running, the gait cycle has two more phases as early and late floats (or flights) (i.e., both feet are off-ground). The percentage of time of the phases are indicated in both figures.

1.3.3 Outcomes

There are several primary and secondary outcomes of the gait analysis. Gait cycle time (defined as the duration of one gait cycle), step duration, and cadence (or step frequency, computed as the inverse function of the step duration) are amongst the basic temporal parameters. The stride (or step) length, defined as the traveled distance during one stride (or step) duration, is considered as one of the essential spatial gait parameters. More importantly, the gait speed (traveled distance in unit time) has been introduced as a key gait outcome. Parameters such as gait symmetry (Sadeghi et al., 2000), step width (Whittle, 2014), gait variability (Hausdorff, 2005), foot clearance (Mariani et al., 2010), and the characteristics of other gait phases (e.g., swing, stance, and flight) are usually considered as the secondary outcomes of the gait pattern.

1.4 Real-world gait speed

As previously discussed, it is crucial to measure gait parameters, especially speed, in real-life situations. This section briefly introduces the most fundamental methods for real-world gait speed monitoring, focusing on using the Inertial Measurement Unit (IMU).

1.4.1 Global Navigation Satellite System (GNSS)

The first and easiest way to measure gait speed in free-living situations is to use GNSS. It is a space-based measurement system consisted of 24 operational satellites covering almost all surface of the globe. In order to measure the 3-Dimensional (3D) position and speed, a GNSS receiver needs to communicate with at least four satellites. The receiver typically uses the Doppler frequency shifts to estimate gait speed (ICAO, 2005). The accuracy of the speed measurement using GNSS depends on several factors such as weather, interference with objects near the receiver (like high buildings, mountains, and trees), the power of the receiver's antenna, and the type of movements. In typical situations with a high quality of communication, the GNSS receiver can estimate the speed of normal gait with an error of 0.05 m/s (Fasel et al., 2017a; Terrier et al., 2000; Witte and Wilson, 2004).

One inevitable drawback of GNSS-based gait monitoring is its high power consumption, limiting the duration of measurements to less than a few hours. Moreover, communicating with the satellites restricts the measurement only to outdoor situations with no interfering objects. More importantly, GNSS ordinarily does not provide the gait parameters like steps count, cadence, step or stride length, and gait phases.

1.4.2 IMU

Another alternative solution is to deploy IMU for the real-world gait analysis, particularly speed estimation. IMU usually consists of an accelerometer and gyroscope, measuring linear acceleration and angular velocity, typically, in all three dimensions. Most IMU available in the market also includes sensors to measure the 3D magnetic field and barometric pressure. IMU provides much higher power autonomy than GNSS that considerably prolongs the measurement duration (up to several days). More importantly, IMU is independent of any external sources and could be used in almost all daily-life situations (i.e., indoors and outdoors). Consequently, IMU is an excellent choice for long-term continuous PA monitoring, especially gait, in free-living situations.

However, using IMU for movement analysis needs several practical considerations. First, the offset and sensitivity of the inertial sensors' axes must be calibrated before a measurement. The calibration is usually performed relative to the Earth's gravity acceleration (Ferraris et al., 1995). Second, according to the type of movement, a proper sampling frequency and range of recorded signal must be chosen to avoid aliasing and saturation, respectively. Third, the possible change of the sensors' temperature environment should be taken into account since it could produce measurement errors, for example, drift (Lambrecht et al., 2016; Martin et al., 2016).

Apart from the sensors' issues, another critical challenge is to design accurate algorithms to derive meaningful gait parameters, including gait speed, from raw sensor data. Depending on the number of IMUs (multiple or single), sensors (e.g., with or without the magnetometer and barometer), their locations on body segments (e.g., lower or upper limbs), and attachment type (e.g., fixed or worn), the functionality and performance of the algorithms would significantly vary (Brognara et al., 2019; Caldas et al., 2017; Chen et al., 2016; Díez et al., 2018; Sprager and Juric, 2015; Yang and Li, 2012).

Furthermore, intra and inter-subject variability could considerably influence gait patterns recorded by inertial sensors and affect algorithms' performance. This variability could happen due to various factors, such as demographic characteristics (e.g., age, gender, height, weight, Body Mass Index (BMI)), health status (healthy versus diseased), obesity (underweight versus overweight), and preferred speed (e.g., slow versus fast walkers) (Brognara et al., 2019; Fukuchi et al., 2019; Obuchi et al., 2020; Panebianco et al., 2020).

In addition, the IMU-based algorithms often require the sensors' exact orientation relative to the anatomical coordinate system defined according to the conventions of biomechanics. As displayed in Figure 1.4, this coordinate system consists of three main axes (vertical, Medial-Lateral, and Anterior-Posterior (AP)) and planes (Sagittal, Frontal, Transverse). The IMU should be fixed either precisely on the body or functionally calibrated using different approaches based on Principal Component Analysis (PCA) or complementary filters (e.g., Madgwick). The sensor orientation alignment must be performed at the beginning of a measurement, respecting the rule that the IMU would not be replaced or taken off. This condition might be inconvenient during long free-living measurements (Bonnet et al., 2009; Madgwick, 2010; Nazarahari and Rouhani, 2019; Wold et al., 1987).

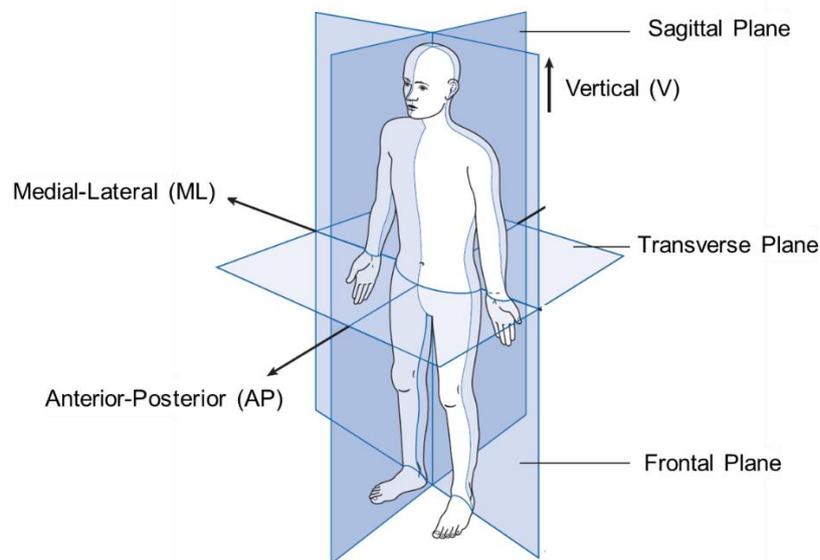

Figure 1.4 – The anatomical coordinate system with three principal planes and axes, defined according to Biomechanics' conventions. The picture is adapted from (Whittle, 2014).

Gait analysis in daily life conditions usually requires an initial stage to detect Gait Bouts (GB, defined as a minimal number of successive strides/steps). Due to the diversity of PA and gait patterns' variability among people in free-living situations, GB detection could be challenging and negatively impact gait analysis performance. One critical error is a low specificity of GB detection, resulting in gait analysis on sensor data that correspond to other activities than gait. Nevertheless, various IMU-based algorithms have been proposed up to now for accurate recognition of GB to be deployed for real-world gait analysis (el Achkar et al., 2016; Avci et al., 2010; Caldas et al., 2017; Díez et al., 2018; Paraschiv-Ionescu et al., 2004; Safi et al., 2015).

In the following subsections, we briefly introduce real-world gait analysis using multiple and single IMU, focusing on the speed and GB detection.

1.4.2.1 Multiple-IMU-based systems

The main concept here is to take advantage of data recorded by several IMU mounted on different body segments, such as feet, shanks, thighs, waist, sternum, and wrists, to achieve a reliable gait analysis, particularly speed estimation (Awais et al., 2019; Ellis et al., 2014; Ermes et al., 2008; Gao et al., 2014; Ghasemzadeh et al., 2010; Liu et al., 2016; Mannini and Sabatini, 2010; Paraschiv-Ionescu et al., 2004; Parkka et al., 2006; Salarian et al., 2007; Yeoh et al., 2008). For instance, multiple IMU, worn on the trunk, thigh, and shank, have been employed to accurately recognize PA, such as lying, sitting, standing, and gait (Paraschiv-Ionescu et al., 2004). Also, complete gait analysis has been performed using several IMU attached to the lower limbs (Aminian et al., 2002; Salarian et al., 2007).

The primary advantage of using multiple IMU is the accurate and precise estimation of PA and gait parameters, even in challenging real-life situations. Fusing data from various body segments allows reliably distinguishing between different body postures and PA (e.g., sitting and standing) and a high-resolution estimation of the gait parameters (i.e., per step or stride parameters).

However, wearing multiple IMU, which must not be replaced or rotated during entire monitoring, could be a real burden to a user in free-living situations. It also could mark the wearer as a subject being monitored, thus, reducing compliance and satisfaction. Apart from these, configuring, activating, and attaching multiple IMU on the body require a high level of expertise, which could be problematic for general users like older adults. An expert is commonly needed to initialize and set up the sensors before every measurement, taking a lot of time and money. Another challenge is to synchronize all sensors during a whole measurement in free-living situations. The synchronization could be affected by an inaccurate sampling rate due to the sensors' temperature changes and internal clock precision. Finally, data of multiple IMU are generally needed to be transferred to a central server for further analysis, and therefore, might not be appropriate for online and real-time applications.

1.4.2.2 Single-IMU-based systems

To overcome the difficulties of using multiple IMU, scientists have recently tried to reduce the number of IMU to a single one. It better matches the free-living requirements and offers a versatile, user-friendly, and easy-to-use monitoring tool. It also provides the opportunity to design systems capable of online gait analysis, beneficial for providing in-field feedback to the user to promote a more active lifestyle. Therefore, the single-IMU-based approach appears as an optimal solution for real-world gait analysis, especially speed estimation (Alaqtash et al., 2011; Aminian et al., 1995a; Bylemans et al., 2009; Fasel et al., 2017a; Kim et al., 2004; Lee et al., 2010; Liu et al., 2015; McCamley et al., 2012; Paraschiv-Ionescu et al., 2019; Pham et al., 2017; Weinberg, 2002; Zhao et al., 2017; Zihajehzadeh and Park, 2016; Zijlstra and Hof, 2003).

A critical point about the existing algorithms is that they are mostly validated only in supervised or semi-supervised laboratory conditions. However, they could lose performance (up to 20 %) in real-world situations where gait patterns might be more diverse and complex (Ermes et al., 2008; Ganea et al., 2012; Gyllensten and Bonomi, 2011). Besides, real-life gait periods might be relatively short, unstable, and non-stationary, making it tough to extract precise gait parameters by only a single IMU. The GB could also be context-dependent in daily life situations. For instance, gait patterns might differ in various situations like a typical path, a busy hallway, or a hill. Therefore, it is crucial to validate existing or new algorithms in real-life situations (Patterson et al., 2014; Storm et al., 2016).

1.5 Locations for single-IMU-based speed estimation

As displayed in Figure 1.5, biomechanically meaningful IMU locations are generally categorized into two positions: 1) the lower body, including feet, shanks, thighs, and 2) the upper body, including waist, wrist, and sternum (Moncada-Torres et al., 2014).

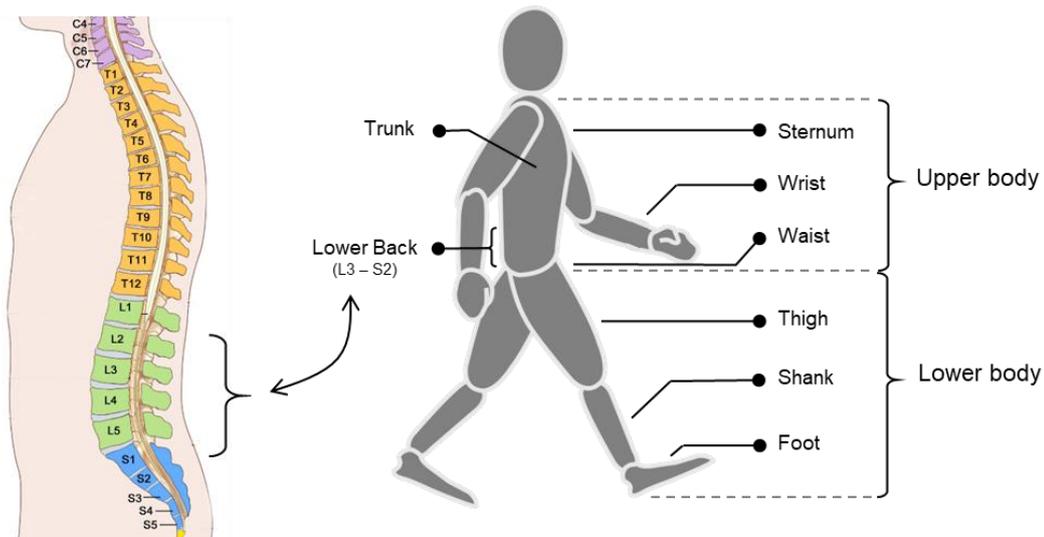

Figure 1.5 – Biomechanically meaningful IMU locations on the body for gait analysis. The left photo³ shows the area between L3-S2.

Since the lower body movements are directly linked to locomotion, gait analysis might lead to better performance than the upper body. However, wearing an IMU on the lower body in free-living situations could be inconvenient since the user's moving legs might change the IMU orientation. Moreover, since the single IMU is attached to only one limb, the gait analysis could provide only one-sided stride-level parameters. Therefore, it might not provide step-related gait parameters such as step length and gait asymmetry, beneficial for clinical assessment (Miyazaki, 1997; Rampp et al., 2015; de Ruyter et al., 2016; Sabatini et al., 2005; Tong and Granat, 1999).

³ <https://www.cancer.gov/publications/dictionaries/cancer-terms/def/spinal-column>

The upper-body segment could be divided into two parts: the wrist and the trunk. The wrist has recently attracted considerable attention as a preferable IMU location for real-world gait analysis due to several reasons. First, it is possible to integrate the IMU inside a watch for discreet monitoring, increasing user satisfaction. Therefore, it becomes one of the most convenient and user-friendly sensor positions, ideal for long-term monitoring during daily life (Fasel et al., 2017a). The watch also provides a unique base to communicate with the user (i.e., send and receive meaningful online feedback) to provide a high-quality service. Finally, the watch's high wearability provides an excellent opportunity for continuous monitoring of PA. This 24h/7d monitoring gives the possibility to assess additional PA features such as circadian rhythms and routine gait behaviors (Cabanas-Sánchez et al., 2020; Hillel et al., 2019).

However, the relationship between the wrist movements and the gait might not always be trivial. While the arms are generally swinging during the gait, there might be real-life situations where arm swing is absent such as carrying a bag, putting the hand in a pocket, or holding a cellphone (Fasel et al., 2017a). Besides, one might perform repetitive and reciprocal arm movements during daily tasks, like tooth brushing, cooking, and gym exercising, which could confuse wrist-based gait analysis algorithms. It becomes even worse considering patients like the PD whose arms might have severe unintentional movements like rest tremor. Moreover, the intra and inter-subject variability, due to various possible arm positions and movements during the gait, challenge establishing general models that are accurate for all people (Cho et al., 2020). Consequently, advanced and robust mathematical approaches are needed to devise algorithms for accurate wrist-based gait detection and speed estimation (Bertschi et al., 2015; Chen et al., 2008; Delgado-Gonzalo et al., 2015; Duong and Suh, 2017a; Fasel et al., 2017a; Gjoreski et al., 2016; Mannini et al., 2013; Nguyen et al., 2015; Park et al., 2012; Renaudin et al., 2012; Shoaib et al., 2016; Yang et al., 2015a; Zhang et al., 2012; Zihajehzadeh and Park, 2016).

Another alternative IMU location is the trunk. Since different parts of the trunk could have different rotations and tilts during walking, it is usually considered more than one segment, like the sternum and the waist (Fasel et al., 2017b). Compared to the waist, the sternum has a higher degree of rotations, tilts, and compensatory movement strategies, especially for impaired gait, which could negatively influence the performance of gait analysis (Broström et al., 2007; Carlson et al., 1988; Crosbie et al., 1997; Thorstensson et al., 1984). The waist is considered a better IMU placement due to proximity to the body CoM. Therefore, it might be more robust to trunk tilts and compensatory movements, especially for impaired gait. (Broström et al., 2007; Carlson et al., 1988; Crosbie et al., 1997; Thorstensson et al., 1984). Around the waist, the Lower Back (LB, an area in the lumbar spine between L3-S2, shown in Figure 1.5) is the preferred location due to several reasons. It is possible to fix the IMU tightly on the bone (e.g., straps, tapes), thus reducing soft tissue artifacts on the recorded signals. By tight fixation, sensors' axes could be aligned with the anatomical or global coordinate

systems using techniques such as PCA and Madgwick (discussed in section 1.4.2) (Fasel et al., 2017b; Madgwick, 2010).

The sensor alignment and IMU's proximity to the body CoM allow for developing biomechanical and empirical models, such as the inverted pendulum model, Weinberg model, and their variations, for estimating the step length (Díez et al., 2018; Gonzalez et al., 2007; Hu et al., 2013; Weinberg, 2002; Zhao et al., 2017; Zijlstra and Hof, 2003). The cadence could also be estimated in both time and frequency domains using step-related peak detection and zero-crossing rates in acceleration signals (Bugané et al., 2012; Lee et al., 2010; McCamley et al., 2012; Panebianco et al., 2020; Paraschiv-Ionescu et al., 2019; Pham et al., 2017; Shin and Park, 2011; Zijlstra and Hof, 2003). Eventually, the proximity to the body CoM provides an excellent opportunity to compute secondary gait outcomes such as asymmetry (Zhang et al., 2018).

However, the gait patterns on the signals (e.g., peaks or amplitude) recorded by the LB-worn sensors during slow or impaired gait might be weak or noisy. Moreover, patients with movement disorders might have compensatory movement strategies which challenge the LB-based biomechanical or empirical models (Díez et al., 2018; Köse et al., 2012; Paraschiv-Ionescu et al., 2019; Weinberg, 2002; Zhang et al., 2018; Zhao et al., 2017; Zijlstra and Hof, 2003).

1.6 Objectives of this thesis

This chapter introduced the gait analysis, particularly speed estimation, and its prominence in people's health status and well-being. It also emphasized the necessity of performing such analysis in real-world circumstances, where people perform according to their actual physical performance. Besides, we introduced the main approaches to estimate the gait outcomes (e.g., speed) in free-living situations by body-worn IMU.

We highlighted the unique potential of a single IMU to get insight into people's daily PA behavior by allowing long-term, pervasive, continuous, and reliable monitoring while ensuring the subject's comfort without hindering the actual activity. The wrist-mounted IMU, possibly integrated inside a watch, achieved a great acceptance due to high user compliance and online feedback. For the impaired gait, however, the LB location was preferred due to robust gait patterns in the proximity of body CoM.

However, there are still several critical aspects to be addressed. PA's high diversity and complexity in free-living situations is a big challenge for approaches based on a single wrist or LB worn IMU. In daily life, the gait patterns recorded on a wrist-mounted sensor significantly vary from one person to another. Even well-known commercial products lose their performance (up to 50%) under real-world conditions (Peake et al., 2018; Wahl et al., 2017). For the LB-worn IMU, the validity of algorithms for people with different levels of physical functioning (affecting gait speed) has not been fully

assessed. Moreover, it has not been determined yet whether it is feasible to employ a single wrist-worn IMU for monitoring and assessment of the gait in large clinical cohort studies in actual-living situations. If the answer is yes, then the most relevant mobility outcomes across various clinical conditions should be recognized and validated. Therefore, in this thesis, we have pursued three main objectives, as follows:

- i. Accurate, precise, and pervasive estimation of gait speed, as well as the detection of GB (as an initial necessary stage), in entirely free-living conditions and without any user supervision.
- ii. Assessing the performance of single-IMU-based gait speed estimation for people with different speeds (slow, normal, fast, walking-aids walkers), caused by health issues, to answer questions like “*what algorithms and under what criteria lead to the best performance?*”.
- iii. Deploying algorithms based on a single wrist-worn IMU for gait analysis in a large clinical cohort study, including community-dwelling subjects and free-living conditions, to investigate: 1) the feasibility and reliability of the devised algorithms in such a complex environment, and 2) highlighting the added values of using gait speed in the prediction of clinical evaluations like frailty prediction.

To these ends, first, we review the state-of-the-art algorithms to describe related attempts so far and to identify their limitations. Next, to accomplish the first goal, we deal with gait analysis challenges based on the wrist-worn sensor (as the most accepted daily-life sensor location) by proposing an online personalization concept and defining biomechanically meaningful features and models. To demonstrate the strength of the proposed personalization idea, we also apply it to a running speed estimation algorithm based on the feet-attached IMU. To achieve the second goal, we start by conducting a technical review to identify the most performant real-world speed estimation algorithms. We focus on the LB sensor location since it is convenient for daily life and provides robust gait patterns even for pathological gait. Then, we implement the selected algorithms, investigate their limitations, and propose new methods to fill the existing gaps. Eventually, we carry comprehensive cross-validation to evaluate the algorithms on people with different speed preferences (due to their health status), to determine which algorithm and under what criteria lead to the best speed estimation in real-life situations. To pursue the third goal, we deploy our proposed wrist-based algorithms (designed during the first goal) for a long-duration (around 13 successive days per person) gait monitoring in a large clinical cohort study (around 3000 participants)

1.7 Outline of the thesis

This thesis consists of seven chapters, organized in four main parts (see Figure 1.6), as follows:

Part I – Introduction and Background: It introduces the main scope and objectives of this thesis and provides insight into the state-of-the-art algorithms.

- **Chapter 1** – (current chapter) presents the real-world GB detection and speed estimation as the focus of this thesis. It provides a comprehensive overview of the gait analysis and its inevitable effects on people’s health and well-being. The significance of gait analysis in real-world situations is also highlighted. Moreover, this chapter expresses the essential approaches for obtaining the gait speed in free-living situations, focusing on inertial sensors. Finally, it ends with the main objectives and outline of the thesis.
- **Chapter 2** – establishes a conceptual framework according to the state-of-the-art algorithms for the real-world gait speed estimation using a single body-worn IMU, focusing on the wrist and LB sensor locations. It also briefly review studies about related commercialized products as customer-oriented activity trackers. Eventually, it puts insight into some calibration ideas to optimize the performance.

Part II – Algorithms Design and Validation: Detailed description of all algorithms devised, implemented, and validated in this thesis for real-world GB detection and speed estimation.

- **Chapter 3** – proposes a new approach for accurately detecting GB in daily life using a wrist acceleration. Several biomechanically meaningful features are defined based on the wrist’s posture and its acceleration’s intensity, periodicity, and noisiness. The features are then fed into a Bayes classifier to detect GB. Two physically meaningful post-classification stages (temporal probability modification and smart decision making) are also proposed to correct the Bayes’ decisions. The proposed method is validated against a multiple-IMU-based algorithm in unsupervised free-living situations (Soltani et al., 2020).
- **Chapter 4** – proposes a wrist-worn single IMU-based algorithm for the accurate and precise estimation of gait speed in real-world situations by online personalization. During the gait periods of a person, we sporadically use the GNSS to sample a few speed data to personalize the speed model with the user’s specific gait patterns in an online learning fashion. The Recursive Least Square (RLS) method is employed to develop the personalized speed model. The proposed real-time and low-power algorithm is validated against the GNSS (Soltani et al., 2019). Besides, to show the usefulness of the proposed personalization model irrespective of the sensor location, we deploy it to improve the feet-based running speed estimation. This work is described as the annex of chapter 4.
- **Chapter 5** – pursues a comprehensive comparison among single-IMU-based gait speed estimation algorithms applied to people with different speeds. Here, the main goal is to investigate which algorithm(s) and under what criteria lead to better performance. To this end, after a careful technical review, the most performant

algorithms for estimating the cadence, the step length (as necessary parameters for speed estimation), and the speed are selected. Since the LB sensor location provides comforts in daily life and robustness of gait patterns (for impaired gait), this chapter focuses on only LB-based algorithms. Then, the algorithms are improved and implemented. Several new algorithms are also proposed. Besides, a novel combination concept is devised to integrate different algorithms towards achieving a more reliable and robust solution. Finally, inclusive cross-validation is carried to evaluate the algorithms for people with different speeds (i.e., slow, normal, fast, and walking-aids). An instrumented walkway and a previously-validated algorithm based on multiple inertial-sensors are deployed as reference systems for the speed.

Part III – Real-world Application: Demonstrating the feasibility, reliability, and added values of deploying the proposed algorithms in a real-world application (i.e., long-term gait monitoring in a large clinical cohort)

- **Chapter 6** – demonstrates the feasibility of using the proposed wrist-worn algorithms (in chapters 3 and 4) to assess the real-world gait in a large clinical cohort (around 3000 people) for a long duration (13 successive days per person, 24 hours). Besides, a comprehensive statistical analysis is carried to illustrate the usefulness of real-world gait speed in predicting frailty conditions and handgrip strength estimation. The association between gait speed and demographic information of participants are also investigated. As a secondary outcome, we identify the speed metrics and GB durations that lead to a better prediction of the frailty conditions.

Part IV – Conclusions: It summarizes this thesis's main contributions, limitations, and possible future work.

- **Chapter 7** – concludes the most important contributions and achievements of this thesis. It also states limitations and some possible ideas to be pursued in the future.

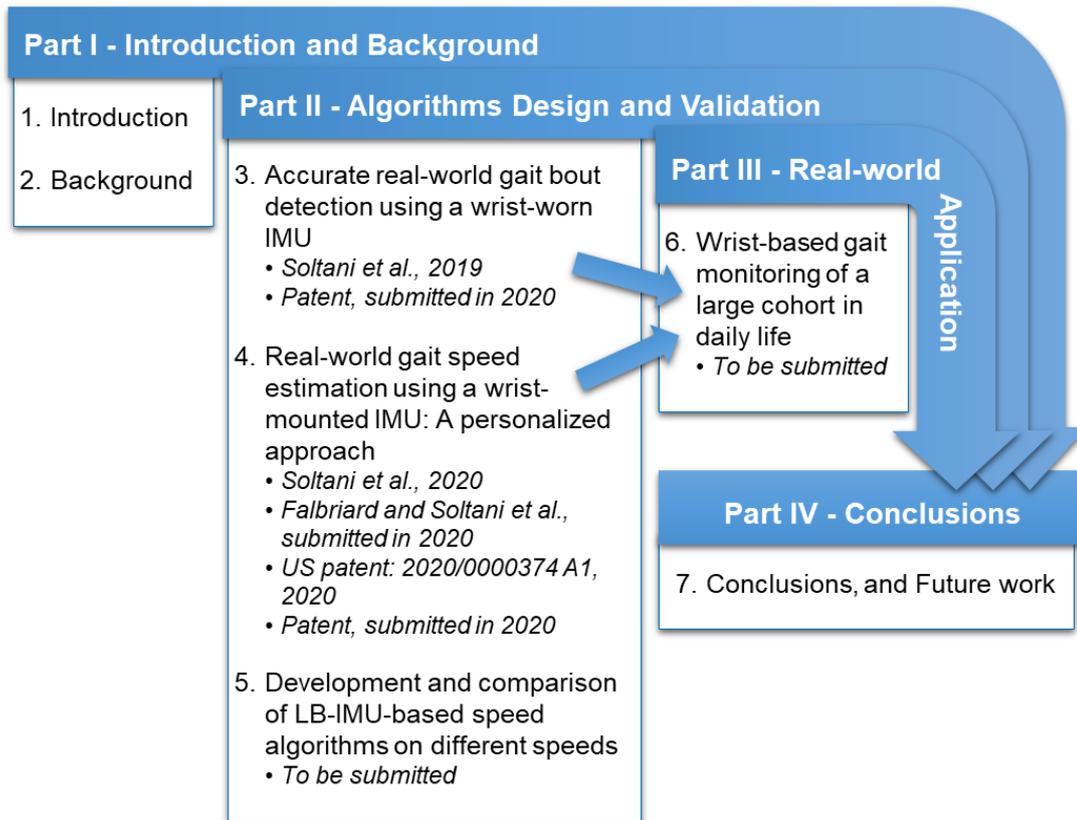

Figure 1.6 – Outline of the thesis. Here, short names of the chapters are used.

2 Background

2.1 Introduction

This thesis primarily targets accurate real-world gait speed estimation using a single IMU mounted on the wrist or the LB as the most accepted sensor locations in everyday life. This chapter puts insight into the related state of the art and provides a conceptual framework for the real-world gait speed estimation. A brief overview of related commercialized products as customer-oriented activity trackers is also provided. Finally, we go through some calibration ideas to optimize the performance of speed estimation algorithms.

2.2 A conceptual framework for real-world gait speed estimation

To provide a better and more realistic view of the literature related to real-world gait speed estimation, we have established a conceptual framework (Figure 2.1), representing the necessary processing stages, as follows:

- **Preprocessing** - enhances and smoothes the inertial signals (i.e., acceleration and angular velocity)
- **GB detection** - recognizes the gait periods in smoothed inertial signals.
- **Gait speed estimation** - computes the gait speed within each GB by either a direct or indirect approach. The latter is the multiplication of cadence and step length.

This conceptual framework focuses on the wrist and LB sensor locations as the main scope of this thesis. Nevertheless, the framework and methodology could be used for other sensor locations as well. In the following subsections, a detailed description of each processing block is provided.

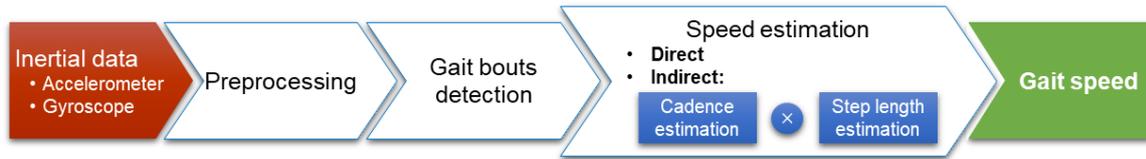

Figure 2.1 – The conceptual framework for real-world gait speed estimation using a single IMU.

2.2.1 Inertial data

The 3D acceleration and angular velocity are typically sampled at a high enough frequency, usually greater than 30 Hz (Allseits et al., 2019), to avoid aliasing. They are also measured in a wide enough range around ± 8 g for the acceleration and ± 2000 degrees/s for the angular velocity. Besides, as discussed in the first chapter, other sensor considerations, such as offset-sensitivity calibration and thermal noise, must be examined (Ferraris et al., 1995; Lambrecht et al., 2016; Martin et al., 2016).

2.2.2 Preprocessing

The main goal here is to outfit the inertial signals as the gait analysis algorithms expect them. The issues are mainly about: (1) noise removal and signal enhancement, and (2) sensor orientation correction due to misalignment with the reference body or global coordinate systems.

The inertial signals are typically enhanced by low-pass filters such as Butterworth, Savitzky-Golay, and FIR, or smoothing techniques like continuous wavelet transformation or Empirical Mode Decomposition (EMD). The purpose here is to highlight the gait-related patterns (e.g., step-related peaks) while discarding unrelated information (e.g., random noise, drift) (Bulling et al., 2014; Figo et al., 2010; Paraschiv-Ionescu et al., 2019; Pham et al., 2017).

In order to align sensors' axes with the global coordinate system, a typical approach is to use complementary filters like Madgwick (Madgwick, 2010). Here, the basic idea is to fuse the accelerometer, gyroscope, and magnetometer for the sensor alignment. The magnetometer could be affected by objects (e.g., the metal used in buildings structures, electronic gadgets, vehicles), especially in indoor situations. Therefore, it might not be an appropriate option for real-world situations. Nevertheless, the good news is that the magnetometer is not required for estimating the vertical acceleration. Another point is that a short static period is necessary at the beginning of each GB to apply the Madgwick filter optimally (Madgwick, 2010).

A typical approach for sensor-to-body alignment is to apply PCA on sensors' data recorded during specific movements. The movements depend on the sensor location on the body. For instance, to estimate the AP acceleration (concerned in this thesis), the

PCA is applied to acceleration data during a straight gait period. It should be noted that the PCA requires enough samples (at least 3-4 seconds) to provide reliable results. (Bonnet et al., 2009; Nazarahari and Rouhani, 2019; Wold et al., 1987). Note that the orientation alignment is not applied for algorithms using the l_2 -norm, by assuming that the acceleration norm defined as in (2.1), is independent of the sensor orientation. In (2.1), a_x , a_y , and a_z are acceleration in X , Y , Z axes of the sensor's frame.

$$a_{norm} = \sqrt{a_x^2 + a_y^2 + a_z^2} \quad (2.1)$$

2.2.3 GB detection

A necessary stage for real-world speed estimation is to detect GB (i.e., periods). This subsection provides a brief overview of the GB detection using a wrist-mounted sensor as the focus of this thesis. Nevertheless, the explained ideas could be effectively applied to other sensor locations, especially on the upper body (e.g., the trunk).

GB detection by a wrist-worn sensor is regularly based on Machine Learning (ML) approach. Figure 2.2 displays its standard procedure where, in the first stage, a rectangular sliding window cuts the acceleration signal (typically the norm) into shorter but overlapped segments. The window length should be sufficiently long for frequency analysis and short enough to provide the required time resolution, typically 4-6 seconds (Banos et al., 2014; Bonomi et al., 2009; Fasel et al., 2017a). Next, various signal features based on statistics, intensity, time-domain (TD), and frequency-domain (FD) are extracted for each segment. Statistical features are usually mean, variance, standard deviation (STD), median, Inter-Quartile Range (IQR), minimum, max, mode, kurtosis, correlation, and cross-correlation. Energy, frequency bands power, dominant frequency power, and the DC component are examples of intensity-based features. The time and FD features include signal period, zero-crossing rate, integration, entropy, and dominant frequency. Finally, the features are fed into different ML models, such as decision-tree, Dynamic Linear Discriminant Analysis, Neural Network (NN), Support Vector Machine (SVM), Naïve Bayes, Random Forest, K-Nearest Neighbor, and Hidden Markov Model, to recognize the gait segments (Avci et al., 2010; Bulling et al., 2014; Chen et al., 2008; Chernbumroong et al., 2011; Dutta et al., 2016; Figo et al., 2010; Gjoreski et al., 2016; Mannini et al., 2013; Moncada-Torres et al., 2014; Nguyen et al., 2015; Ordóñez and Roggen, 2016; Safi et al., 2015; Shoaib et al., 2016; Sprager and Juric, 2015; Zhang et al., 2012).

Figure 2.2 – Typical pipeline for GB detection based on ML.

A critical point here is that most previous studies have developed and validated their models in a supervised or semi-supervised laboratory environment. Participants are restricted to specific instructions and are required to follow a list of specific predefined activities (e.g., lying, sitting, standing, walking). Each activity lasts for a long time (a few minutes) and is repeated in a specific order. The whole measurement protocol is recorded in a short period (a few hours) and limited space (e.g., a laboratory or home-shaped room) (Avci et al., 2010; Bulling et al., 2014; Chen et al., 2008; Chernbumroong et al., 2011; Dutta et al., 2016; Figo et al., 2010; Gjoreski et al., 2016; Mannini et al., 2013; Moncada-Torres et al., 2014; Nguyen et al., 2015; Ordóñez and Roggen, 2016; Safi et al., 2015; Shoaib et al., 2016; Sprager and Juric, 2015; Zhang et al., 2012).

Such conditions might not represent free-living situations where even basic tasks like daily walking in a house, shopping, socializing, carrying a bag, cooking, tooth brushing, and exercising might be very complicated and problematic for a wrist-based GB detection. It becomes even worse considering that a person might switch rapidly between the daily-life tasks (i.e., shorter activities) or performing some of them simultaneously (i.e., complex movements). The GB detection algorithms validated under laboratory conditions significantly lose their performance (up to 20 %) in real-world situations (Ermes et al., 2008; Ganea et al., 2012; Gyllensten and Bonomi, 2011; Warmerdam et al., 2020). A few previous studies have validated their algorithms in free-living situations, reporting a low sensitivity of 75 % to detect GB (Awais et al., 2019; Hickey et al., 2016). Consequently, we propose a new accurate wrist-based GB detection algorithm in chapter 3 of this thesis, which could be reliably used even in challenging real-world situations.

2.2.4 Speed estimation

After recognizing gait periods, the next stage is to estimate speed within these periods. Here, the main focus is on the wrist and LB sensor locations. Nevertheless, the methodologies could also be applied to other sensor locations like the sternum. For speed estimation using a single IMU worn on the wrist or LB, two basic approaches exist, as follows:

Direct approach: It is a direct estimation of speed by ML models. A few studies, mostly based on the wrist-worn IMU (typically acceleration norm), have followed this approach, whose processing pipeline is similar to Figure 2.2. The studies have employed similar segmentation and features as expressed for the GB detection. Besides, they defined various additional speed-specific features such as acceleration amplitude, step-frequency (i.e., cadence), users' demographic information (e.g., height, weight, gender, age), and path inclination (estimated by an additional barometer sensor). Finally, they build an ML model such as Linear Regression, Regular or Adaptive Gaussian Process, Regularized Kernel method, NN, and Support Vector Regression to estimate the speed (Aminian et al., 1995b; Bertschi et al., 2015; Bulling et al., 2014; Caldas et al., 2017;

Cho et al., 2020; Fasel et al., 2017a; McGinnis et al., 2017; Park et al., 2012; Vathsangam et al., 2010; Zihajehzadeh and Park, 2016; Zihajehzadeh et al., 2018).

These ML-based methods do not impose any biomechanical assumptions and could reach an acceptable performance by providing sufficient training data. However, they are prone to overfitting to a specific population and typically need to be re-trained for each population. They could also only provide average speed within a processing window (i.e., segment) rather than in step or stride granularity.

Indirect approach: It takes advantage of the biomechanical rule, stating that the multiplication of the cadence (step/unit time) and the step length (m/step) results in speed (m/unit time). Therefore, the speed estimation issue is split into two more straightforward problems (i.e., cadence and step length). This simplification allows designing different and more effective approaches to estimate each parameter better, thus, accurate speed estimation. Besides, this approach provides cadence and step length, which themselves are two important gait parameters. The cadence could be estimated in time or frequency domains. The step length could also be estimated by designing Biomechanical Models (BM), Double Integration (DI), and ML.

2.2.4.1 Cadence estimation

Cadence could be estimated by TD or FD approaches. In the following, well-known methods within each category are described.

2.2.4.1.1 TD approach

In this approach, the cadence is usually computed as the inverse function of the step duration. A primary method to estimate the step duration is to detect the gait's temporal events such as IC, mid-swing, and toe-off. To this end, after filtering and smoothing the acceleration signal (norm, vertical, or AP, see preprocessing subsection), several techniques such as peak detection, zero-crossing rate, morphological filters, and sign change detection are employed. Finally, the step duration is computed as the period between two same and successive gait events of two feet (e.g., from the IC of the right foot to the IC of the left foot). Another method to estimate the step duration is based on the assumption that the gait generates a periodic pattern in the time domain. Therefore, techniques like Auto-Correlation Function are used to estimate the gait pattern period, as the step duration (Bugané et al., 2012; Lee et al., 2010; McCamley et al., 2012; Panebianco et al., 2020; Paraschiv-Ionescu et al., 2019; Pham et al., 2017; Shin and Park, 2011; Zijlstra and Hof, 2003).

2.2.4.1.2 FD approach

This approach estimates the acceleration's dominant frequency (also known as the fundamental or pitch frequency) during the gait as the cadence. To this end, a straightforward method is to apply Fast Fourier Transform (FFT) on a sufficiently long

segment of the acceleration (typically the norm and more than 3-4 seconds) to compute the spectrum. Then, the frequency that belongs to the maximum peak is searched as the dominant frequency. In order to reduce the risk of finding a wrong peak, the frequency search region is usually limited to a reasonable range between (0.5-5) Hz (Fasel et al., 2017a; Karuei et al., 2014; Paraschiv-Ionescu et al., 2019). Another issue is the possibility of confusion between the step and stride frequencies, especially for the impaired gait. To avoid this issue, (Fasel et al., 2017a) have applied a comb-shaped function to the spectrum to amplify the step-related peak and its harmonics. Then, the maximum likelihood technique is employed to identify the correct peak as the step frequency.

2.2.4.1.3 Performance evaluation

While the TD algorithms provide promising results on regular gait cadence (around 0.5 ± 2 steps/min absolute error for average cadence), they could face a severe problem for impaired gait, which has high variability and noisy irrelevant peaks (around 2 ± 7 absolute error). Nevertheless, they detect temporal events (e.g., IC), which are necessary for some step length estimation algorithms (e.g., based on BM, explained later). On the other hand, the FD algorithms are less sensitive to peaks or specific gait patterns. However, they could easily confuse the step and stride frequencies due to reasons like gait asymmetry, producing a significant error. Apart from this, the FD algorithms are not able to provide the cadence in step or stride granularity. They require a long enough segment of data (4-6 seconds) to perform frequency analysis and provide the segment's overall cadence. They have shown an absolute error around 1 ± 3 steps/min for a healthy population and 2 ± 9 steps/min for impaired gait (Fasel et al., 2017a; Paraschiv-Ionescu et al., 2019).

2.2.4.2 Step length estimation

Step length could be computed by three main approaches: BM, DI, and ML (Díez et al., 2018). The following subsections present the popular step length algorithms, focusing on a single IMU mounted on the LB or the wrist.

2.2.4.2.1 BM

A conventional approach for step length calculation is to design models based on biomechanical rules to describe different body segments' movements during the gait. Zijlstra is a pioneer of this approach who has proposed the inverted pendulum model, describing the movements of body CoM during walking (Figure 2.3).

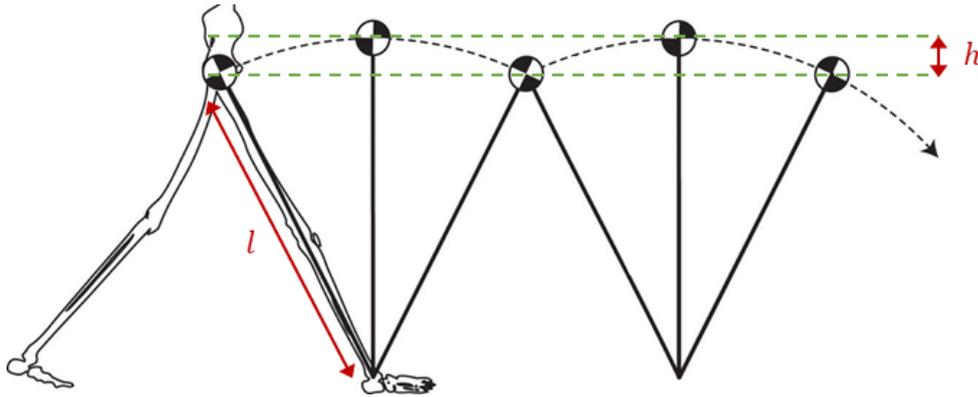

Figure 2.3 – The inverted pendulum model, describing the movements of body CoM during walking (photo adopted from (Matthis and Fajen, 2013)).

In this model, the step length, $STPL$, is estimated according to (2.2), which needs a user's leg length, l . The parameter h is the vertical displacement of body CoM during a step, which could be estimated by DI of vertical acceleration between two IC. Here, K is a factor that should be tuned for each person or at least each population to optimize performance (Zijlstra and Hof, 1997, 2003). Today, several variations of this model exist in the literature, which attempts to refine the original model by including additional subject-specific information, like the knee joint angle or shoe size (Díez et al., 2018; Zhao et al., 2017).

$$STPL = 2K\sqrt{2lh - h^2} \quad (2.2)$$

An alternative is the so-called empirical models established to avoid integrating the acceleration signal needed for the inverted pendulum model. Weinberg has proposed a popular empirical model, relating the vertical acceleration, a_v , to the step length through (2.3). Here, $\max(a_v)$, and $\min(a_v)$ are the maximum and minimum values of preprocessed vertical acceleration (previously discussed) during a step. The parameter K is also the tuning factor which should be set for each individual or each population. Many variations of this model have been proposed in the literature with the aim to improve it or to propose more efficient ways to derive the tuning factor K (Bylemans et al., 2009; Díez et al., 2018; Kim et al., 2004; Weinberg, 2002; Zhao et al., 2017).

$$STPL = K^4\sqrt{|\max(a_v) - \min(a_v)|} \quad (2.3)$$

Furthermore, it is worth mentioning that the biomechanical approach is more suitable for the LB sensor location than the wrist. One reason might be a high degree of freedom of the wrist movements during the gait. Nevertheless, if the wrist motion is restricted (e.g., by a walker as shown in Figure 2.4 (A)), it is possible to establish simple wrist-based BM to estimate the traveled distance during the gait (Duong and Suh, 2017b).

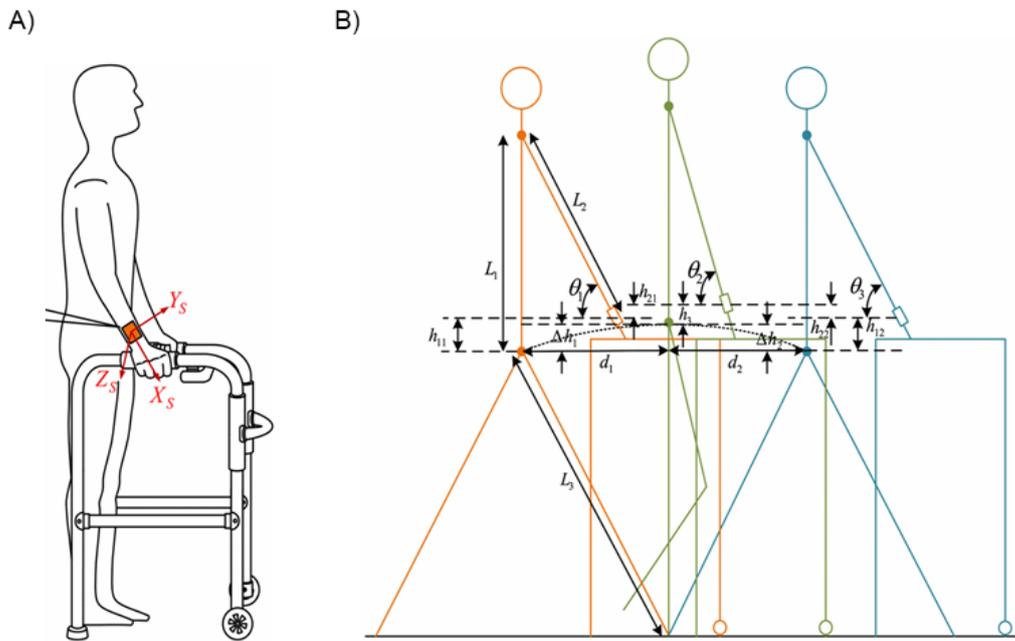

Figure 2.4 – The wrist-based step length BM, designed according to the inverted pendulum model (adapted from (Duong and Suh, 2017b)).

Figure 2.4 (B) illustrates a wrist-based BM, inspired by the inverted pendulum model, to estimate the step length according to (2.4).

$$STPL = \sqrt{L_3^2 - (L_3 - \Delta h_1)^2} + \sqrt{L_3^2 - (L_3 - \Delta h_2)^2} \quad (2.4)$$

Where the Δh_1 and Δh_2 can be computed by (2.5) and (2.6).

$$\Delta h_1 = h_{11} + h_{21} - h_3 \quad (2.5)$$

$$\Delta h_2 = h_{21} + h_{22} - h_3 \quad (2.6)$$

2.2.4.2.2 DI

In physics, linear acceleration is defined as the change of speed over time. The speed itself is the linear displacement of an object over time. Consequently, the linear displacement could be theoretically computed by double integrations of linear acceleration. In the field of gait analysis, this concept has been used to estimate the step length. However, DI usually leads to a significant drift (Djurić-Jovičić et al., 2012). One reason for the drift is errors in estimating correct linear AP acceleration during the gait. Another source is the difficulties of determining an initial value for the integration. (Djurić-Jovičić et al., 2012).

A common technique to encounter the integration drift is called Zero-velocity Update (ZUPT) during the gait stance phase since the foot is on the ground, thus having almost zero speed in this period. This technique works well when the sensor is attached to a

lower-body segment, especially close to the foot (Cho et al., 2018; Mannini and Sabatini, 2014; Mariani et al., 2010; Peruzzi et al., 2011; Qiu et al., 2016; Rebula et al., 2013; Sabatini et al., 2005). However, the ZUPT assumption might not be valid for IMU worn on the upper-body segments, which might be moving even during the stance phase. For a single sensor mounted on the LB, a few studies have attempted to reduce the integration drift by various highpass filtering and detrending techniques, like the EMD, before the first and/or the second integrations (Alvarez et al., 2018; Köse et al., 2012; Zhao et al., 2017; Zok et al., 2004).

2.2.4.2.3 ML

This approach is similar to the direct estimation of speed, discussed at the beginning of this section. Here, however, the goal is to estimate the step length or traveled distance. This approach is broadly used in pedestrian dead reckoning and indoor navigation systems where GNSS is not available.

Similar to Figure 2.2, the idea is to extract useful features from a segment of the inertial signals and build an ML model on the feature space to estimate the step length. Here, essential features are the step frequency (i.e., cadence) and user's demographic information, especially height. Additional statistical and biomechanical features similar to the direct speed estimation are also employed. Most studies have deployed linear or non-linear regressions to establish an optimized relationship between the features and the step length (or traveled distance). In addition, NN, Gaussian process regression, and fuzzy logic are also employed as models (Diaz and Gonzalez, 2014; Díez et al., 2018; Gusenbauer et al., 2010; Lai et al., 2016; Lee and Mase, 2001; Li et al., 2015; Liu et al., 2015; Omr, 2015; Renaudin et al., 2013; Shin et al., 2007; Song et al., 2007; Sun et al., 2008; Tian et al., 2015; Wahdan et al., 2013; Yang et al., 2015b).

2.2.4.2.4 Performance evaluation

Theoretically, the DI approach is expected to perform better since it is not based on any models but only on physical definitions (i.e., acceleration is the second derivative of the displacement). However, in reality, sensor measurement noise and artifacts (caused by improper sensor fixation or soft tissue artifact) could lead to a considerable integration drift (error). It becomes even worse considering the difficulty of removing the drift for the LB-worn sensor where ZUPT is not applicable directly. It is usually required to employ advanced and complex de-drifting techniques (e.g., EMD), which threaten the robustness and reliability of step length estimation, especially in daily life situations.

Compared to DI, the BM approach is less sensitive to sensor noise and misorientation. However, the models' efficacy depends on the validity of the assumptions used to design the models. Factors such as asymmetry, rotations of body joints (e.g., the pelvis, knee, trunk, ankle), and the trunk's excessive movements during the gait, especially for patients, could challenge the models. Moreover, tuning coefficients of BM-based models require to be set for each subject or at least population to optimize the performance. It

is worth mentioning that estimating the vertical displacement of the body CoM, needed for the inverted pendulum, could face the integration drift as the DI approach. In this case, similar approaches introduced for the DI (such as high pass filtering, EMD) should be used to reduce the drift.

On the other hand, the ML approach can model complex phenomena like the gait by observing a population's general behavior. As soon as a dataset is ready, various ML models could be easily trained and tested under different conditions to customize the best possible solution. However, the ML approach suffers from several problems. First, preparing sufficiently large datasets for proper training imposes time and money costs. Second, the ML-based algorithms are very prone to overfitting, meaning that they might not generalize the models to all unforeseen circumstances. Moreover, they are usually required to be re-trained for each population separately to provide better performance. Even in some cases, it is required to personalize the models for each user.

According to the existing literature, the DI algorithms have shown a range of 3.5 % error in estimating the traveled distance. This error goes up to around 12 % for BM. For ML, however, an RMSE of around 5 % is reported (Díez et al., 2018). Since the existing studies have reported very different performance parameters on various types of datasets with very different conditions, it is difficult and probably unfair to judge their performance (Alvarez et al., 2008; Kim et al., 2004; Köse et al., 2012; Liu et al., 2015; Schimpl et al., 2011a; Weinberg, 2002; Zhao et al., 2017). That is why, in a part of this thesis, we develop and implement all the approaches and conduct comprehensive cross-validation for a fair and reliable comparison (Chapter 5).

2.3 Commercialized activity trackers

Day-by-day breathtaking technological advances of electronic devices have offered smaller, lighter, and more accessible inertial sensors. Today, almost all kinds of smart gadgets, like cellphones, watches, wrist bands, and belts, provide integrated inertial sensors that could be deployed for monitoring a wide range of PA, especially the gait (Althoff et al., 2017; Böhm et al., 2019; Brickwood et al., 2019; Evenson et al., 2015; Henriksen et al., 2020; Lee and Finkelstein, 2014; Ridgers et al., 2016; Shin et al., 2019; Straiton et al., 2018; Takacs et al., 2014; Tedesco et al., 2017; Wahl et al., 2017). For instance, the built-in accelerometer of smartphones has been employed to analyze 68 million days of PA of more than 700000 people, showing the inequality of the distribution of activities among more than 100 countries (Althoff et al., 2017). Apart from this, recent clinical findings have intensified public awareness about the importance of long-term 24h/7d monitoring of daily-life PA (Cabanas-Sánchez et al., 2020; Firmann et al., 2008; Hillel et al., 2019; Rosenberger et al., 2016).

Therefore, a few years ago, a tremendous public demand for such handy smart gadgets emerged, which attracted much attention and industrial investments. As a consequence, a wide range of commercial activity trackers have been introduced to the

market. Fitbit Charge 4, Garmin Vivosmart 4, Samsung Galaxy Fit, Apple Watch Series 6, Whoop 3, Xiaomi Mi Band 5 are among brand-new activity trackers introduced in 2020. Such customer-oriented activity trackers could analyze a broad spectrum of PA and related parameters like step counts, traveled distance, consumed calories, and sleep¹. Researches have demonstrated a positive effect of wearing such commercialized activity trackers in promoting a more active lifestyle (up to twice for PA, step counts, and energy expenditure) in different groups of people, from children to community-dwelling older adults (Brickwood et al., 2019; Ridgers et al., 2016; Straiton et al., 2018).

The main issue related to these commercialized activity trackers is the accuracy of estimated parameters, especially in real-life situations and clinical populations. A few studies have attempted to evaluate them but in minimal situations. While the accuracy of different parameters has not been clearly determined, the step count seems more accurate and reliable than distance estimation. It has been shown that these fancy customer-oriented activity trackers could have up to 50 % of errors in different real-life situations. Moreover, the algorithms inside such activity trackers are rarely published or presented. Sometimes, even access to raw data is prohibited. Therefore, there is a big debate about the validity of using such black boxes in research, especially for clinical studies (Evenson et al., 2015; Henriksen et al., 2020; Lee and Finkelstein, 2014; Shin et al., 2019; Straiton et al., 2018; Takacs et al., 2014; Tedesco et al., 2017; Wahl et al., 2017).

Another critical problem is that these activity trackers mainly employ GNSS to estimate distance (or step length) and the speed. Therefore, their battery life is short (usually less than one week), which is not proper for long-term monitoring in daily life situations. Besides, their distance and speed estimation might not be valid where the GNSS is not available. Consequently, they lose track of indoor activities, as a major portion of daily life. Recently a few companies, like Apple², have attempted to add indoor gait analysis to their activity trackers, but there is no reliable information about their algorithms and performance.

2.4 Algorithms calibration

This section describes an additional stage for calibrating the speed estimation algorithms based on several factors (explained later) towards improving performance. This calibration could be performed by optimizing the thresholds used in the models (e.g., thresholds for peak detection in cadence estimation) or further training of ML models (Altini et al., 2014; Barnett and Cerin, 2006; Mannini and Sabatini, 2014; Supratak et al., 2018; Zihajehzadeh and Park, 2016).

¹ <https://www.wareable.com/fitness-trackers/the-best-fitness-tracker>

² <https://www.apple.com/newsroom/2020/06/watchos-7-adds-significant-personalization-health-and-fitness-features-to-apple-watch/>

An important calibration is to personalize the algorithms according to each user. People might have different gait patterns and strategies to manage their speed. For instance, they might change their speed by controlling either the step length, the cadence, or both. Therefore, a part of the user's gait activity could be used to personalize the speed algorithms (Altini et al., 2014; Barnett and Cerin, 2006; Mannini and Sabatini, 2014; Zihajehzadeh and Park, 2016). Another user-dependent calibration is to tune the models according to the user's demographic information like height, weight, BMI, age, and gender. It has been shown that demographic information is effective on the gait speed. For example, a tall person probably has a higher range of step length and speed (Bendall et al., 1989; HIMANN et al., 1988; Samson et al., 2001).

Furthermore, the calibration could be performed according to a population's characteristics rather than an individual user. For instance, diseased populations like PD or MS might have different gait patterns and speed ranges than healthy ones. Therefore, each population's data could be used to tune the models (Supratak et al., 2018). Moreover, conditions such as speed range (e.g., slow, normal, and fast) could also be used to tune the models. A few studies, first, predict if the gait is slow, normal, or fast, and then deploy models calibrated for the predicted range (Zihajehzadeh et al., 2018).

Almost all previous studies have performed the calibration procedure offline. To this end, a batch of data describing a new situation is collected and used to tune the models before using it in the real situation. For instance, a few short trials of a user's gait are collected and used to adapt a speed model to the user's specific gait patterns before using it. The offline calibration requires collecting a tuning dataset, which might be difficult or even impossible (e.g., not all users might be accessible), and might spend a lot of time and money. Chapter 4 of this thesis proposes an online personalization approach that does not need any data collections before using the algorithm. In this approach, when a person is walking, the algorithm sporadically uses GNSS to collect some tuning data. Then, the recursive least square method is employed to automatically personalize the speed models to the person's gait pattern.

2.5 Overall conclusions

This chapter reviewed the state of the art related to real-world gait speed estimation and its related parameters using a single IMU. It structured the previous works in a conceptual framework, consisted of preprocessing, GB detection, and speed direct/indirect (cadence and step length) estimation. Several important open questions were highlighted. In the following, the issues are summarized, and this thesis's solutions are briefly explained.

- The wrist-based GB detection algorithms were mainly developed and validated only in controlled supervised or semi-supervised situations. They significantly lost performance in real-life situations. Therefore, chapter 3 of this thesis proposes an

accurate GB detection algorithm using a wrist-mounted sensor unit and validates it in an entirely free-living condition against a multiple-IMU-based algorithm. To this end, some biomechanically meaningful features are designed and fed into the Bayes classifier, followed by two physically meaningful post-classification stages.

- The ML-based speed estimation approaches required preparing sufficiently large datasets. Besides, they might not be able to generalize the trained models to all unforeseen circumstances (e.g., different users), especially by a wrist-mounted sensor unit. Moreover, similar to the GB detection, the speed estimation algorithms were mainly validated in laboratory settings. To overcome these issues, chapter 4 of this thesis proposes an online personalization procedure to devise a personalized ML-based speed estimation algorithm using a wrist-mounted sensor. The main idea is to sporadically use GNSS during a user's gait to sample a few speed data and employ them to train and adapt the speed models. The RLS technique is deployed for online training. The method is validated against the GNSS in real-life outdoor situations. Apart from this, we show the usefulness of the personalization model for other sensor locations by applying it to the feet-based running speed estimation in the annex of chapter 4.
- The speed estimation algorithms, particularly based on LB-worn single IMU, were rarely tested and compared on people with different preferred speed (i.e., slow, normal, fast, and walking-aids walkers). They were also validated on very different populations with very different performance parameters. Therefore, it was difficult and unfair to judge their performance. In chapter 5 of this thesis, we select, develop, and implement the well-known algorithms to perform comprehensive cross-validation to compare the algorithms under different speed conditions. We also try to improve the algorithms and propose a new combined approach towards a more reliable solution. The algorithms are validated against an instrumented walkway and a multiple-IMU-based algorithm.
- Activity trackers showed great potential for long-term monitoring of PA in large cohort studies. However, the customer-oriented activity trackers were almost like black-boxes (i.e., their algorithms have been rarely published and validated). Research-grade activity trackers were more transparent and gave access to the raw data. However, they rarely estimated gait speed without using GNSS. Chapter 6 of this thesis shows the feasibility of deploying the wrist-based algorithms (designed in chapters 3 and 4) to evaluate everyday gait speed in a large clinical cohort study (around 3000 people) for a long duration (13 successive days per person, 24 hours). More importantly, the added values of using real-world gait speed in predicting frailty conditions and handgrip strength estimation are investigated.

Part II – Algorithms Design and Validation

3 GB detection using a wrist sensor: an unsupervised real-life validation¹

3.1 Abstract

GB, as a prominent indication of PA, contain valuable fundamental information closely associated with human's health status. Therefore, an objective assessment of GB (e.g., detection, Spatio-temporal analysis) during daily life is critical. A feasible and effective way of GB detection in real-world situations is using a wrist-mounted IMU. However, the high degree of freedom of the wrist movements during daily-life situations imposes serious challenges for a precise and robust automatic detection. This study deals with such challenges and proposes an accurate algorithm to detect GB using a wrist-mounted accelerometer. Features, derived based on biomechanical criteria (intensity, periodicity, posture, and other non-gait dynamicity), along with the Bayes estimator followed by two physically meaningful post-classification procedures, are devised to optimize the performance. The proposed method has been validated against a shank-based reference algorithm on two datasets (29 young and 37 elderly healthy people). The method has achieved a high median [IQR] of 90.2 [80.4, 94.6], 97.2 [95.8, 98.4], 96.6 [94.4, 97.8], 80.0 [65.1, 85.9] and 82.6 [72.6, 88.5] % for the sensitivity, specificity, accuracy, precision, and F1-score of the detection of GB, respectively. Moreover, a high correlation ($R^2 = 0.95$) was observed between the proposed method and the reference for the total duration of GB detected for each subject. The method has also been implemented in real-time on a low power consumption prototype.

Keywords: Real-world, GB, PA, wrist accelerometer, ML, low-power, real-time.

3.2 Introduction

PA is one of the fundamental aspects of daily life, closely associated with well-being, and recognized as a Leading Health Indicator of populations (Healthy people 2020²). WHO has reported a strong connection between PA and risk of falling, cognitive function, muscular fitness, and functional health level of older adults (WHO, 2010). PA becomes even more critical when the increasing trend of aging populations (from 524 million people in 2010 to 1.5 billion in 2050 (WHO, 2015)) is considered. PA is a crucial component of healthy aging (WHO, 2015) and is a significant factor for preventing chronic non-communicable diseases such as diabetes, hypertension, cardiovascular diseases, depression, obesity, and some types of cancer, which cause over 60 % of global deaths (Chodzko-Zajko et al., 2009; Pate et al., 1995; Tonino, 1989).

Among different PA types, gait (e.g., walking and running) is one of the most important and effective ones. The objective gait assessment could provide useful and valuable information about the physical functioning of people. The advances in wearable technologies have led to developing IMU-based PA monitoring systems using various configurations, for example, attached to the lower limbs (el Achkar et al., 2016; Lau et al., 2008; Skotte et al., 2014; Tang and S. Sazonov, 2014; Zhu and Weihua, 2011), on the upper body (Bonomi et al., 2009; Bouten et al., 1997; Choudhury et al., 2008; Curone et al., 2010; Godfrey et al., 2011; Gyllensten and Bonomi, 2011; Hickey et al., 2016; Najafi et al., 2003; Panahandeh et al., 2013; Rodriguez-Martin et al., 2013; Storm et al., 2018; Sun et al., 2008; Zhang and Sawchuk, 2013) or a combination of on-body sensor locations (Awais et al., 2019; Banos et al., 2012; Ellis et al., 2014; Ermes et al., 2008; Gao et al., 2014; Ghasemzadeh et al., 2010; Leutheuser et al., 2013; Liu et al., 2016; Mannini and Sabatini, 2010; Paraschiv-Ionescu et al., 2004; Parkka et al., 2006; Salarian et al., 2007). Sometimes, IMU in a smartphone has been employed, where the phone has been fixed to different parts of the body (Kwon et al.; Lu et al., 2017; Shoaib et al., 2014; Susi et al., 2013; Wang et al., 2016; Zois et al., 2013).

While these systems allow detecting the gait outside the laboratory, they suffer from several drawbacks. Wearing multiple sensors (e.g., on foot, shank, thigh, hip, or chest) might be cumbersome, uncomfortable, and awkward in daily-life situations, mainly when long-duration measurements are targeted. Fixation and alignment of the sensors on body segments might require the presence of an expert and additional tests. This procedure affects the system's usability and could easily disturb the wearer and modify his/her normal daily activities. Moreover, such systems' power consumption might be high due to using multiple IMU or modality (e.g., gyroscope), limiting the duration of continuous measurements. Another issue is that multiple-IMU-based algorithms generally have high complexity and are not appropriate for real-time data analysis, relevant for generating real-time feedback to users. For most existing systems, the recorded raw data must be transferred to a computer for offline analysis.

² <https://www.healthypeople.gov>

Considering the above limitations, an alternative for PA monitoring, particularly gait, is to use a single IMU mounted on the wrist (Chen et al., 2008; Chernbumroong et al., 2011; Da Silva and Galeazzo, 2013; Delgado-Gonzalo et al., 2015; Dutta et al., 2016; Gjoreski et al., 2016; Mannini et al., 2013; Moncada-Torres et al., 2014; Nguyen et al., 2015; Shoaib et al., 2016; Yang et al., 2015a; Zhang et al., 2012). It offers comfort, high usability, and discreet monitoring (e.g., integrating inside a wristwatch), thus, increasing user compliance. Therefore, wrist-worn PA trackers have experienced significant growth in two main directions: (i) consumer-grade and (ii) research-grade. Each group has specific advantages and limitations (Tedesco et al., 2019). Technological advances and increasing demand and interest for long-term monitoring of PA lead to the emergence of many consumer-oriented activity trackers that nowadays gain popularity due to their low cost and accessibility on the market. Although they appear useful to promote a more active lifestyle, there is also a growing consensus about these devices' limitations in healthcare research settings since their reliability and validity have seldom been assessed (only 5 % are validated yet). Several studies showed a significant drop of the performance (up to 50 % of error) of such commercial products under different conditions (Peake et al., 2018; Wahl et al., 2017). On the other hand, the research-grade PA trackers are consistently reported to be more accurate than consumer-grade ones. Some of them allow access to the raw IMU data (e.g., 3D acceleration). However, the analysis software of such PA trackers is generally expensive. Another limitation of the consumer-oriented devices is the lack of information about the methodology used to estimate the reported PA parameters (e.g., steps, moderate to vigorous activity intensity), complicating the interpretation and comparison of the results across studies.

Thanks to the research-grade PA trackers, big cohort databases have been created worldwide that contain long-term real-life wrist IMU/acceleration data of thousands of people (Doherty et al., 2017; Gubelmann et al., 2018; da Silva et al., 2014). Therefore, the researchers have been motivated to validate new algorithms, allowing a comprehensive and transparent assessment of real-life PA behavior (e. g., GB and parameters such as cadence, speed) in clinical or research settings (Fasel et al., 2017a; Lin et al., 2018; Soltani et al., 2019; Urbanek et al., 2018; Zihajehzadeh and Park, 2016).

Most wrist-based PA assessment methods have used abstract modeling where several raw data (accelerometer norm) features based on TD, FD, and statistics are extracted and fed into various types of ML models (e.g., decision tree, SVM, Bayes). Such methods are independent of sensor orientation, therefore, no need for sensor calibration and alignment, which is suitable for long-term measurements of gait in real-world situations. However, the association of gait activity with the wrist motion is more challenging than the upper body or lower limbs. The wrist might have “*independent*” movements from the gait (e.g., carrying bag, hand-in-pocket) and non-gait (e.g., moving wrist when sitting or standing), which is problematic for accurate GB detection in everyday-life conditions.

Another issue regarding GB detection is the validity of the existing methods under unsupervised or real-world conditions. Most methods were validated only in supervised (i.e., controlled laboratory settings including short measurements in limited space) or semi-supervised conditions (e.g., a series of activities lasting longer time, simulating real-life situations under the supervision of an observer). Such conditions might not match real-world situations where the gait activity is context-dependent, self-initiated, and purposeful. It has been shown that the performance of in-laboratory validated PA classification algorithms significantly drops when they are applied to data recorded in real-life circumstances (Ermes et al., 2008; Ganea et al., 2012; Gyllensten and Bonomi, 2011). Only a few works have evaluated their methods under entirely real-world conditions, without any supervision or pre-defined sequences of PA (Awais et al., 2019; Hickey et al., 2016). Those methods used a subject-borne camera as a reference to label PA in free-living conditions. In particular, (Awais et al., 2019) reported an accuracy of 96 % for daily life PA detection using two sensors, located at thigh and LB. They showed that the accuracy dropped to 75 % by using only a wrist-worn IMU.

This study describes an accurate and precise algorithm to detect GB in completely free-living conditions using a single 3D accelerometer on a wrist. Biomechanically-derived features and the naïve Bayes classifier, followed by two physically meaningful post-classification procedures, have been used to optimize the algorithm performance. We target a low-power, calibration-free algorithm that needs low computation to be implemented inside a wristwatch, which is proper for online feedback in everyday situations. The algorithm was validated in real-world conditions on healthy young and older adults against an accurate and pre-validated wearable system (Paraschiv-Ionescu et al., 2004).

3.3 Methods

3.3.1 Measurement protocol

The measurement protocol consisted of two datasets: M1, including young and active people, and M2, including old and less active subjects. In dataset M1, 29 healthy young volunteers (14 women, 15 men, age 37 ± 9 years old, height 172 ± 10 cm, and weight 68 ± 11 kg) wore two time-synchronized IMU (Physilog® IV, GaitUp, CH, see Figure 1.1 (D)) on both wrists using elastic straps (Figure 1.1 (A)). Only single (left or right) wrist-recorded 3D acceleration (range ± 16 g), sampled at 200 Hz, was used to devise the GB detection algorithm. Data recorded on both wrists enabled comparison of the algorithm performance between the two sides. Besides, another time-synchronized IMU (Physilog® IV) was attached to the shank (using elastic straps), measuring 3D acceleration (range ± 16 g) and angular velocity (range ± 2000 degrees/s) sampled at 200 Hz. The shank-mounted IMU was used only by the reference system (Paraschiv-Ionescu et al., 2004). Participants wore the IMUs for two days, one weekday and one weekend

(to keep enough diversity of PA in daily life), around 12 hours per day, during their real free-living conditions without any constraints or supervision.

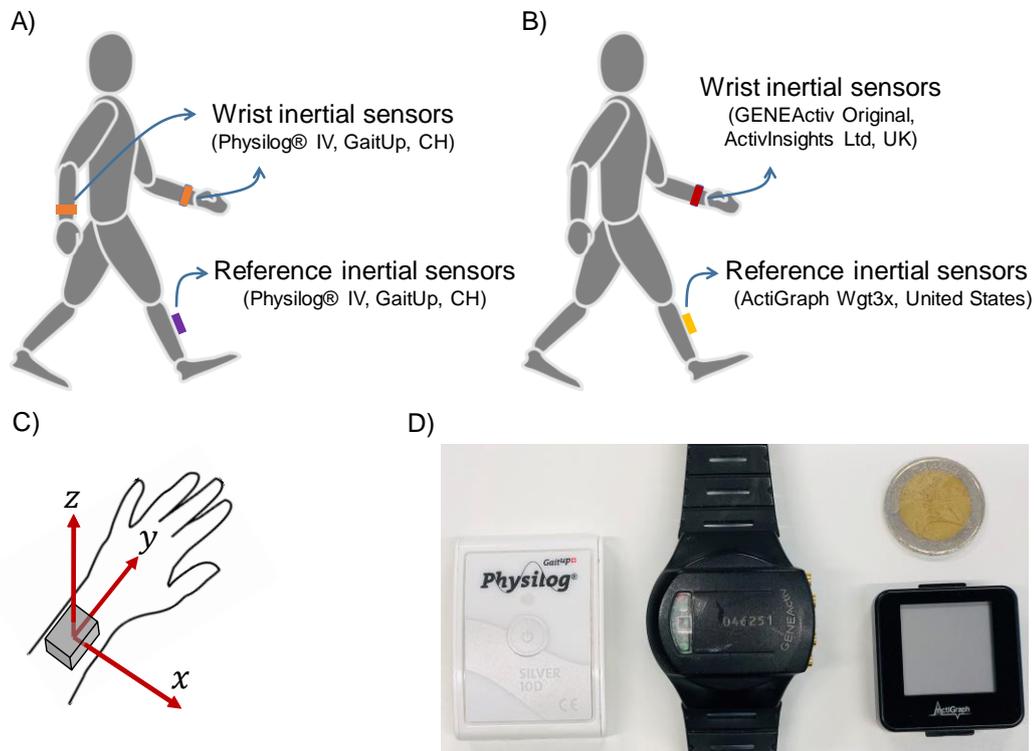

Figure 3.1 – A) Sensor configuration of dataset M1. A single sensor was worn on each wrist and one shank. B) Sensor configuration of dataset M2. A single sensor was mounted on one wrist and one shank. C) Local coordinate frame of the wrist accelerometer in both measurements. D) Inertial monitoring device. From left to right: Physilog® IV (Gait-Up, CH), GENEActiv Original (ActivInsights Ltd, United Kingdom), Actigraph GT9X Link (United States).

For the dataset M2, 37 old participants (19 women, 18 men, age 64 ± 11 years old, height 167 ± 10 cm, and weight 77 ± 12 kg) were included. They wore a data logger (GENEActiv Original, ActivInsights Ltd, United Kingdom, see Figure 1.1 (D)) measuring 3D acceleration (range ± 8 g, sampled at 40 Hz) on one wrist (Figure 1.1 (B)). Moreover, as a reference, an IMU (ActiGraph GT9X Link, United States, see Figure 1.1 (D)) was attached to the shank to measure the 3D acceleration (range ± 8 g) and angular velocity (range ± 2000 degrees/s) at a sampling rate of 50 Hz. These sampling frequencies are sufficiently high to avoid aliasing and capture the gait pattern (Allseits et al., 2019). Each subject carried the wrist device and the reference system for around 12 hours (within one day) in real-world situations. Local research ethics committees approved experimental protocols for both datasets, and all participants signed written informed consent before the measurements. It should be noted that the measurements have been collected at a different time in different research sites, which provided the opportunity to show the robustness of the proposed method by including 1) more subjects, 2) different populations (i.e., young and elderly), and 3) IMU from different companies.

3.3.2 Labels for GB detection

The inertial signals recorded with the shank-worn IMU were used by a validated noncommercial accurate algorithm to obtain reference data (Paraschiv-Ionescu et al., 2004). The algorithm provided labels for GB and non-GB in real-life situations with a resolution of one second. In (Paraschiv-Ionescu et al., 2004), the algorithm was validated against visual observation and achieved a sensitivity and specificity of 97.1 % and 97.9 % for GB detection. This algorithm has already been used in several studies as a reference for the technical validation of algorithms in free-living conditions and the clinical assessment in various healthy and diseased populations (Moufawad El Achkar et al., 2016; Paraschiv-Ionescu et al., 2012, 2013).

3.3.3 Wrist-Based GB detection

Figure 3.2 represents the block diagram of the proposed wrist-based method where the measured 3D accelerometer signals (A_x, A_y, A_z see Figure 1.1 (C)) were segmented and relevant features were extracted. Then, the probability of gait occurrence was estimated using the Bayes estimator trained by the extracted features and their corresponding labels from the reference system. In the next step, the temporal information of past-detected activities was used to update the gait occurrence probability based on the histogram of gait durations in real-life situations. Finally, “*gait*” or “*non-gait*” bouts were classified using a smart rule based on the probability resulted from the previous steps. Here, $L[n]$ is a vector containing the predicted label of each window of extracted features. In the following, a more detailed description of each step is provided.

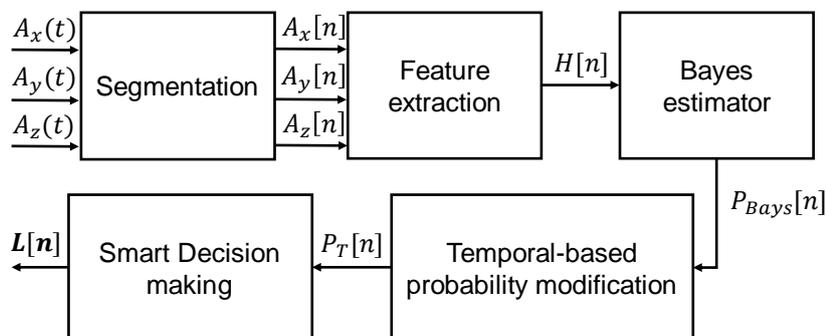

Figure 3.2 – Block diagram of the proposed wrist-based method. First, wrist acceleration signals (A_x, A_y, A_z) were segmented using a 6-second moving rectangular window with 5-seconds overlap. Then, relevant features ($H[n]$) were extracted for each window. Next, the Bayes estimator was trained to estimate the probability of gait occurrence ($P_{Bays}[n]$). The probability of the Bayes estimator was modified ($P_T[n]$) by a temporal classifier based on the histogram of GB duration. Eventually, a smart algorithm was proposed to decide if the window is gait or not based on the probability obtained from the previous steps. $L[n]$ is the final estimated label, provided at the system output on a 1-second time-base.

3.3.3.1 Segmentation

First, the acceleration signal of dataset M2 was up-sampled to 200 Hz to have the same sampling frequency as dataset M1. As mentioned previously, the original sampling frequency of dataset M2 (40 Hz) was already high enough to avoid aliasing. Then, we employed a 6-second moving rectangular window (i.e., 1200 samples per window) with a 5-second overlap to generate segmented wrist acceleration signals ($A_x[n], A_y[n], A_z[n]$), where n refers to the window number. The window length and shift were experimentally found to optimize the algorithm performance, which is also consistent with the literature (Banos et al., 2014; Bonomi et al., 2009; Fasel et al., 2017a). The amount of data of each window is also optimal because it is short enough to have the required time resolution and long enough to have sufficient data for consistent frequency analysis. It is worth mentioning that the output of the proposed system (i.e., the estimated label $L[n]$, indicating gait/non-gait) is provided on a 1-second time base.

3.3.3.2 Feature extraction

We defined various features based on the wrist movements, such as intensity, periodicity, posture, and other non-gait dynamicity, to highlight intrinsic differences between the gait and non-gait. The Least Absolute Shrinkage and Selection Operator (LASSO) feature selection method was used to specify the best possible features set to optimize the performance on the training dataset (Tang et al., 2014). As we expected, the LASSO selected features that cover all biomechanical criteria (i.e., intensity, periodicity, posture, other non-gait dynamicity). Totally, 13 features related to the four biomechanical criteria were chosen and categorized, as described in the following.

Intensity-based features – One key difference between GB and non-GB is the intensity of the wrist acceleration signal. In order to capture this information, we computed the following features:

$NI[n]$: It is the acceleration norm intensity, calculated according to (3.1).

$$NI[n] = \log_{10} \left(\frac{1}{N} \sum_{i=1}^N SA[f_i] \right) \quad (3.1)$$

Where $SA[f_i]$ is the amplitude of the power spectrum of the acceleration norm computed according to (3.2) and (3.3).

$$SA[f] = |FFT(A[n])| \quad (3.2)$$

$$A[n] = \sqrt{A_x[n]^2 + A_y[n]^2 + A_z[n]^2} \quad (3.3)$$

In order to estimate the spectrum, we used the N -point FFT with Blackman windowing (experimentally selected) where N is the number of samples within a time window (i.e.,

$N = 1200$ in this case). Moreover, f_i refers to the frequency resolution of the method, which is indicated in (3.4). We used the logarithm transform to shorten this feature's range and its histogram's heavy tail, which is proper for later Bayesian modeling.

$$f_i = \{0, 0.17, 0.34, \dots, 100\} \quad 1 \leq i \leq 1200 \quad (3.4)$$

MeanA[n]: It is the mean value of the acceleration norm within a time window.

Periodicity-based features – Considering the cyclic nature of the gait, five features related to the periodicity of the acceleration signals were included as follows:

NACFmax[n]: The autocorrelation function of the acceleration norm is computed and normalized to the first sample (i.e., the zero-lag). Then, its maximum peak, *NACFmax*, excluding the zero-lag sample, was reported for each window.

NACFp2p[n]: This is the peak-to-peak value of the maximum peak and the minimum valley of the normalized autocorrelation function, excluding the zero-lag sample.

SAmx[n]: The normalized spectrum of acceleration norm (*NSA*) was estimated using *SA[f_i]* according to (3.5), and the amplitude of its maximum peak was computed as *SAmx[n]*.

$$NSA[f_i] = \frac{SA[f_i]}{\sum_{j=1}^N SA[f_j]} \quad (3.5)$$

DomSAmx[n]: We designed this score to quantify how sharp the maximum peak of *NSA* was, compared to its neighboring samples. This feature was computed according to (3.6) where f_{max} , f_{max-1} and f_{max+1} referred to the frequencies of the maximum peak of *NSA*, a sample before and after that, respectively.

$$DomSAmx[n] = \frac{NSA[f_{max}]}{\sum_{f=\{f_{max-1}, f_{max}, f_{max+1}\}} NSA[f]} \quad (3.6)$$

Cad[n]: This is the cadence (number of steps per minute), which is generally bounded in a short range around 120 steps/min (≈ 40 -300 steps/min). The rationale for including this feature is that, in addition to the acceleration's periodicity, the period itself is important information to distinguish between GB and non-GB. The *Cad[n]* was computed using the algorithm presented in (Fasel et al., 2017a).

Posture-based features – During GB, the wrist generally has a more specific and predictable posture than during non-GB. Consequently, extracting information about the posture of the wrist should be useful for GB detection. We defined θ as the angle between the y -axis of the accelerometer on the wrist and the global horizontal plane $\langle x_{Global}, y_{Global} \rangle$ (the plane made by x and y -axes of the global coordinate system perpendicular to the gravity vector, Figure 3.3).

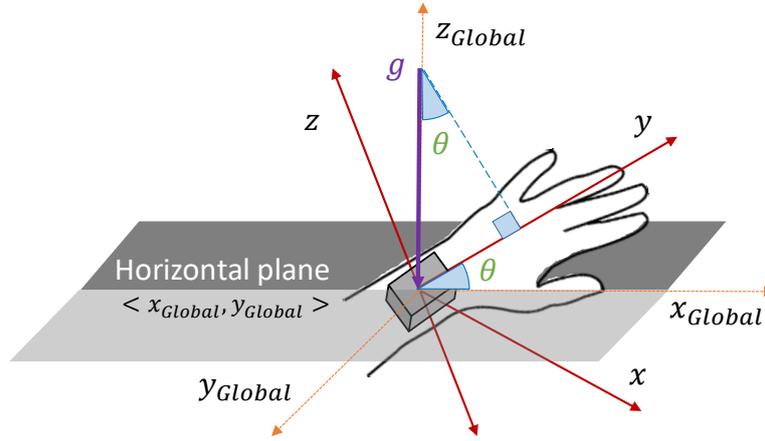

Figure 3.3 – Estimation of the wrist posture. Here, θ is the angle between the wrist and the horizontal plane made by $\langle x_{Global}, y_{Global} \rangle$. x , y , and z are the axes in the sensor frame, and g is the global gravity vector.

By assuming that the sensor could only rotate around the wrist, the sensor's y -axis is almost aligned with the wrist's longitudinal axis. According to Figure 3.3, if the dynamic acceleration of the wrist movement remains low, the projections of gravity vector on the sensor's y -axis, and on the plane made by x and z axes of the sensor, $\langle x, z \rangle$, are:

$$A_y[n] = g \sin(\theta[n]) \quad (3.7)$$

$$A_{\langle x, z \rangle}[n] = \sqrt{A_x[n]^2 + A_z[n]^2} = g \cos(\theta[n]) \quad (3.8)$$

Where $A_{\langle x, z \rangle}[n]$ is the amplitude of resultant acceleration vector on the plane $\langle x, z \rangle$ for window n . Here, g is the standard gravity. Consequently, the angle $\theta[n]$ could be estimated by (3.9).

$$\theta[n] = \arctan\left(\frac{A_y[n]}{\sqrt{A_x[n]^2 + A_z[n]^2}}\right) \quad (3.9)$$

Finally, the proposed postured-based feature was defined as:

$$WristPost[n] = \text{mean}(\sin(\theta[n])) \quad (3.10)$$

Non-gait dynamicity features – During GB, the wrist acceleration signal is pseudo-cyclic with energy mostly in low-frequency bands. On the other hand, in non-GB, the acceleration signal is somewhat random and erratic, with energy distributed on a broader frequency band. Therefore, like the Signal-to-Noise Ratio, the gait/non-gait power ratio is expected to be higher in the presence of gait than non-gait periods. Consequently, several features were devised to separate GB from dynamic signals that might be observed during non-GB by using the level of “noise” (i.e., non-GB) in the desired signal (i.e., GB). These features are as follow:

$HLR[n]$: This feature is the ratio between the intensity in high to low frequencies, as expressed in (3.11). The frequency threshold was experimentally set to 3.5 Hz to optimize the performance.

$$HLR[n] = \frac{\sum_{f_i \geq 3.5 \text{ Hz}} SA[f_i]}{\sum_{0 < f_i < 3.5 \text{ Hz}} SA[f_i]} \quad (3.11)$$

$ZCR[n]$: The zero-crossing rate in the acceleration norm, expected to be higher for non-GB due to the noisy and erratic nature of the wrist movements. First, the mean value of the acceleration norm within a time window was removed. Then, any linear trends in the resulted signal were discarded using the MATLAB function “*detrend*”. Eventually, the number of zero crosses was counted as feature $ZCR[n]$.

$SEF[n]$: The Spectral Edge Frequency, computed according to (3.12), estimates the frequency where α percent of the acceleration energy is observed below that frequency (Drummond et al., 1991). We found that $\alpha = 70 \%$ provided the best performance in our application.

$$SEF[n] = \min_{f_i} \left(\left| \sum_{j=1}^i NSA[f_j] - \frac{\alpha}{100} \right| \right) \quad (3.12)$$

$RandA[n]$: By assuming that the wrist acceleration is less random during GB than non-GB, the feature $RandA[n]$ was defined according to an autocorrelation-based test presented in (Brockwell et al., 2002) to measure how much the signal is random. According to this test, if a time series comes from a stationary random process (which is almost the case for the acceleration norm of non-GB within a short window of 6 seconds), samples of the autocorrelation of the time series will be mainly bounded between $\pm 1.96/\sqrt{N}$ where N is the number of samples within a time window (i.e., 1200). We defined $RandA[n]$ as the percentage of autocorrelation samples outside the range of $\pm 1.96/\sqrt{N}$. High values of $RandA[n]$ means less randomness of the signal.

$Kurtosis A[n]$: Kurtosis is a statistical measure quantifying how much the distribution of data is outlier-prone (Westfall, 2014). We hypothesized that the acceleration norm of non-GB contains more outliers than GB due to the acceleration’s higher randomness. Therefore, the kurtosis of the acceleration norm within a time window was computed as another feature.

Eventually, for each time window n , $H[n]$ was built as the feature vector, including all selected features.

3.3.3.3 Bayes estimator

We evaluated several models such as the Bayes, decision tree, SVM, and NN for the GB detection on the training data. We experimentally chose the Bayes approach since it

showed the best performance. Besides, the Bayes approach is fast and straightforward enough for a hardware implementation inside a wristwatch for real-time onboard computations. Consequently, each window's probability of gait occurrence is estimated using the Bayes estimator (3.13).

$$P_{Bayes}[n] = P_{G|H[n]} = \frac{P_G P_{H[n]|G}}{P_G P_{H[n]|G} + P_{NG} P_{H[n]|NG}} \quad (3.13)$$

Where $P_{G|H[n]}$ is the probability of gait occurrence conditioned on the observed feature vector, $H[n]$. Also, $P_{H[n]|G}$ and $P_{H[n]|NG}$ are the probabilities of occurrence of $H[n]$ within the gait (G) and non-gait (NG) classes, respectively. Furthermore, P_G and P_{NG} are respectively prior probabilities of gait and non-gait occurrences. We considered multivariate multinomial distributions (function “*mvmn*” in MATLAB) for the Bayes estimator. Moreover, to manage the intrinsic imbalances of samples between GB and non-GB (in real-world situations, non-GB are significantly more frequent than GB), we took advantage of the Laplace smoothing parameter (Liu and Martin, 2011) as follows:

$$P_G = \frac{N_G + l}{N_G + N_{NG} + 2l} \quad (3.14)$$

$$P_{NG} = \frac{N_{NG} + l}{N_G + N_{NG} + 2l} \quad (3.15)$$

Where N_{NG} , and N_G are the total number of samples observed for non-GB and GB, and l is a smoothing parameter, empirically fixed to $(N_G + N_{NG})/10$.

3.3.3.4 Temporal-based probability modification

We took advantage of the information on past-detected activities to increase the certainty of the decision made for the current activity. As shown in Figure 3.4, assume that $q[n-1]$ and $d[n-1]$ are the type and the duration of the last activity detected up to window $n-1$ (i.e., the last activity was started from window $n-d[n-1]$ to window $n-1$). $P_{q[n]=q[n-1]|d[n-1]}$ is also the probability of having the same activity in window n (i.e., $q[n] = q[n-1]$) knowing the type ($q[n-1]$) and duration ($d[n-1]$) of last activity.

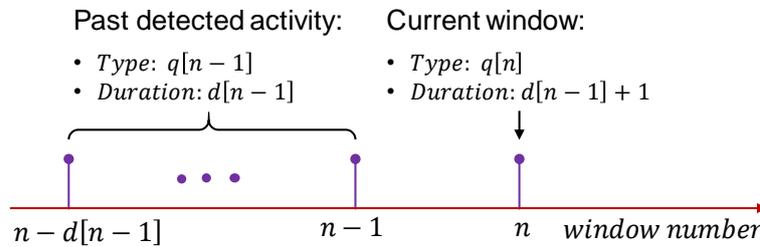

Figure 3.4 – Procedure developed to update the probability of gait occurrence of the current window using temporal information of the past detected activities. q and d are the type and duration of activities.

To this end, two exponential functions (see (3.16) and (3.17)) were fit to probability distribution function of the duration of GB and non-GB specific to daily life.

$$P_{q[n]=G|d[n-1]} = \beta_G e^{-\tau_G(d[n-1]+1)} + \gamma_G e^{-\rho_G(d[n-1]+1)} \quad (3.16)$$

$$P_{q[n]=NG|d[n-1]} = \beta_{NG} e^{-\tau_{NG}(d[n-1]+1)} + \gamma_{NG} e^{-\rho_{NG}(d[n-1]+1)} \quad (3.17)$$

Here, the parameters of the functions (i.e., $\beta_G, \gamma_G, \tau_G$) were obtained from the training session of the method. The exponential distributions were chosen due to their essential properties (Balakrishnan, 2018), such as: (i) ability to describe samples including many small values and a few large values (as empirically observed for the duration of real-life GB (Orendurff et al., 2008; Paraschiv-Ionescu et al., 2013)), (ii) great mathematical tractability. Then, since the probability given by the Bayes estimator (P_{Bayes}) was generally more reliable than $P_{q[n]=q[n-1]|d[n-1]}$ due to using several features obtained from acceleration signal, the modification effect of $P_{q[n]=q[n-1]|d[n-1]}$ was reduced by a linear mapping into a shorter range of [0.05, 0.20] (experimentally adjusted) through (3.18) to obtain $\tilde{P}_{q[n]=q[n-1]|d[n-1]}$.

$$\tilde{P}_{q[n]=q[n-1]|d[n-1]} = 0.15 P_{q[n]=q[n-1]|d[n-1]} + 0.05 \quad (3.18)$$

Eventually, the modified probability of gait occurrence (P_T) of time window n was computed through (3.19) where the function “*min-max*” was used to limit the probability to the range of [0,1], where ψ was defined according to (3.20).

$$P_T[n] = \min(\max(P_{Bayes}[n] + \psi \tilde{P}_{q[n]=q[n-1]|d[n-1]}, 0), 1) \quad (3.19)$$

$$\psi = \begin{cases} +1, & q = G \\ -1, & q = NG \end{cases} \quad (3.20)$$

3.3.3.5 Smart decision making

When $P_T[n]$ is far enough from 0.5, it is easy to decide if the window n is gait or not. However, making a decision is challenging when $P_T[n]$ is close to 0.5, which could happen in the proximity of transients between the activities since a part of the feature window is gait and the other part is non-gait. Consequently, we designed the following algorithm to make a smart decision based on $P_T[n]$. If $P_T[n] < 0.3$ or $P_T[n] > 0.7$, the decisions were NG or G, respectively. We called these windows as reliable windows. On the other hand, if $0.3 \leq P_T[n] \leq 0.7$ (called ambiguous windows), then we analyzed the period between the last and next reliable windows. Imagine for ambiguous window n , windows m , and k are respectively the last and next reliable windows ($m < n < k$, see Figure 3.5). If $k - m + 1 \leq 10$, then we changed the threshold of decision making from conventional 0.5 to $1 - \text{mean}(P_T[m < n < k])$. Otherwise, decisions were G or NG if $P_T[n] > 0.6$ or $P_T[n] < 0.4$, respectively, and for $0.4 \leq P_T[n] \leq 0.6$, the last reliable decision was assigned to window n (i.e., $L[n] = L[m]$).

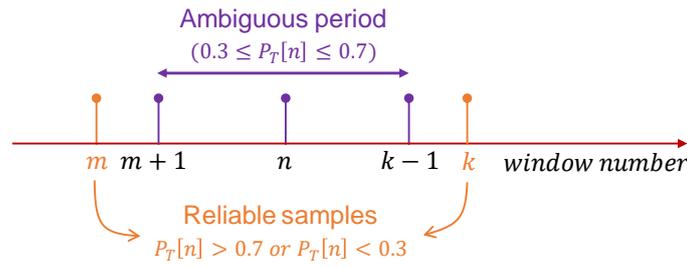

Figure 3.5 – An example of an ambiguous period and its reliable samples. We defined 10 samples as the maximum duration of an ambiguous period.

Table 3.1 briefly explains the algorithm of the proposed smart decision-making. In the worst-case scenario, the algorithm could impose a maximum delay of 10 seconds (10 shifts of 10 overlapped windows) to the whole system, which is acceptable for the system’s real usage (i.e., GB detection) in real-life situations.

Table 3.1 – Assigning activity label (G or NG) to window n according to $P_T[n]$. Here, m and k are the number of last and next reliable windows for window n , respectively.

```

START
IF  $P_T[n] > 0.7$ , THEN  $L[n] = G$ 
IF  $P_T[n] < 0.3$ , THEN  $L[n] = NG$

ELSE  $L[n] = L[m]$ 
END
    
```

3.3.4 Cross-validation and error computation

The proposed method was validated against a reference system (Paraschiv-Ionescu et al., 2004). Well-known leave-one-subject-out cross-validation was applied where the model was trained using data of all subjects except one and tested with the one absent in the training dataset. This procedure was repeated until all subjects were selected once to be in the test set. The algorithm was tested on both young (M1) and old (M2) healthy populations. Furthermore, to evaluate the generalization ability, the model was trained on M1 and tested on M2 (and vice versa). We compared the reference results with the proposed wrist-based method with a resolution of 1 second in all cases. In the dataset M2, due to clock drift of the sensors, the shank-IMU signals were not well synchronized with the wrist IMU, and up to a 10-second shift was observed.

Consequently, to compare the wrist’s results and the reference in this dataset (i.e., M2), we considered one sample tolerance. It means that each sample of the wrist-based method was compared with three samples of the reference method (i.e., one sample before and after the current sample), and if only one of those samples matched the wrist method, it was counted as a correct decision.

Standard performance parameters such as sensitivity (also known as recall, the detection rate in class G), specificity (detection rate in class NG), accuracy, precision, and F1-score were computed according to (3.21) to (3.25).

$$Sensitivity = \frac{T_P}{T_P + F_N} \times 100 \quad (3.21)$$

$$Specificity = \frac{T_N}{T_N + F_P} \times 100 \quad (3.22)$$

$$Accuracy = \frac{T_P + T_N}{T_P + T_N + F_P + F_N} \times 100 \quad (3.23)$$

$$Precision = \frac{T_P}{T_P + F_P} \times 100 \quad (3.24)$$

$$F1 = \frac{2 \times T_P}{2 \times T_P + F_P + F_N} \times 100 \quad (3.25)$$

Where T_P , T_N , F_P , F_N were true positives, true negatives, false positives, and false negatives, respectively. These performance parameters all together provide a proper evaluation of the proposed method, especially on imbalanced real-life datasets (Branco et al., 2016; Sun et al., 2009). Moreover, since the time window necessary for robust feature extraction is 6 seconds, we ignored the activities shorter than 6 seconds for both reference and wrist algorithms for the computation of the performance parameters. Spearman rank correlation method was used to compute correlations between parameters (Kendall, 1938). Additionally, the median and IRQ of each parameter were computed. The number of non-zero coefficients reported by LASSO during 100 iterations was computed as a score, showing each extracted feature’s importance. The higher value of the LASSO score means the higher importance of the feature for classification.

3.3.5 Real prototype implementation

To show the feasibility of a hardware implementation of the proposed method and to evaluate the power consumption, we developed a real prototype of the proposed method using commercial electronics components. Due to implementation constraints, the prototype employed only 8 features (NI , $MeanA$, $SAmax$, $DomSAmax$, Cad , $WristPost$, ZCR , $RandA$) and worked with a sampling frequency of 20 Hz. It should be noted that

the real prototype was used only to evaluate power consumption. For the rest of the analysis, the set of all 13 features was used.

3.4 Results

The following subsections report the results obtained from applying the proposed method on 1283 hours of free-living PA recorded in 66 young and old participants (datasets M1 and M2).

3.4.1 Performance of GB detection

For one representative subject (#1 from dataset M1), Figure 3.6 gives insight into the decisions made in daily life by the proposed wrist-based method and the reference. Due to the reference algorithm's limitations, it was not possible to know what exactly activities B1-B14 were, only whether they were gait or not. As illustrated, during typical gait with swinging arm (e.g., bouts B1 plus the first part of B5, B7, B9, B11, and B13), the proposed method correctly detected all the GB. Besides, when the subject and the wrist were motionless (e.g., the first part of bout B2 and the middle part of bout B6), non-GB was detected entirely. Interestingly, the proposed method dealt with challenging periods when the subject did not engage in gait activity, but the wrist was moving (e.g., the beginning and end of B6, B8, B10, and B14). Nevertheless, the wrist's abnormal movements caused few misclassifications due to the wrist's vast freedom of motion (e.g., bouts B3 and B12).

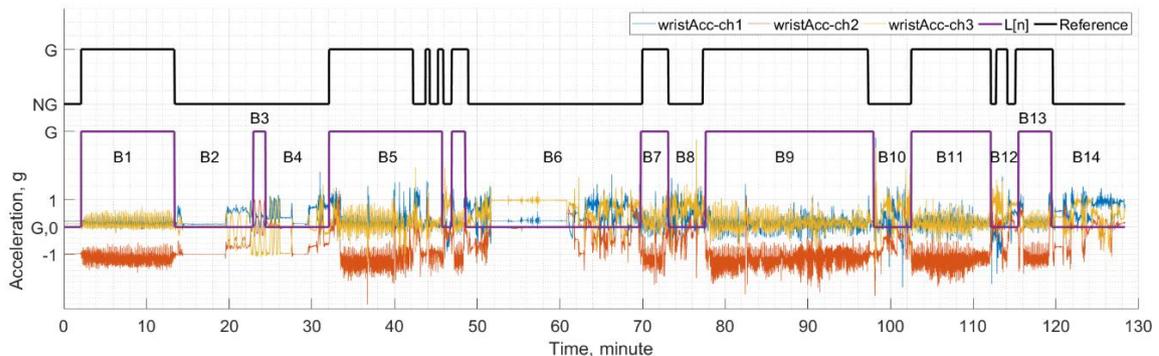

Figure 3.6 – An illustration of the wrist acceleration recorded during daily life and the decisions made by the reference (black) and the proposed wrist-based method (purple, $L[n]$) for subject # 1 from the dataset M1. Here, B1, B2, ..., B14 are arbitrary names assigned to each bout for referring purpose.

In order to show the generalization ability, we evaluated the proposed method through different combinations of training and test sets using M1 and M2 datasets (Table 3.2). When training and testing sets were the same, we employed the leave-one-subject-out cross-validation strategy. The confusion matrix (Table 3.3) was also estimated by considering both datasets (M1 and M2).

Table 3.2 – Overall performance of the proposed method under different training and test conditions for activities longer than 6 seconds. Median (IQR) values in % are reported.

Train	Test	Sensitivity	Specificity	Accuracy	Precision	F1-score
M1	M1	93.6 [90.7 , 97.5]	97.9 [96.6 , 98.5]	97.3 [95.8 , 98.0]	82.8 [80.1 , 87.0]	88.3 [81.4 , 90.4]
M1	M2	72.2 [54.7 , 80.6]	99.0 [98.3 , 99.5]	96.6 [95.1 , 97.9]	88.5 [72.1 , 92.7]	75.4 [61.4 , 84.4]
M2	M1	89.7 [81.9 , 94.8]	99.0 [98.4 , 99.4]	98.0 [97.0 , 98.5]	91.5 [87.2 , 94.3]	89.9 [82.2 , 91.8]
M2	M2	87.1 [72.6 , 91.8]	96.7 [95.5 , 97.6]	95.2 [94.1 , 96.7]	71.8 [56.4 , 76.3]	74.9 [63.6 , 83.6]
M1 & M2	M1 & M2	90.2 [80.4 , 94.6]	97.2 [95.8 , 98.4]	96.6 [94.4 , 97.8]	80.0 [65.1 , 85.9]	82.6 [72.6 , 88.5]

Table 3.3 – Confusion matrix of the proposed method using both datasets m1 & m2 as training-test sets. All values are presented in hours.

Confusion matrix	Wrist method		Total (reference)	
	Gait	Non-Gait		
Reference	Gait	131.6	17.0	148.6
	Non-Gait	30.1	1105.0	1135.1
Total (wrist)		161.7	1122.0	1283.7

For testing the proposed algorithm’s sensitivity to experimentally-adjusted parameters, 10 % changes were applied on the frequency threshold in $HLR [n]$, the α in $SEF [n]$, and the l in the Bayes estimator (all individually tested). We observed a maximum of 0.1 absolute changes (with 0.1 IQR) in the median sensitivity and no more than 0.2 (with 0.4 IQR) in precision and F1-score, while specificity and accuracy remained unchanged.

The Probability Density Function (PDF) of features within each class (gait: blue, non-gait: red) are displayed in Figure 3.7. Here, the features are grouped based on the biomechanical criteria used to define them. Moreover, the models built by the Bayes estimator (through training) on each feature to detect GB (green curve) and non-GB (black curve) classes are also displayed. The LASSO scores are also reported, which determine the importance of each feature.

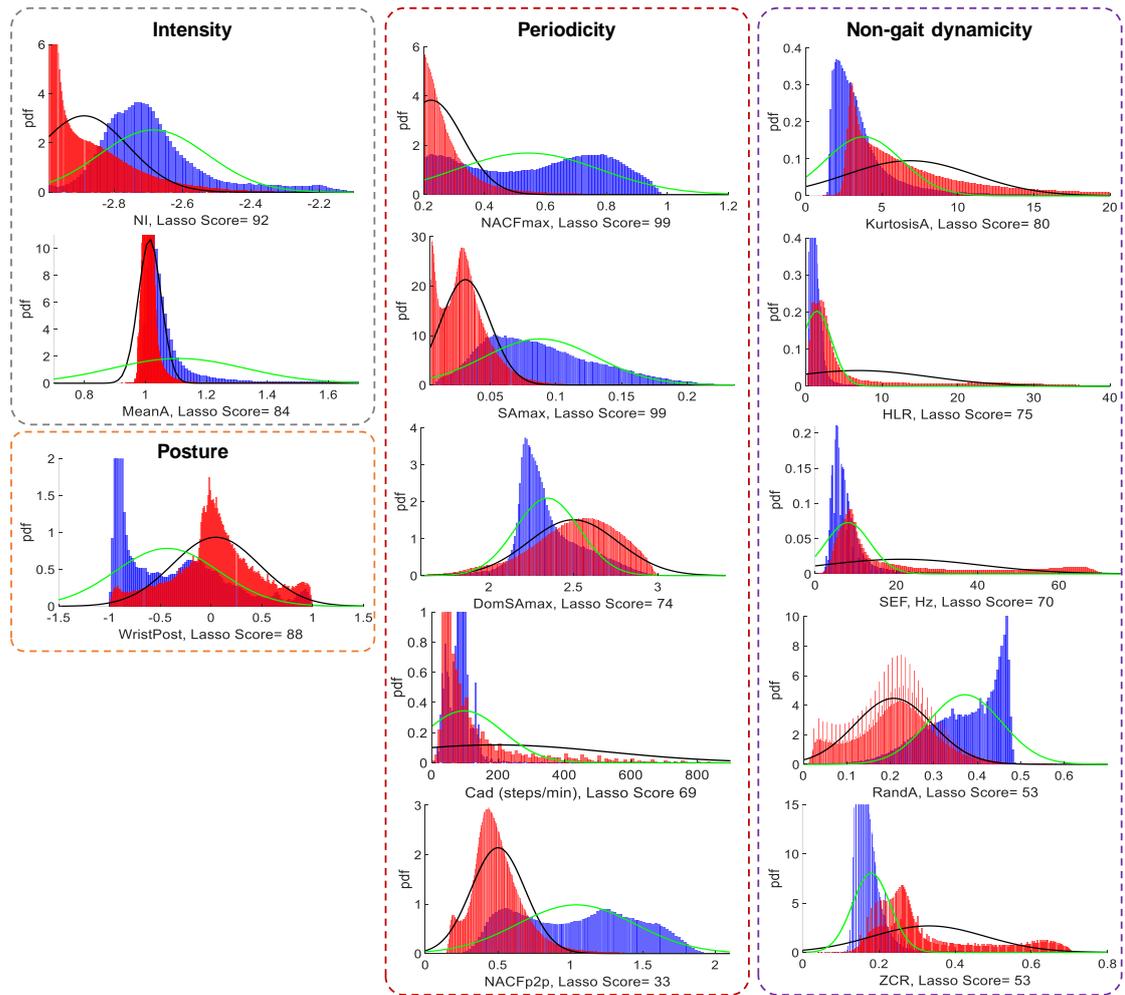

Figure 3.7 – PDF of the extracted features within each class (gait: blue, non-gait: red) based on different biomechanical criteria. In addition, the models built by the Bayes estimator on each feature for GB (Green) and non-GB (Black) are presented. The LASSO score of each feature is also reported.

As the proposed method is based on a wrist-worn sensor, it is essential to evaluate and compare the performance between the left and right wrists. Table 3.4 reports the performance parameters in the dataset M1, where the participants wore accelerometer sensors on both wrists simultaneously.

Table 3.4 – Performance of the proposed method on wrists left and right using dataset m1. Median (IQR) in % is reported.

Wrist	Sensitivity	Specificity	Accuracy	Precision	F1-score
Left	94.2 [87.7,98.1]	97.9 [96.7,98.7]	97.3 [96.0,98.1]	84.0 [81.9,89.5]	87.9 [82.2,90.6]
Right	93.5 [90.7,97.1]	97.9 [96.2,98.3]	97.2 [95.3,97.9]	82.2 [80.0,86.6]	88.2 [81.0,90.0]

3.4.2 Effect of bouts duration on performance

As shown in Figure 3.8, the Spearman test demonstrated a high correlation ($R^2 = 0.95$) between the total (summed) duration of GB of each subject detected by the proposed wrist-based method and the reference, using both datasets M1 and M2.

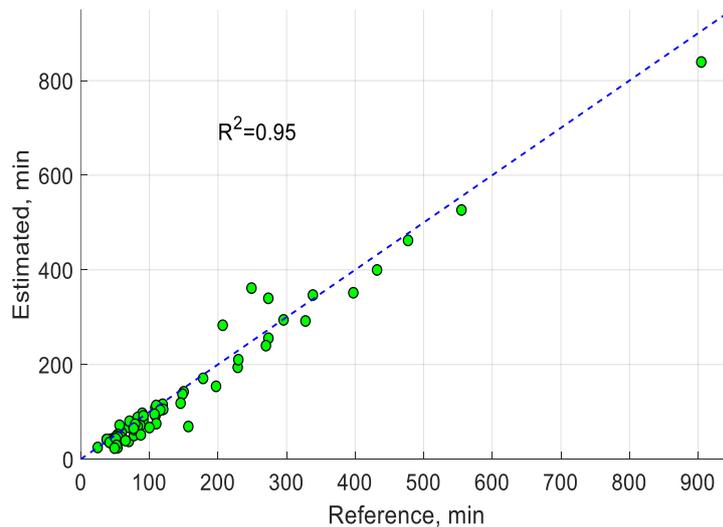

Figure 3.8 – High correlation observed between the estimated versus reference values for the total duration of GB of each subject in datasets M1 and M2. Here, each point represents one subject.

More specifically, the proposed method showed a median [IQR] error of +12.6 [2.9 – 27.3] minutes (14 [6 – 26] %) for the estimation of the total duration of GB of each subject. Note that the reference reported a median [IQR] of 73.6 [45.1 – 153.0] minutes for the total duration of GB of each subject. Figure 3.9 displays the higher sensitivity of the proposed method for longer GB while the specificity remains almost constant.

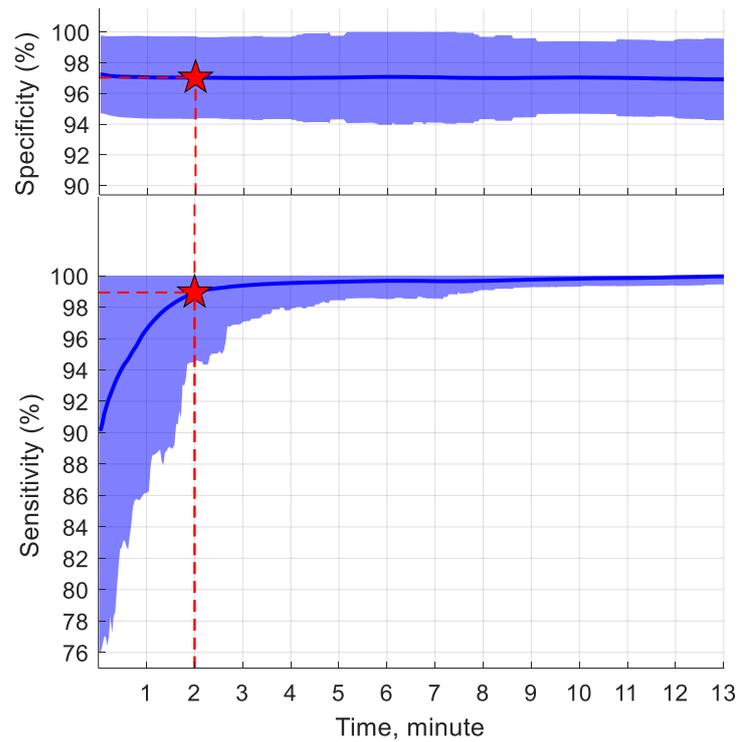

Figure 3.9 – Performance of the proposed method versus duration of GB. Here, the dark curves and shadows indicate inter-subjects' median and IQR of the specificity and sensitivity. For example, the red stars show median sensitivity and specificity of around 99 % and 97 %, respectively, for the proposed method in detecting GB longer than 2 minutes.

3.4.3 Power consumption and computation time

We employed a low-power accelerometer (MC 3635, mCube Inc.) as well as an ARM microprocessor (nRF52840, @ 64MHz, Cortex-M4) including 256kB RAM and 1MB FLASH memory (see Figure 3.10) in the designed prototype. Our analysis shows around 135.5 mAh power consumption of the proposed method for practical usage during a whole year. Moreover, the computation time for processing one feature window (6 seconds at 20 Hz, resulting in 120 samples) is around 1 ms.

Figure 3.10 – Proposed method's real prototype. The main goal is to show the feasibility of a hardware implementation of the method and evaluate power consumption.

3.5 Discussion

In this study, an accurate and precise algorithm was devised to recognize GB and estimate their durations using a single low-power accelerometer mounted on the wrist in unsupervised real-world situations. Two different datasets (younger and elderly, recorded in free-living conditions) were employed to validate the proposed algorithm. Moreover, the importance of the features, the effect of GB duration, and wearing the sensor on the left/right wrist were investigated.

The proposed method was highly capable of following the shank-based reference algorithm (see typical example in Figure 3.6). Almost all GB with arm swing was correctly recognized (e.g., bouts B1, B7, B9, B11, and B13). These GB should probably occur during outdoor where regular arm swing exists to reduce energetic cost and facilitate the leg's movement (Meyns et al., 2013). Moreover, the results in Figure 3.6 demonstrate that the proposed method dealt with challenging arm-in-motion non-GB that could frequently occur in daily life (e.g., B6, B8, B10, and B14). The proposed method might miss a few short-duration bouts (e.g., end of B5) mainly due to performing a window-based analysis (6 seconds). Eventually, non-GB in which the arm has a periodic movement with a period similar to the gait (0.5-2 seconds) could challenge the proposed method. Our analysis demonstrated that the algorithm is robust to variations ($\pm 10\%$) of the experimentally-adjusted thresholds. This result is important, mainly when the algorithm is applied to complex and complicated real-world situations where acceleration patterns might vary significantly.

In order to obtain sufficient activity diversity, the method was validated on two different free-living datasets, M1 (young and active) and M2 (older and less active). When only dataset M1 was used for training, the proposed method obtained the highest performance on the same dataset (Table 3.2), but the performance dropped on the M2 dataset. Using the M2 dataset for training, the method reached almost an acceptable performance on both datasets. Better results were achieved when both M1 and M2 were employed to train the proposed method. Under this condition, the proposed method achieved a median and IQR of 90.2 [80.4, 94.6], 97.2 [95.8, 98.4], 96.6 [94.4, 97.8], 80.0 [65.1, 85.9], and 82.6 [72.6, 88.5] % for the sensitivity (recall), specificity, accuracy, precision, and F1-score of detection of GB, respectively. A higher value of sensitivity than precision indicates that the proposed method is more sensitive in detecting gait than non-GB. Therefore, the misdetection of non-GB as gait was more frequent than vice versa. This result ensures that the method successfully detects most of the GB, which is crucial in daily life where there is a limited GB number. As Table 3.3 specifies, for more than 1280 hours of recording of free-living PA, including 148 hours of GB, only 17 hours of GB were missed, less than 11 %. For non-GB, the performance was much better, where only around 3 % of the bouts were misclassified.

According to Figure 3.7, the PDF of the biomechanically-derived features (i.e., intensity, periodicity, posture, and non-gait dynamicity) illustrated a high ability of the selected

features to distinguish between gait and non-GB. The LASSO scores showed that *NACFmax*, *SAMax*, *NI* and *WristPost* are among the best features. In addition, the periodicity was a better criterion to separate GB and non-GB. As illustrated in Figure 3.8, a high correlation (0.95) was observed between wrist and reference methods for the total duration of GB of each person, indicating that the proposed method could accurately estimate how long a person is engaged in gait during the monitoring time. However, the wrist-based method showed a slight overestimation (around +13 min, where the subjects had a median total gait duration of 75 min). One reason for this overestimation could be using the Laplace parameter to determine the prior probability of GB and non-GB classes for the Bayes estimator. This issue should be considered when the method is applied for clinical assessment, primarily when patient populations with critically limited numbers and GB durations are targeted. Analysis of data from the left and right wrists (Table 3.4) illustrated that sensor location does not significantly affect the results.

According to Figure 3.9, the proposed method shows significantly higher performance (mainly sensitivity) for more prolonged GB than short ones. For GB longer than 2 minutes (probably occurring outdoor), the method could detect almost all activities correctly (99 %). However, the detection of short GB, especially around 6 seconds, was challenging. One reason could be the acceleration signal's higher stability within a window (6 seconds) in long GB. Moreover, short GB happens mainly in indoor situations where more artifacts (e.g., sudden stops, turns, transients) exist. Another point is that, since the number of long non-GB is usually much more significant than the number of short non-GB, the specificity does not change a lot through removing short duration non-GB.

Using only one low-power accelerometer, and optimizing features computation and code implementation techniques, an optimized implementation of the proposed method showed a very low power consumption (135.5 mAh per year) in real-world conditions. The implemented method offers around one year of continuous GB detection with a primary normal battery cell (250 mAh). This high autonomy is an excellent advantage since many medical and sports applications crucially need long-duration PA measurements in real-life situations. Moreover, the simplicity of the proposed method and its low computation time (1 ms per window) offers the possibility of real-time and onboard analysis of PA, allowing for generating real-time feedback that could be important in many clinical and interventional applications.

Compared to previous works, the proposed method has obtained an excellent performance, considering that only one single accelerometer sensor mounted on the wrist was used, which is challenging for GB detection in real-world situations. For a fair comparison of the results, only a few works have been validated in free-living situations (Awais et al., 2019; Hickey et al., 2016). The authors in (Awais et al., 2019) have employed 22 features extracted from wrist-worn accelerometer and gyroscope sensors to classify four types of PA in daily life (walking, standing, sitting, lying) and

obtained accuracy and F-measure of 75.8 and 58.1 %, respectively. They also used multiple IMU, mounted on the thigh and LB, which achieved accuracy and F-measure of 96.8 and 88.1 %, respectively. Another study (Hickey et al., 2016) performed GB detection in real-life situations based on BM to obtain an absolute intra-class correlation of 0.94 using a single accelerometer attached to the LB. Unfortunately, none of the mentioned methods reports the sensitivity and specificity parameters.

Most previous works have validated their algorithms only in supervised (e.g., in a controlled laboratory setting) or semi-supervised (e.g., simulated real-life) situations. Table 3.5 lists some of the methods, which are particularly wrist-based for classification of PA. They employed long (e.g., 2-5 minutes) and clean trials of PA in a pre-defined sequence to test their methods. It is shown that the validation of PA detectors in real-world situations will lead to a significant performance drop (up to 20 %) of the performance (Ermes et al., 2008; Ganea et al., 2012; Gyllensten and Bonomi, 2011). Even in this unfair situation, the proposed method overtakes the existing algorithms using fewer features and sensors, providing a high autonomy of one year. Besides, the method works in real-time, where a small portion of data (6 seconds) with limited resources is used.

Table 3.5 – Performance of recent wrist-based methods developed for classification of PA in supervised or semi-supervised situations. “Acc.,” “Gyr.,” and “Pres.” are the accelerometer, gyroscope, and barometer.

The proposed method, validated in unsupervised daily situations in young and elderly subjects, offers a high potential to be used in clinical settings to monitor patients with activity restrictions due to various diseases. For instance, the system is currently being used in a large population of older adults to characterize the distribution of daily GB and the effect of various factors such as aging, obesity, and frailty on the quality and quantity of PA in daily life situations. More importantly, the proposed method could be used as a primary stage of many PA analysis algorithms where accurate GB detection

is needed, such as cadence (Fasel et al., 2017a) and speed (Soltani et al., 2019) estimations.

3.6 Conclusions

This study presented an accurate and precise method for detecting GB in free-living situations using wrist acceleration data. We extracted biomechanically-derived features integrated with the Bayes classifier, followed by two physically meaningful post-classification stages, to deal with the difficulties posed by the wrist's movements in real-world situations. Such a wrist-based, low-power, and calibration-free system offers a versatile measurement tool with high usability and autonomy, perfect for long-term monitoring PA in free-living situations. Besides, the simplicity of the proposed method and being real-time allows the implementation of the method inside a wristwatch, increasing the user's compliance and satisfaction. The watch also could provide meaningful online feedback to users in daily life to promote an active lifestyle.

4 Real-world gait speed estimation using a wrist sensor: A personalized approach¹

4.1 Abstract

Gait speed is an important parameter to characterize people's daily mobility. For real-world speed measurement, GNSS or IMU could be used on the wrist, possibly integrated into a wristwatch. However, the power consumption of GNSS is high, and data are only available outdoor. Gait speed estimation using a wrist-mounted IMU is generally based on ML. This approach suffers from low accuracy due to the inadequacy of using limited training data to build a general speed model that is accurate for the whole population. In order to overcome this issue, a personalized model was proposed, which took each subject's unique gait style into account. Cadence and other biomechanically-derived gait features were extracted from the wrist-mounted accelerometer and barometer. Gait features were fused with few GNSS data (sporadically sampled during gait) to calibrate each subject's step length model through online learning. The proposed method was validated on 30 healthy subjects where it has achieved a median [IQR] of RMSE of 0.05 [0.04-0.06] m/s and 0.14 [0.11 0.17] m/s for walking and running, respectively. The results demonstrated that the personalized model provided similar performance as GNSS. It used 50 times less training GNSS data than the non-personalized method and achieved even better results. This parsimonious GNSS usage allowed extending battery life. The proposed algorithm met requirements

4.2 Introduction

Gait speed is among the most important parameters to characterize people's daily mobility. It is a primary outcome in aging and is associated with survival in elderly subjects (Del Din et al., 2016a, 2016b; Elble et al., 1991). In clinical applications, gait speed is employed to characterize orthopedic diseases, to quantify impacts of intervention, to design functional assessments after treatment, and to predict the risk of falling (Maki, 1997; Perera et al., 2015; Quach et al., 2011; Rochat et al., 2010; Salarian et al., 2004; Weiss et al., 2014). Gait speed is also used in sports to design personalized training sessions and evaluate athletes' performance (Norris et al., 2014).

For accurate measurement of instantaneous speed, camera-based motion capture systems and instrumented walkways with pressure sensors were introduced (Balasubramanian et al., 2007; Chen et al., 2016; Hirokawa and Matsumara, 1987). However, apart from being restricted to the laboratory, these need considerable time for preparation, measurement, and post-processing. Gait features (e.g., step length) significantly differ between free-living and laboratory conditions; one might have shorter gait distances in the latter (Bonato, 2005; Brodie et al., 2016; Robles-García et al., 2015). It is shown that a few steps of a person in a controlled laboratory setting cannot completely represent his/her real performance during daily life (Organization, 2002). For objective outcome evaluation, knowledge about patients' mobility in the real-world is more important than short clinical visits and tests (Dobkin and Dorsch, 2011; Weiss et al., 2011). Consequently, it is crucial to develop gait speed measurement systems for real-life conditions.

GNSS is the first choice to measure gait speed in everyday situations. It offers ambulatory speed and position measurements with high accuracy (0.05 m/s of error) (Fasel et al., 2017a; Terrier et al., 2000; Witte and Wilson, 2004). However, the GNSS receiver has high power consumption, limiting its usefulness as a portable device when long-duration measurements are required. Besides, communicating with satellites might not be possible in situations like indoors, near high buildings, and narrow valleys.

IMU (including accelerometer, gyroscope, and possibly barometer and magnetometer) has been used to estimate gait speed based on movements of the lower or upper body, like feet (Rampp et al., 2015; de Ruiter et al., 2016; Sabatini et al., 2005), shanks (Aminian et al., 2002; Del Din et al., 2016b; Salarian et al., 2013; Tong and Granat, 1999), thighs (Miyazaki, 1997; Yeoh et al., 2008), trunk (Moe-Nilssen and Helbostad,

2004; Zijlstra and Hof, 2003), and waist (Aminian et al., 1995b; Hu et al., 2013). In some cases, data captured from multiple IMU (located at different parts of the body) were fused to achieve better performance (Alaqtash et al., 2011; Carcreff et al., 2018; Tao et al., 2012). These systems computed the cadence (number of steps per unit time) by detecting certain events at each gait cycle (e.g., initial and terminal contacts or mid-swing of the foot). Step length was also estimated through either modeling of human's gait (Aminian et al., 2002), DI of acceleration (Sabatini et al., 2005), or abstract modeling based on ML (Aminian et al., 1995b; Herren et al., 1999; Yeoh et al., 2008). Eventually, instantaneous gait speed was obtained by multiplying cadence and step length. Such systems' main advantage was that they provided a relatively accurate estimation of gait speed outside the laboratory in free-living environments. They overcame the GNSS problems by reducing power consumption and being independent of external sources (i.e., satellites). However, they are not as accurate as GNSS. They might also suffer from inconvenient sensor fixation (e.g., skin patch or elastic straps), especially when multiple IMU are required, which complicates their use and might need an expert to install them on the body.

A more convenient approach to estimate gait speed would be to wear IMU on the wrist (e.g., as a wristwatch). The wrist IMU location could offer several advantages: usability, comfort, and a handy user interface. However, contrary to the trunk and lower limbs, the association between the wrist movements and locomotion is not straightforward, especially during daily activities. The hand might be motionless (e.g., in a pocket, carrying a bag) during gait or moving during rest (e.g., sitting or standing). These “*independent*” movements of the arm are potentially a severe challenge for accurate wrist-based speed estimation. This issue is also confirmed by limitations of speed estimation algorithms in many accelerometer-based smartwatches, targeting the consumer market, and probably why the hand has hitherto not been favored for IMU location to estimate speed in research or clinical settings (Evenson et al., 2015).

A few methods have recently been introduced in the existing literature to estimate gait speed based on a single wrist-mounted IMU. These methods extracted several features from raw sensor data and then mapped them to the gait speed through linear or non-linear modeling. Generally, the features were chosen to indicate intensity, energy, cadence, and mean/zero-crossing rate. However, statistical features, such as mean, STD, mode, and median of acceleration norm, have also been employed (Bertschi et al., 2015; Delgado-Gonzalo et al., 2015; Duong and Suh, 2017a; Fasel et al., 2017a; Park et al., 2012; Renaudin et al., 2012; Zihajehzadeh and Park, 2016). Altitude changes, measured by a barometer, were also used as a feature to improve gait speed estimation (Fasel et al., 2017a). In order to model the gait speed, several ML approaches have been tested. The approaches include Gaussian Process Regression (Zihajehzadeh and Park, 2016), LASSO regularized least squares regression (Zihajehzadeh and Park, 2016), (Renaudin et al., 2012), regularized kernel method (Park et al., 2012), and piecewise linear regression (Fasel et al., 2017a).

An essential issue in ML when designing a model is the training strategy. In general, a subsample of a population is considered to train a general model optimized for all individuals belonging to the entire population. Such an approach does not consider individual strategies involved in gait modulation. For instance, one might change speed by controlling cadence, whereas another might vary step length for the same purpose. Therefore, a population-based training approach cannot perform well for all gait styles, and there is a need to personalize the speed model to each individual.

The usefulness of personalization in gait speed estimation has been shown in a few previous works (Altini et al., 2014; Barnett and Cerin, 2006; Mannini and Sabatini, 2014). Generally, they improved estimation of speed by using a reference value (e.g., from the GNSS or marked walkway) to collect a bunch of data from each user. They calibrated their general speed model to the specific user by applying an offset or scaling factor to the model. However, such approaches' main drawback was that they collected their personalization data only from a very short walking period and/or in a controlled setting. The gait speed might vary due to changes in seasons and living environments. Moreover, all these studies are based on offline personalization, which means that they need all personalization data to calibrate the speed model once.

This study aims to design and validate a method based on a single wrist-mounted accelerometer and barometer for accurate and precise estimation of instantaneous speed during real-world walking and running. We hypothesize that a personalized speed model is feasible and will improve the performance of the system. To this end, when a person is walking or running, we sporadically use the GNSS to acquire few speed data, and then we personalize the speed model to the user's specific gait style through online learning. We propose physically meaningful gait features based on the wrist movement's biomechanics during gait for further improvement. Eventually, we consider real-time and low-power applications' requirements to optimize the gait speed estimation algorithm for subsequent implementation inside a smart wristwatch by proposing a recursive algorithm that uses parsimoniously acquired GNSS samples.

4.3 Methods

4.3.1 Material and Measurement protocol

Thirty healthy and active volunteers (14 women, 16 men, age 37 ± 9 years old, height 172 ± 10 cm, and weight 68 ± 11 kg) participated in this study. Participants wore two time-synchronized IMU (Physilog® IV, GaitUp, CH) on the wrists using elastic straps. The proposed method is based on data from a single wrist. However, we recorded data on both wrists to compare the proposed method's performance between the wrists. Figure 4.1 (A) and (B) show sensor configuration and local coordinate frame of the wrist accelerometer. Sensors recorded 3D acceleration (range ± 16 g) at 500 Hz and barometric pressure at 50 Hz. The accelerometer sensor was calibrated, according to (Ferraris et

al., 1995). Furthermore, as ground truth, a GNSS receiver (CAMM8Q, u-blox, CH) with an external active antenna (ANN-MS, u-blox, CH) was mounted on the head Velcro attached to a cap. The GNSS receiver was set to pedestrian mode with a sampling frequency of 10 Hz.

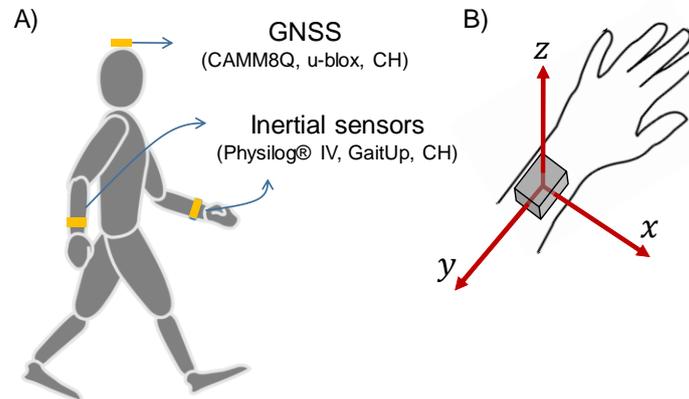

Figure 4.1– A) IMU configuration of the measurement. A single IMU was fixed on each wrist, and the GNSS receiver was used as the reference method. B) Local coordinate frame of the wrist accelerometer.

The measurement protocol consisted of outdoor walking and running in free-living conditions lasting around 90 minutes. In order to cover real-life gait diversity, the activities were performed on various terrain conditions, including uphill, downhill, and flat. Further, the participants were asked to perform the activities at self-adjusted normal, slow, and fast speeds. We manually excluded all rest periods. Figure 4.2 illustrates trial types, elevation profile of the track, and GNSS speed change during the measurement. A local human research ethics committee had approved the proposed protocol.

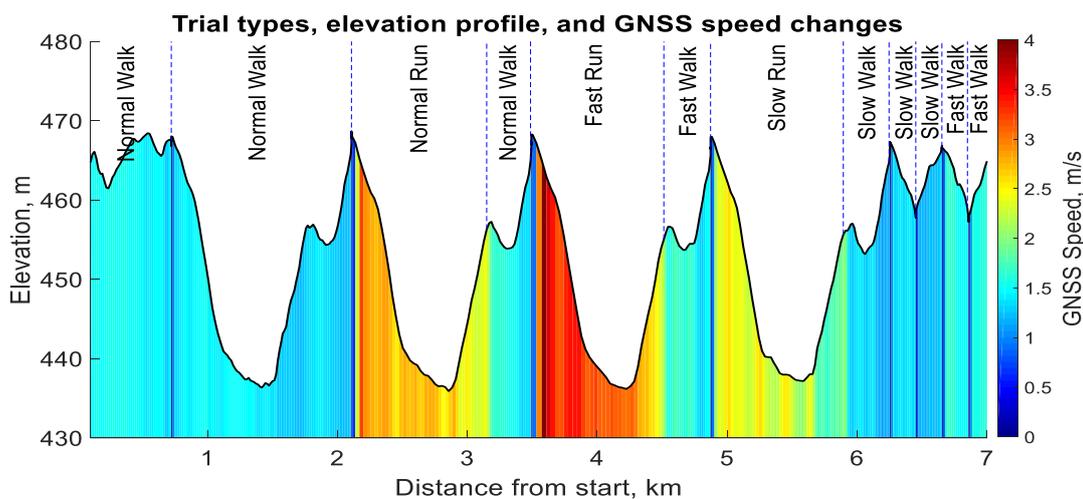

Figure 4.2 – Trial types and elevation profile of the measurement. The color bar shows one example of how the GNSS speed was changed during a whole measurement for one participant (ID #1).

4.3.2 Reference values for speed

The GNSS provided the instantaneous speed at 10 Hz with its corresponding measurement error. As shown in Figure 4.3, we processed the GNSS speed in two steps: enhancement and down-sampling.

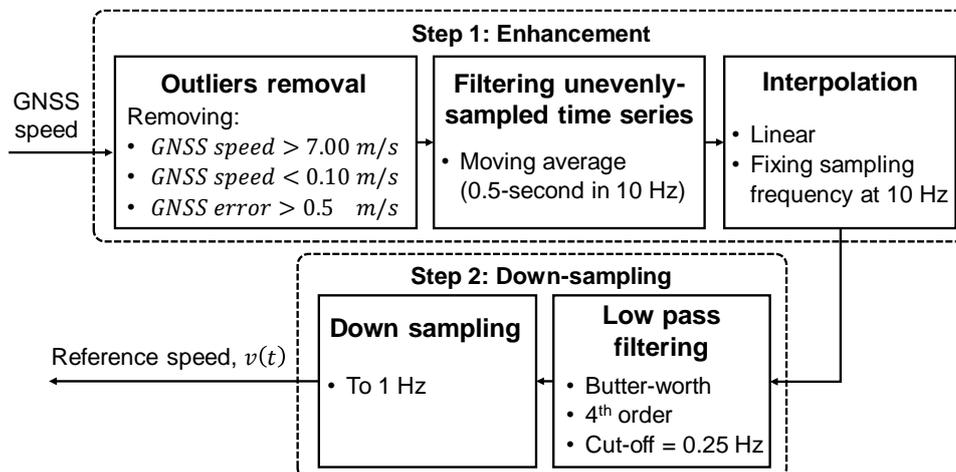

Figure 4.3 – Processing GNSS speed. Step 1: Enhancing the speed samples. Step 2: Down-sampling the speed to 1 Hz required for the wrist-based algorithm.

In the enhancement step, samples of GNSS speed outside the range of $[0.10, 7.00]$ m/s were discarded and not included in neither training nor test. In fact, according to (Berthoin et al., 1994), the maximum speed of regular and long-term running (e.g., marathon) was less than 6 m/s. Besides, based on our manual labels, the GNSS speed values were higher than 0.1 m/s for all GB. GNSS samples with speed less than 0.1 m/s corresponded to non-GB such as shuffling around, standing, and sitting. Here, the reported speed values were in the range of GNSS reported error (i.e., 0.12 m/s, a median error during our measurement), even though the manufacturer reported a speed mean error of 0.05 m/s at 30 m/s. Then, we removed samples with GNSS error higher than 0.5 m/s, which probably occurred due to insufficient satellite coverage. This sample removal and data loss of the GNSS receiver led to an unevenly-sampled time series for the speed signal. Consequently, we filtered both the speed values and the corresponding time instants using a moving average filter with a width of 0.5 seconds (in 10 Hz) to obtain a smoothed signal.

Finally, we used linear interpolation to generate an equally spaced sampled speed time series at 10 Hz. Since the proposed wrist-based speed estimation algorithm needs GNSS speed values at 1 Hz, we designed a down-sampling step. To this end, first, an anti-aliasing fourth-order low-pass Butter-worth filter (with a cutoff frequency of 0.25 Hz) was applied to the signal. Second, the resulting signal was resampled at 1 Hz. The obtained gait speed, $v(t)$, was considered as (i) actual speed values for the personalization procedure provided in section 4.3.3, and (ii) reference speed for validation in section 4.3.4.

4.3.3 The personalized wrist-based speed estimation algorithm

The proposed wrist-based algorithm used the 3D accelerometer signal, $a(t)$, barometric pressure, $p(t)$, and a subset of the reference speed, $v(t)$. Gait speed is the product of step length and cadence. We have already developed an accurate algorithm for cadence estimation (Fasel et al., 2017a). Therefore, instead of modeling gait speed, which involves non-linearity, we modeled step length and multiplied that with cadence. Figure 4.4 shows the block diagram of the algorithm. First, recorded signals were segmented, and relevant features were extracted to estimate step length. Then, the algorithm included two recurrent phases: personalization and estimation. The personalization phase models fluctuations in step length during walking and running due to differences in individual functional ability and specific aspects of the environment. In the estimation phase, the personalized model was used to estimate the speed. A more detailed description of the method is provided below.

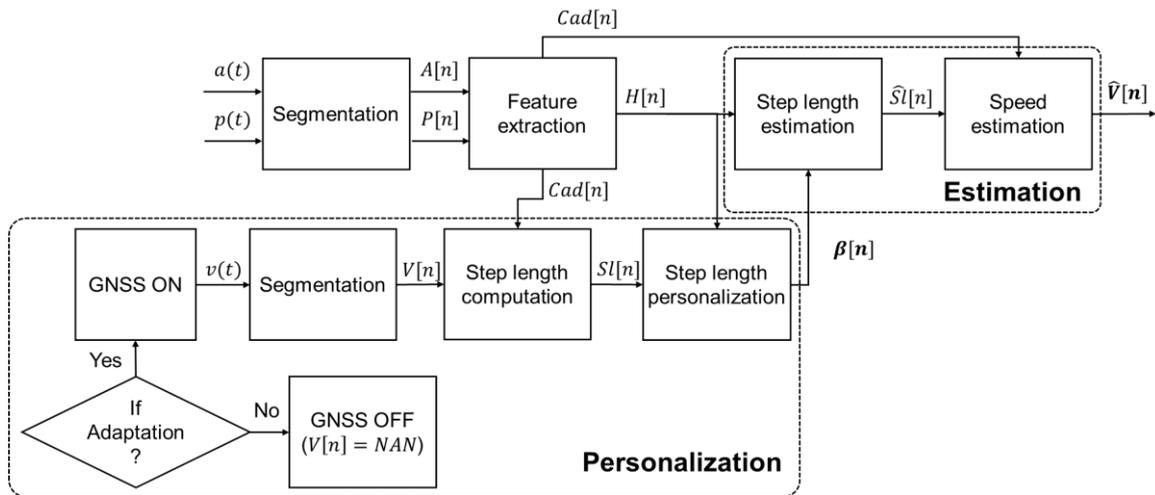

Figure 4.4 – Block diagram of the proposed method. Data were first segmented, and relevant features were extracted. During the personalization phase, the step length model was personalized using the extracted features, and a few speed data sampled randomly for each individual during daily life. In the estimation phase, the step length was estimated using the extracted features, and the most updated model resulted from the personalization phase. Eventually, the speed was calculated using the estimated cadence, $Cad[n]$, and the step length, $\hat{S}l[n]$.

4.3.3.1 Segmentation

First, both $a(t)$ and $p(t)$ were low-pass filtered using a fourth-order Butterworth filter at 4 Hz, according to (Fasel et al., 2017a). Then, the signals were segmented every second using a 7-second moving window with 6-second overlap to provide segmented acceleration, $A[n]$, and pressure signal, $P[n]$, where n indicates window number. $S_x[n]$, $S_y[n]$ and $S_z[n]$ were denoted as segmented acceleration (Figure 4.1 (B)). The

window length was selected to be long enough to have sufficient data for frequency analysis and short enough to provide the required time resolution.

4.3.3.2 Feature extraction

To represent walking and running, we defined various features based on the biomechanics of wrist movement (such as energy, periodicity, and posture) and statistics (like mean, median, STD, and kurtosis). We employed the LASSO feature selection method according to (Tang et al., 2014) to create the best possible features sets for walking and running using the training dataset. Since the movement and posture of the wrist during walking and running are different, two different sets of features were chosen. Consequently, it is necessary to distinguish between walking and running before using the proposed method. In this study, we labeled manually walking and running periods. For running, four features were chosen as follows:

$Cad[n] = Cadence$: It has a high correlation with step length and was estimated based on the algorithm proposed (Fasel et al., 2017a).

$Alt_{\Delta}[n] = Altitude\ change\ of\ the\ path$: While running, gait speed might change with the slope of the path. For instance, longer flight phases might be observed during downhill than a level running. Altitude change of the path was computed within window number n from barometric pressure as the slope of a line fitted to $(-1) \times P[n]$ using the least-squares method, according to (4.1).

$$Alt_{\Delta}[n] = -\frac{\sum_{i=1}^q (i - \bar{i})(P^i[n] - \bar{P}[n])}{\sum_{i=1}^q (i - \bar{i})^2} \times F_s \quad (4.1)$$

Where q is the number of samples within window number n , F_s is the sampling frequency, and $P^i[n]$ is the i -th sample of the pressure vector within window number n . In addition, $\bar{P}[n]$ and \bar{i} are computed based on (4.2) and (4.3).

$$\bar{P}[n] = \frac{1}{q} \sum_{i=1}^q P^i[n] \quad (4.2)$$

$$\bar{i} = \frac{1}{q} \sum_{i=1}^q i \quad (4.3)$$

$E_{S_y}[n] = energy\ of\ acceleration\ along\ axis\ y$: When a person increases his step length, the range of hand movement might increase as well, which leads to an increase in the energy of the acceleration signal along the longitudinal axis of the hand (y in Figure 4.1 B). $E_{S_y}[n]$ was estimated using STD, as shown in (4.4).

$$E_{S_y}[n] = STD(S_y[n]) \quad (4.4)$$

Jerk[n] = Mean absolute jerk: During GB, repetitive impacts appear on the wrist acceleration at the step frequency. The mean absolute value of jerk (time derivative of acceleration) provides information about the load changes of such impacts. We hypothesized that the mean absolute value of jerk (adapted from (Rangayyan and Reddy, 2002)) of axis y would be correlated with step length during running. Equation (4.5) shows how to compute this feature within window n where $S_y^i[n]$ is the i -th sample of vector $S_y[n]$.

$$Jerk[n] = \frac{1}{q} \sum_{i=1}^q |S_y^i[n] - S_y^{i-1}[n]| \quad (4.5)$$

In conclusion, the feature vector for running ($h_{run}[n]$) was defined by (4.6). Our data revealed a non-linearity between altitude change and step length. Therefore, we also included the square of $Alt_{\Delta}[n]$ to the running feature vector.

$$h_{run}[n] = [1 \quad Cad[n] \quad Alt_{\Delta}[n] \quad E_{S_y}[n] \quad Jerk[n] \quad Alt_{\Delta}[n]^2] \quad (4.6)$$

For walking step length estimation, two new walking-specific features were chosen through LASSO, supporting the fact that arm movement's nature during walking and running gives rise to fundamental differences in wrist-recorded acceleration. For instance, during walking, the extended arm and forearm lead to a sort of pendulum swing movement of the wrist in the relative transverse plane of the wrist ($\langle x, z \rangle$), whereas while running, the flexed forearm prevents such a transverse swing. Therefore, in addition to $Cad[n]$, $Alt_{\Delta}[n]$ and $Jerk[n]$, we defined the following two new walking-specific features:

$I_s[n] = \textit{intensity of hand swing}$: it is the energy of acceleration in the transversal plane relative to the wrist $\langle x, z \rangle$, computed through (4.7). Owing to the wrist's cylindrical geometry, our combined use of data from both axes, forming the transversal plane, makes this feature robust to sensor rotation, which might sometimes occur during walking.

$$I_s[n] = std\left(\sqrt{S_x[n]^2 + S_z[n]^2}\right) \quad (4.7)$$

$\overline{Norm}[n] = \textit{mean of acceleration norm}$: During walking, the trunk movement's amplitude is related to the step length (Zijlstra and Hof, 2003). In walking, we could consider the arm as a moving pendulum, which swings about the shoulder joint. We hypothesized that the arm's back and forth movement, relative to the trunk, would have an average value associated with the trunk movement. Therefore, the feature \overline{Norm} was computed according to (4.8) to capture this information.

$$\overline{Norm}[n] = mean\left(\sqrt{S_x[n]^2 + S_y[n]^2 + S_z[n]^2}\right) \quad (4.8)$$

Eventually, the feature vector ($h_{walk}[n]$) was defined according to (4.9) for walking speed estimation.

$$h_{walk}[n] = [1 \text{ } Cad[n] \text{ } Alt_{\Delta}[n] \text{ } Jerk[n] \text{ } I_s[n] \text{ } \overline{Norm}[n]] \quad (4.9)$$

4.3.3.3 Personalization phase

We propose to calibrate each user's step length model in the personalization phase by sporadically sampling the GNSS signal during daily life. The GNSS samples, along with the corresponding features, were used to calibrate the step length model.

GNSS sampling and segmentation – In order to keep power consumption low, it is vital to restrict GNSS usage to a minimum but still have enough speed data. Ideally, the GNSS should be used when a significant change in user gait pattern occurs. In this study, as the first attempt for the GNSS data selection, we used random sampling. The speed, $v(t)$, was obtained from random GNSS sampling and was segmented as $V[n]$ (similar to the segmentation rule described above). This segmented speed, $V[n]$, along with the corresponding feature vectors ($h_{walk}[n]$ or $h_{run}[n]$) constituted our personalization data set.

Step length computation – Parameter $Sl[n]$ is the actual step length computed through (4.10) for each window n from the personalization data set. In (4.10), parameters $V[n]$, $Cad[n]$, and $Sl[n]$ are the GNSS speed m/s, cadence steps/min, and step length m, respectively.

$$Sl[n] = 60 \times \frac{V[n]}{Cad[n]} \quad (4.10)$$

Step length personalization – $H[n]$ and vector $SL[n]$ were defined as the feature matrix and the actual step length vector, respectively, from the start of personalization up to time n .

$$H[n] = \begin{bmatrix} h[1] \\ \vdots \\ h[n] \end{bmatrix} \quad (4.11)$$

$$SL[n] = \begin{bmatrix} SL[1] \\ \vdots \\ SL[n] \end{bmatrix} \quad (4.12)$$

We chose a linear approach to model the step length by assuming a quasi-linear relationship between our features and the step length. Moreover, this approach decreased computational cost and facilitated the implementation of the speed algorithm on wearable devices (e.g., smartwatches). More importantly, the linear model needs much less training data than non-linear models, thereby reducing the GNSS usage time. This parsimonious leads to a reduction in power consumption of the system. Eventually, the step length was modeled according to (4.13).

$$SL[n] = H[n]\beta + \varepsilon \quad (4.13)$$

Where β is a column vector providing model coefficients. According to the conventional least-squares approach, we have:

$$\beta = (H[n]^T H[n])^{-1} H[n]^T SL[n] \quad (4.14)$$

Equation (4.14) needs all personalization data from the beginning of personalization up to time n , which this consumes a lot of memory and requires much computation. Therefore, a Recursive Least Squares (RLS) fitting approach was employed, which provide an acceptable computational cost for the system and could work in real-time. Moreover, the RLS works in an online fashion that avoids storing all personalization data, thus, reducing memory usage.

Let $H[n-1]$ and $\beta[n-1]$ be the matrix of features and model coefficients vector up to time $(n-1)$. In order to compute the coefficient vector at time n , $\beta[n]$, in an online fashion, the RLS approach is used based on (4.15).

$$\beta[n] = \beta[n-1] + D[n]h[n](SL[n] - h[n]^T \beta[n-1]) \quad (4.15)$$

Where $h[n]$ and $SL[n]$ are respectively, the feature vector and the actual step length of personalization data in time n . Besides, $D[n]$ is defined in (4.16).

$$D[n] = (H[n]^T H[n])^{-1} \quad (4.16)$$

We computed $D[n]$ in a recursive way according to (4.17) where only the matrix $D[n-1]$ and the personalization data at time n were needed. $K[n]$ is defined according to (4.18).

$$D[n] = D[n-1](I - h[n](I + K[n])^{-1}h[n]^T D[n-1]) \quad (4.17)$$

$$K[n] = h[n]^T D[n-1]h[n] \quad (4.18)$$

Figure 4.5 depicts a detailed block diagram for the proposed step length personalization method. For each subject, the first 50 seconds (experimentally adjusted) of the personalization data set was used to build an initial model $(H[50], SL[50], D[50], \beta[50])$, named “*Model initialization*”. Then, the initial model was adapted to every new personalization sample during “*Online Learning*”.

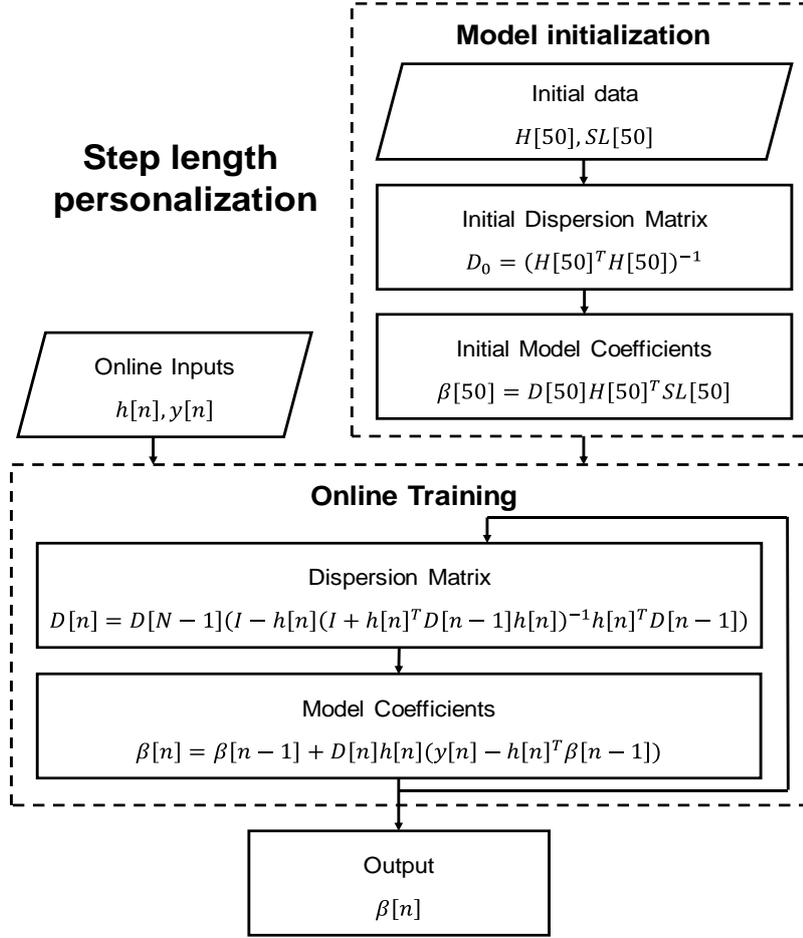

Figure 4.5 – Block diagram of the proposed step length personalization according to the RLS. For each individual, the step length personalization consists of model initialization (using the first 50 seconds of the GNSS data) and online learning based on the RLS. The output is the most updated model coefficients, $\beta[n]$.

4.3.3.4 Estimation phase

When GNSS data were not used (e.g., the GNSS receiver was deactivated), the vector of the updated model coefficients, $\beta[n]$, resulted from the personalization phase, and the extracted features were used to estimate the step length ($\hat{S}l[n]$) according to (4.19).

$$\hat{S}l[n] = h[n] \beta[n] \quad (4.19)$$

Finally, the gait speed ($\hat{V}[n]$, m/s) was estimated through (4.20) using cadence ($Cad[n]$, steps/min) and step length ($\hat{S}l[n]$ (m/step)).

$$\hat{V}[n] = \frac{Cad[n]}{60} \times \hat{S}l[n] \quad (4.20)$$

4.3.4 Cross-validation and error computation

The proposed personalized speed estimation method was validated against the GNSS data (as reference). For each subject, first, the data was divided into packets of 10 seconds. Then, half of each trial's packets were randomly selected for online learning, and the other half was selected as the test set.

The error between the reference and the proposed method in the test data set (personalization data was excluded) was computed sample-by-sample with a 1-second resolution. The Lilliefors test was used to check the normality of intra-subjects speed error. In the case of non-normal distribution, median (as bias), IQR (as precision), and Root Mean Square Error (RMSE) of the speed errors were computed for all trials of each subject. Inter subjects, median, and IQR of bias, precision, and RMSE were reported.

The Bland-Altman approach (Bland and Altman, 2003) was used to display error plots for estimated speed. To analyze the correlations between parameters, we performed the Spearman rank correlation (Kendall, 1938). In addition, we used the Kruskal–Wallis (Daniel, 1978) to investigate whether trial circumstances and/or participant physical conditions had significant effects on the speed estimation error.

In order to evaluate the effect of personalization on the speed error, we compared the personalized algorithm to a kind of its non-personalized version. The non-personalized method used the same features and model (i.e., the conventional least square instead of RLS) as the personalized one. However, the difference is the way of training (i.e., offline instead of online). For a fair comparison, the following procedure was done for an arbitrary subject λ : the personalized method was trained using half data of the subject λ (randomly selected in time) in an online fashion and tested using the other half of its data. For the non-personalized method, the model was trained on data from all subjects except the subject λ , and then tested on the same test data as the personalized method. This process was repeated until each subject was as the test subject exactly once. The non-personalized model's error was estimated in the same way as the personalized model (described previously).

4.4 Results

We analyzed the outdoor activities of 30 participants, both wrists, including a total of 41.7 hours of walking and 17.5 hours of running under real-life circumstances. The GNSS sensor reported a median speed error of 0.11, 0.11, and 0.12 m/s for slow, normal, and fast walking activities (see Table 4.1 for the definition of different walking), respectively. It also showed a median speed error of 0.16, 0.17, and 0.17 m/s for slow, normal, and fast running.

4.4.1 Personalization performance

For a typical subject, Figure 4.6 illustrates an example of the proposed personalized method's high ability to follow the reference speed under various speed ranges and outdoor circumstances during both walking and running.

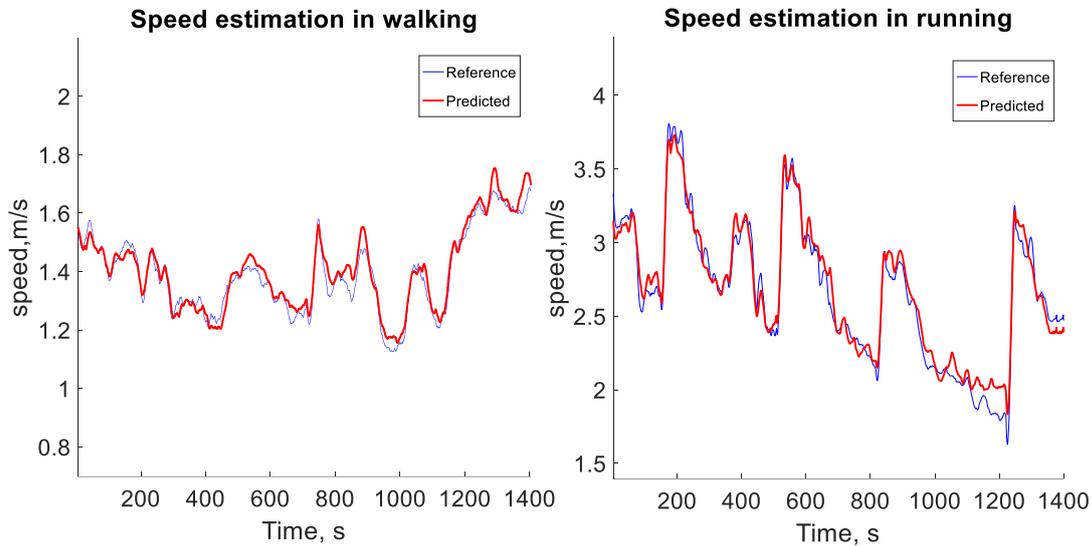

Figure 4.6 – An illustration of the reference and predicted speed values during daily walking and running for a typical subject (ID#1)

The Lilliefors test showed that instantaneous speed error does not follow a normal distribution ($p < 0.001$). Consequently, for each subject, we computed the median (as bias), IQR (as precision), and RMSE of the estimation error in the test dataset (personalization data set was excluded). Table 4.1 reports inter-subjects median and IQR of RMSE, bias, and precision for different walking and running conditions performed on the track (Figure 4.2) on either both or single wrist.

Totally, for walking, the proposed personalized method has achieved an RMSE of 0.05 [0.04 0.06] m/s, a bias of 0.00 [-0.01 0.00] m/s, and a precision of 0.06 [0.05 0.07] m/s. For running, it has obtained an RMSE of 0.14 [0.11 0.17] m/s, a bias of 0.00 [-0.01 0.02] m/s, and a precision of 0.18 [0.14 0.23] m/s. Figure 4.7 displays distribution of speed error versus trial conditions thorough boxplot.

Table 4.1 – Errors of the personalized speed estimation algorithm for daily walking and running under various speed ranges and terrain conditions on either both or single wrist. Here, the Bias and Precision are intra-subjects median and IQR error. Also, all values are inter-subject median [IQR].

Wrists Condition		Walking error, m/s			Running error, m/s		
		RMSE	Bias	Precision	RMSE	Bias	Precision
Both	Slow	0.05 [0.04 0.08]	0.01 [0.00 0.03]	0.07 [0.05 0.08]	0.15 [0.11 0.22]	0.06 [0.02 0.10]	0.17 [0.12 0.25]
	Normal	0.04 [0.04 0.06]	-0.01 [-0.02 -0.01]	0.05 [0.04 0.06]	0.13 [0.10 0.16]	-0.02 [-0.05 0.00]	0.15 [0.12 0.21]
	Fast	0.07 [0.04 0.10]	-0.04 [-0.08 -0.01]	0.06 [0.04 0.11]	0.14 [0.10 0.22]	-0.03 [-0.11 0.03]	0.17 [0.07 0.26]
	Downhill	0.05 [0.04 0.07]	0.01 [-0.01 0.02]	0.06 [0.04 0.08]	0.13 [0.11 0.18]	0.00 [-0.02 0.03]	0.17 [0.13 0.22]
	Flat	0.05 [0.04 0.06]	-0.01 [-0.01 0.00]	0.06 [0.05 0.07]	0.12 [0.09 0.17]	0.01 [-0.03 0.03]	0.16 [0.11 0.22]
	Uphill	0.05 [0.04 0.07]	0.00 [-0.01 0.01]	0.07 [0.05 0.09]	0.15 [0.11 0.21]	0.02 [-0.03 0.05]	0.20 [0.14 0.30]
	Total	0.05 [0.04 0.06]	0.00 [-0.01 0.00]	0.06 [0.05 0.07]	0.14 [0.11 0.17]	0.00 [-0.01 0.02]	0.18 [0.14 0.23]
Left	Total	0.05 [0.05 0.07]	0.00 [-0.01 0.00]	0.06 [0.05 0.07]	0.14 [0.11 0.19]	0.00 [-0.02 0.02]	0.18 [0.14 0.22]
Right	Total	0.05 [0.04 0.06]	0.00 [-0.01 0.00]	0.06 [0.05 0.08]	0.14 [0.12 0.17]	0.01 [0.00 0.02]	0.19 [0.14 0.23]

For walking, $v(t) \leq 1.5$, $1.5 < v(t) \leq 1.8$ and $v(t) > 1.8$ m/s were considered as slow, normal, and fast. For running, slow, normal and fast were respectively defined as $v(t) \leq 2.5$, $2.5 < v(t) \leq 3.5$ and $v(t) > 3.5$ m/s. We defined downhill, flat and uphill as $Alt_{\Delta} < -0.01$, $-0.01 \leq Alt_{\Delta} \leq 0.01$, $Alt_{\Delta} > 0.01$, respectively.

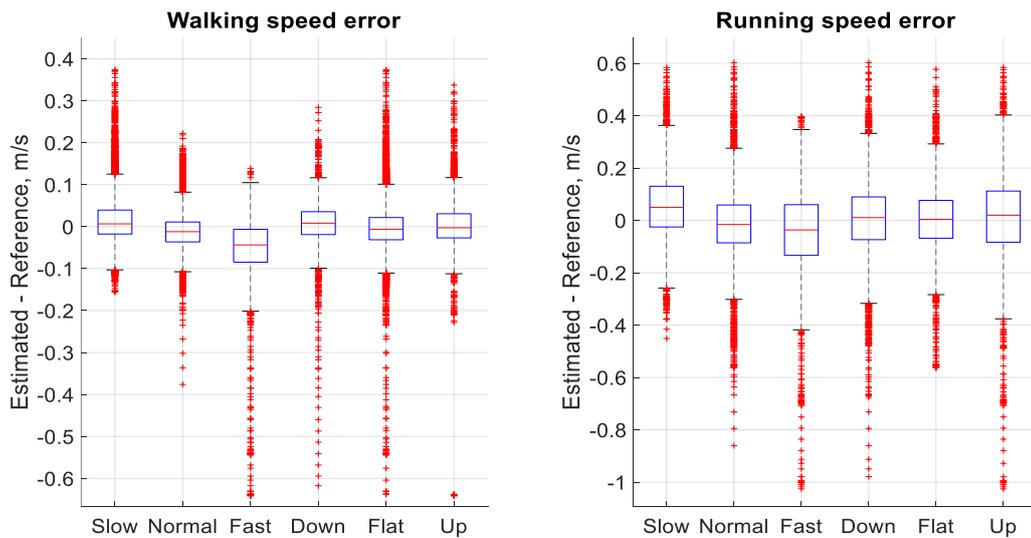

Figure 4.7 – Boxplot of walking and running speed errors versus trial conditions. Blue boxes and the lines inside are IQR and median values. Dashed lines are whiskers, which show 3/2 of IQR measured from each box’s top and bottom (see footnote of Table 4.1).

Spearman’s test showed a high correlation ($R^2 = 0.96$ for walking and $R^2 = 0.94$ for running) between the reference and predicted speed values. For average speed per person, the correlation coefficients increased to $R^2 = 0.99$ for both walking and running. Figure 4.8 illustrates the Bland-Altman plot for speed estimation, confirming a low correlation between the error and estimated speed values ($R^2 = 0.07$ for running and $R^2 = 0.06$ for walking).

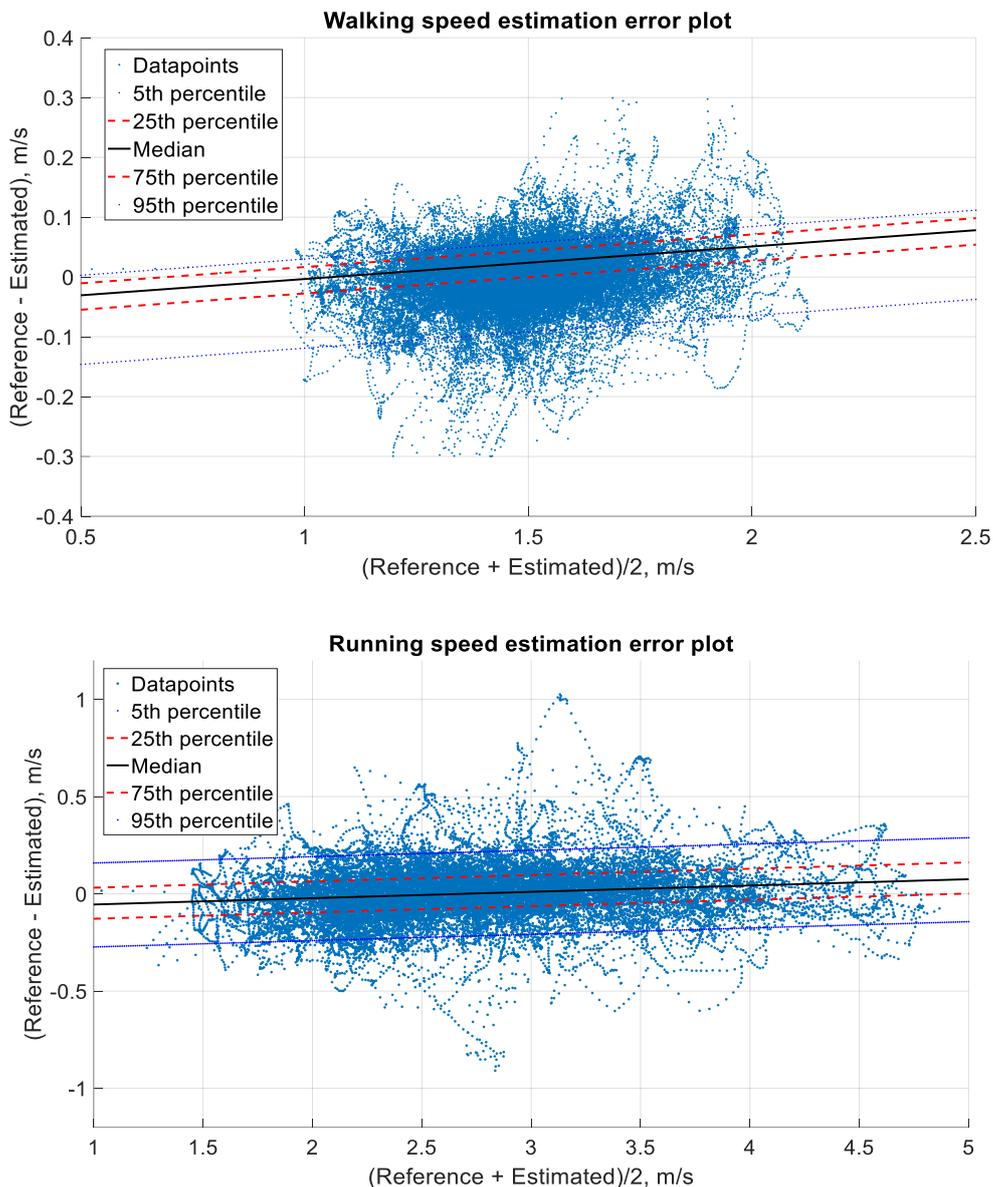

Figure 4.8 – Error plots for walking and running speed estimation. For walking, the 5th, 25th, median, 75th, 95th percentiles (PCT) are -0.09, -0.02, 0.00, 0.03, and 0.07 m/s, respectively. For running, the parameters are -0.23, -0.08, 0.00, 0.08, and 0.22 m/s, respectively.

Kruskal–Wallis test demonstrated a significant effect ($p < 0.001$) for altitude changes of the path and participants on the speed error during walking and running. Lastly, the

predicted speed values and age, height, and weight for both walking and running were uncorrelated ($R^2 < 0.06$).

4.4.2 The personalized versus non-personalized methods

The importance of personalization for step length modeling is demonstrated in Figure 4.9. This example shows how a high correlation ($R^2 > 0.83$) between the individual cadence ($Cad[n]$), as a typical feature, and the individual step length was dropped ($R^2 > 0.12$) when data of the two participants were mixed. Generally, biomechanically-derived features showed different degrees of correlation with step length ranging from $R^2 \in [0.10 \ 0.95]$. Nevertheless, each feature has reached a $R^2 \geq 0.41$ for at least one subject, which highlights the usefulness of all features.

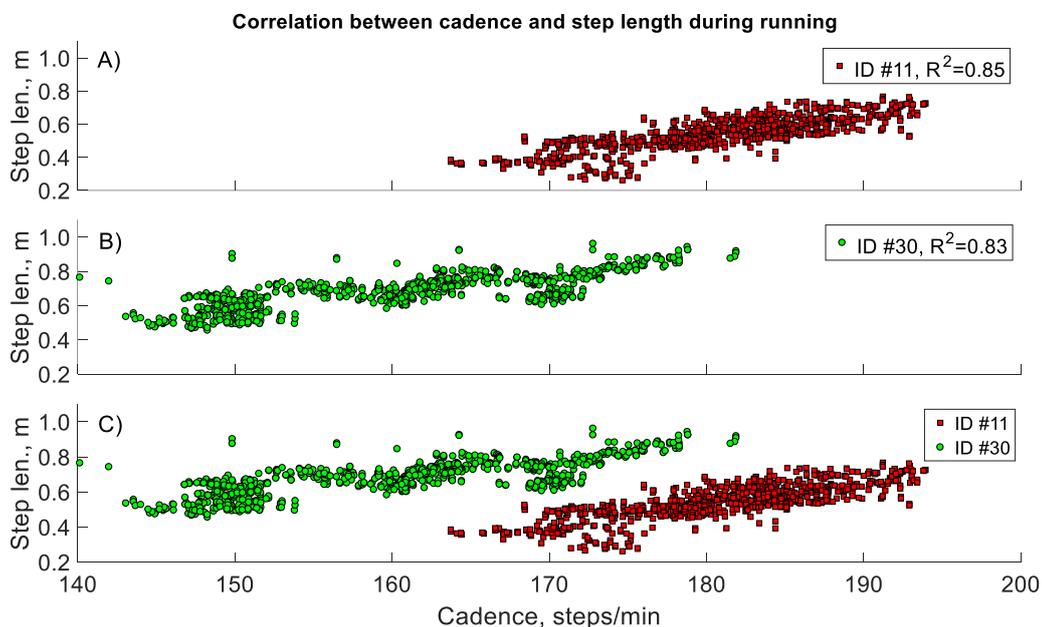

Figure 4.9 – Importance of personalization for step length modeling. (A), (B) and (C) show the correlation between the feature cad (cadence) and the step length of participants #11 (red squares), #30 (green circles), and both together. R^2 Spearman's correlation values were also indicated for each case.

Figure 4.10 indicates the evolution of RMSE of the proposed speed estimation method over the personalization procedure. In order to obtain this result, for each subject, training samples were fed one-by-one into the recursive personalization procedure where, after feeding each sample, the most updated model was evaluated through all data in the test set (i.e., half data of the subject). Then, inter-subjects mean and STD of RMSE were computed as the dark line and the shadow in Figure 4.10, respectively. According to this figure, using only 600 samples of GNSS for personalization decreased the RMSE value to less than 0.1 and 0.2 m/s, respectively.

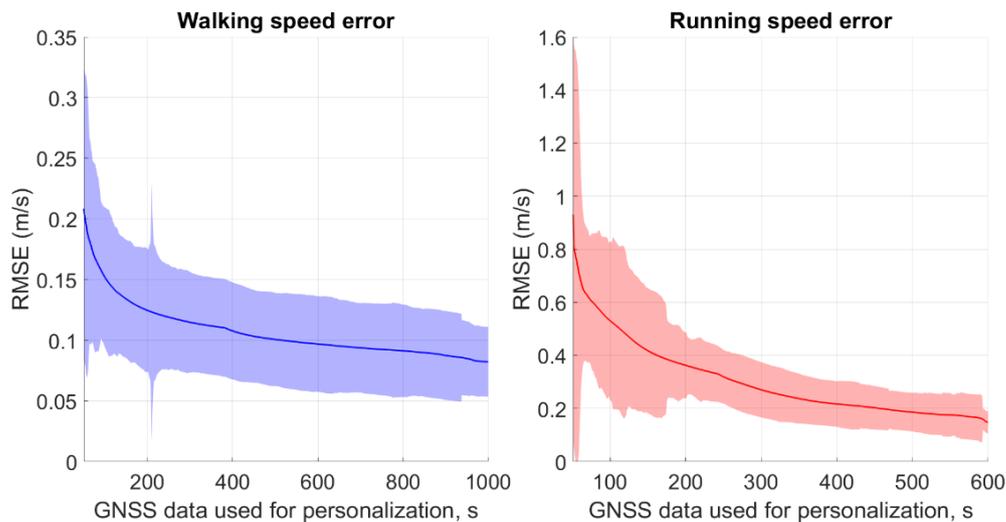

Figure 4.10 – Evolution of the RMSE error of the proposed speed estimation method over the personalization procedure for both walking and running. The dark line and the areas are the mean and STD of RMSE error over all subjects. The x -axis corresponds to the numbers of GNSS data used for personalizing the step length model.

Table 4.2 compares the proposed personalized method’s overall performance and its non-personalized version, according to the average number of samples and numbers of training subjects to build each model. Both methods are evaluated on the test data set, which is half the data of each subject (randomly selected), and the personalization data set was excluded from error computation. In order to build a non-personalized speed estimation model, on average, 70000 and 30000 samples collected from 29 subjects were used for walking and running, respectively. However, for the personalized model, only 600 and 1200 samples (on average) of only one subject were employed for walking and running, respectively.

Table 4.2 – Overall performance of the personalized and non-personalized approaches for speed estimation in daily walking and running. Here, Bias and Precision are intra-subjects median and IQR error. Also, all values are inter-subject median [IQR] in m/s.

Method		Non-Personalized	Personalized
# Subjects		29	1
Walking error, m/s	# Samples	70000	1200
	RMSE	0.10 [0.07 0.12]	0.05 [0.04 0.06]
	Bias	0.00 [-0.05 0.06]	0.00 [-0.01 0.00]
	Precision	0.08 [0.07 0.10]	0.06 [0.05 0.07]
Running error, m/s	# Samples	30000	600
	RMSE	0.31 [0.25 0.42]	0.14 [0.11 0.17]
	Bias	-0.02 [-0.20 0.17]	0.00 [-0.01 0.02]
	Precision	0.31 [0.26 0.39]	0.18 [0.14 0.23]

Figure 4.11 indicates the Cumulative Distribution Function (CDF) of RMSE, bias, and precision of the proposed personalized and non-personalized methods.

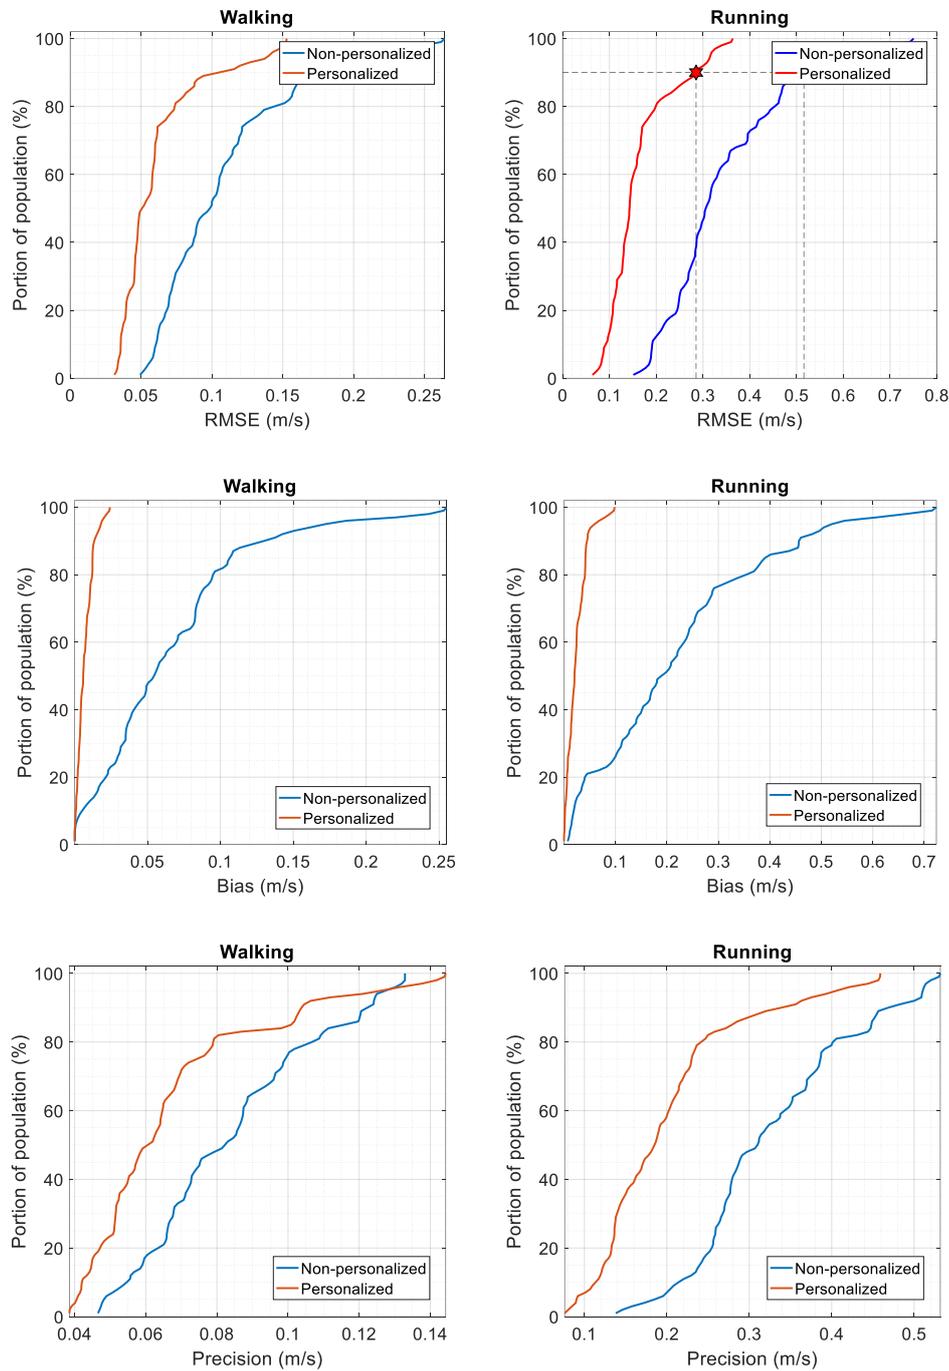

Figure 4.11 – CDF of RMSE, bias, and precision of the proposed personalized and non-personalized methods for walking and running. For example, on the most top-right plot, the red star demonstrates that the personalized method’s RMSE error is less than 0.27 m/s for 90 % of the population. However, for the non-personalized method (i.e., blue star), this value is less than 0.53 m/s.

Eventually, Figure 4.12 displays the correlation between the actual and estimated speed values through the proposed personalized and non-personalized methods.

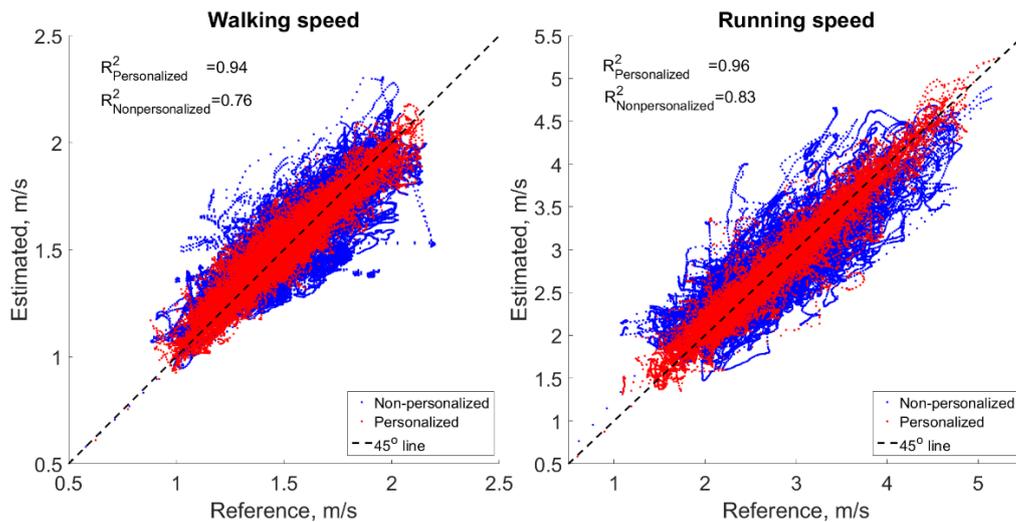

Figure 4.12 – Estimated speed versus reference for the proposed personalized and non-personalized methods.

4.5 Discussion

This study devised a personalized approach for accurate speed estimation during walking and running using a wrist-mounted accelerometer and barometer under various real-world conditions. Several terrain conditions, as well as speed ranges, were considered for testing the method.

Our analysis showed that the correlation between features and step length might be high when each individual was considered separately. However, it significantly dropped by mixing the data of two or more individuals (see Figure 4.9). Consequently, to provide a more accurate speed estimation, a personalized model was designed for each individual. The personalized model was updated whenever new GNSS data were acquired to adapt the model to the user’s new gait styles. As depicted in Figure 4.10, at the beginning of the personalization procedure, the estimated speed error was relatively high since there was not enough data to build a reliable speed model. However, as more and more personalization data were given to the online RLS-based learning process, the RMSE was gradually decreasing. The personalized approach relied on the same features and similar rules as the non-personalized approach (RLS instead of the conventional least square), where only the training data were different. The personalized model was initialized through training by a small initial dataset coming from the participant. An alternative was to train the initial model by the data belonging to the whole population. However, the initial model that we proposed led to faster convergence of the model and did not require a large training dataset involving high numbers of participants.

The proposed personalized method was able to follow GNSS speed every second under different speed ranges ([0.5 5.2] m/s) and environmental conditions (i.e., uphill, flat, downhill). Compared to GNSS speed, the proposed method has achieved a proper RMSE of 0.05 [0.04 0.06] m/s and 0.14 [0.11 0.17] m/s for walking and running, respectively. It also provided almost zero bias for both walking and running. Eventually, the method has obtained a very good precision of 0.06 [0.05 0.07] m/s and 0.18 [0.14 0.23] m/s for walking and running, respectively (see Table 4.1). These errors determined how much the proposed method was different from GNSS speed, which itself showed a median measurement error of 0.12 m/s, despite the accuracy provided in the GNSS receiver datasheet (0.05 m/s). Our algorithm performed better for walking than running, and this was due to the greater robustness of the walking features extracted from hand movement. Moreover, the proposed method was also robust enough to have similar performance on both wrists.

In order to show the power of personalization, we compared the personalized method with its non-personalized version where features, the model, and test data were the same, and the difference came from the training approach. We demonstrated that using 50 times less training samples than the non-personalized method (i.e., 600-1200 samples compared to 30000-70000), the personalized method has achieved a better RMSE, bias, and precision. It should also be noted that the personalized method was trained by data of only one subject, compared to the non-personalized method trained by data of 29 subjects. In particular, by personalization, the IQR of bias dropped by at least ten times, which led to a more accurate estimation of average speed within a speed measurement period. Moreover, the personalization led to a significant improvement of the RMSE and precision (at least three times), which resulted in precise instantaneous speed estimation. Figure 4.11 supports these results by showing that the proposed personalized method performs excellent for almost all types of people where the range of error is very low (e.g., RMSE varies in ranges [0.06 0.36] and [0.03 0.15] m/s for walking and running, respectively).

On the other hand, the performance of the non-personalized method highly varies among different types of people (e.g., RMSE varies in ranges [0.14 0.75] and [0.04 0.26] for walking and running, respectively). Consequently, the personalized model is more reliable than the non-personalized method. However, imagine a case where the data of a specific person is not enough to train a reliable personalized model, depending on the variety of his/her gait styles. In that case, the non-personalized method might perform better due to the support of a much higher training data. This issue could be seen in the most bottom left subfigure of Figure 4.11, where for a small number of subjects, the precision of the non-personalized walking speed method was slightly better than the personalized one. Figure 4.12 illustrated that personalization increased the correlation between the reference and predicted speed by 23 % and 15 % for walking and running. The results show that the personalized method's performance was more similar to that of the reference GNSS system than the non-personalized one.

The personalized method used a few GNSS samples, which implies having the GNSS activated only for a few minutes (i.e., 10 minutes) for each subject. This parsimonious GNSS usage could be distributed over one or two weeks (e.g., some GNSS samples per day) to obtain enough diversity in the gait styles (e.g., different speeds, terrain conditions) of a user. In this study, we employed a random selection strategy to choose a subset of GNSS samples to personalize the speed estimation model. However, a more smart strategy could be designed (as a prospective of this study) to activate the GNSS when there is new information in the user's gait style. This procedure leads to capturing the most informative GNSS samples by using the GNSS as less as possible.

In addition to personalization, we defined wrist-based biomechanically-derived features to obtain a more accurate speed estimation. These features showed different degrees of correlation with step length depending on the individual's gait style, as was illustrated for cadence in Figure 4.9. The results determined that each feature reached a $R^2 \geq 0.41$ for at least one subject. These results demonstrated that all the proposed features conveyed useful information and had complementary effects. By selecting only a few but relevant gait features, we reduced computation and complexity costs of the step length model, which is essential for real-time algorithms implemented on portable devices like wristwatches.

The results highlighted the dependence of the gait speed error on the speed values. Overestimation for low speed and underestimation for high speed were observed (Figure 4.8). One possible reason could be the linear model limitation, which was preferred to decrease computation and algorithm complexity. Another reason might be the limited number of training samples at low and high speed. Another issue is the outliers, which could be seen in Figure 4.7. One possible reason for these might be the lack of perfect synchronization between the proposed wrist-based speed estimation method and the reference GNSS system. The wrist-based method used a 7-second sliding window that prevented it from responding to rapid speed changes, which might be quite probable in real-life situations. Hence, sometimes, there was a time delay between the proposed personalized wrist-based method and the GNSS reference system, which led to generating the outliers observed in our error plots. Apart from this, the GNSS sometimes yielded very noisy data due to the low quality of satellite signals or unexpected body movement, which alone could generate outliers. The method, presented in section 4.3.2 and Figure 4.3, aimed at reducing noise in GNSS data. However, other techniques for better GNSS signal enhancement could be considered.

Compared to previous studies, the proposed personalized speed estimation algorithm has achieved excellent performance even though the IMU placement on the wrist was challenging, and measurements were performed in the free-living environment. For walking, the personalized method provides a median error of 0.00 m/s and an IQR of 0.06 m/s. A recent non-personalized algorithm reached a median and IQR error of 0.02 and 0.18 m/s by an accelerometer and barometer (Fasel et al., 2017a). Methods based

on the feet IMU have also reported a mean error of 0.01 m/s and the precision of 0.08 m/s for indoor walking (Mariani et al., 2010), where both accelerometer and gyroscope sensors were employed. Moreover, the shanks and thighs IMU-based algorithms used at least three sensors to provide a precision of 0.10 m/s (Aminian et al., 2002). For running, a few works have been introduced to estimate speed using IMU. The proposed personalized method has obtained a median error of 0.00 m/s and an IQR of 0.18 m/s for running speed estimation. The Feet-worn IMU was used to estimate running speed with a median error of 0.07 m/s and a range of 0.13 m/s (de Ruiter et al., 2016). Yang et al. also estimated running speed on a treadmill using an accelerometer and gyroscope mounted on the shanks with an RMSE of 0.10 m/s (Yang et al., 2011). Moreover, (Zrenner et al., 2018) tested four different speed estimation algorithms using an IMU implemented into a shoe insole and reported a mean (\pm STD) error of 0.03 (\pm 0.27) m/s.

The proposed method offers a versatile measurement tool that could be used in a variety of target populations. In sports applications, it could help trainers and trainees optimize their walking/running performances. In clinical applications, the method provides the potential to monitor patients or older adults. For instance, in chapter 6 of this thesis, we have applied this method to a large population to study the effect of various diseases (e.g., obesity, frailty, cardiovascular disorders) or aging on people's activity profile (i.e., gait speed). However, the proposed method would need to be complemented by other GB detection techniques (as proposed in chapter 3 of this thesis) to automatically classify GB that could then be used for speed estimation. Our analysis showed that using only one unique model for walking and running speed estimation could increase the error up to 4 times. Therefore, it is required to develop an algorithm to distinguish between running and walking. Moreover, since the proposed personalized method has been optimized for a healthy population, it might need some tuning and further validation for patient populations.

To conclude, the present study provided a personalized approach for accurate, precise, and low-power estimation of instantaneous speed during daily-life gait. It demonstrated that personalization leads to a significant improvement of speed estimation based on the wrist sensor (despite the challenges posed by the IMU location) by achieving results comparable to the GNSS reference. As future work, the proposed algorithm could be improved to manage non-linearity between the chosen features and the step length. It could also be validated on abnormal gaits and integrated with an automatic GB detection algorithm (Mannini et al., 2013; Zhang et al., 2012). Finally, a smart strategy could be developed to minimize GNSS usage, thus reducing the system's power consumption.

4.6 Acknowledgment

The CTI Grant No. 18730.2 PFNM-NM supported the present study. We would like to thank all participants who took part in our measurements.

4.7 Appendix: Running speed estimation using foot-worn inertial sensors²

This appendix shows how the proposed personalization idea could be applied to speed algorithms on other sensor locations (i.e., foot-mounted IMU). In this study, three approaches, based on direct integration, linear regression, and personalized model, are designed. The main contribution to this study was in devising the personalized model (explained in section 4.7.3.5), data collection and cleaning (section 4.7.3.1), and GNSS data cleaning (4.7.3.2). A contribution was also made in the statistical analysis, interpreting the results, and drafting the manuscript.

4.7.1 Abstract

The gait speed is the main outcome in running analysis. Contrary to treadmill running, where the speed is fixed, most of the gait parameters are affected when running overground at various speeds. Today, most wearable systems for running speed estimation are based on GNSS. However, these devices have a high power consumption and could suffer from sparse communication with the satellites. In this study, we proposed three different approaches to estimate the overground speed in the running based on the measurements of foot-worn IMU and compare them to GNSS considered as reference. First, a method is proposed by direct strap-down integration of the foot acceleration. Second, a feature-based linear model and finally, a personalized online-model based on the RLS method were devised. We also evaluated the performance differences between two sets of features; one automatically selected set (i.e., optimized) and a set of features based on the existing literature. The data set of this study was recorded in a real-world setting, with 33 healthy individuals running at low, preferred, and high speed. The direct estimation of the running speed achieved an inter-subject mean \pm STD accuracy of 0.08 ± 0.1 m/s and a precision of 0.16 ± 0.04 m/s. In comparison, the best feature-based linear model achieved 0.00 ± 0.11 m/s accuracy and 0.11 ± 0.05 m/s precision, while the personalized model obtained a 0.00 ± 0.01 m/s accuracy and 0.09 ± 0.06 m/s precision. The results of this study suggest that (1) the direct estimation of the velocity of the foot are biased, and the error is affected by the overground velocity and the slope; (2) the main limitation of a general linear model is the relatively high inter-subject variance of the bias, which reflects the intrinsic differences in gait patterns among individuals.; (3) this inter-subject variance could be nulled using a personalized model.

² This chapter is submitted as Falbriard, M., Soltani, A., & Aminian, K. (2020). Running speed estimation using shoe-worn inertial sensors: direct integration, linear and personalized model to *Frontiers in Sports and Active Living*. Contributions are as follows: design and implementation of the personalized model; data collection; contribution to data analysis, performance evaluation and drafting the manuscript.

4.7.2 Introduction

The overground speed is the most useful metric in training and performance analysis of running. Researchers have tried for decades to understand the physiological and biomechanical adjustments occurring at different ranges of running speeds (Moore, 2016; Nummela et al., 2007; Thompson, 2017; Williams and Cavanagh, 1987). However, most of the existing studies were performed in a controlled environment (i.e., treadmill running inside a laboratory) where the runner has to adapt his gait to run at a constant speed. In overground running, change of environment, surface, slope, obstacles, and turns alter the gait and the running speed. Many studies have discussed the biomechanical adaptations associated with running on a treadmill versus running overground (Van Hooren et al., 2019). While standard motion capture (i.e., stereophotogrammetry and force plate) offers accurate measurements in laboratories, the recent emergence of wearable systems is paving the shift towards studies carried overground and in real-world conditions (Benson et al., 2018).

The real-world estimation of the overground speed is generally obtained using a body-worn GNSS. Although these systems provide accurate and reliable measurement of the locomotion speed (Terrier et al., 2000; Witte and Wilson, 2004), they suffer from several limitations: (1) their high power consumption restricts their duration of use in portable devices, (2) the communication between the receiver and the satellite is not always guaranteed (e.g., indoor, near high buildings), and (3) the measurement accuracy decrease during rapid changes of speed and position (Rawstorn et al., 2014; Varley et al., 2012). As a solution to the latter limitation, systems based on the data fusion of body-worn inertial and GNSS sensors have been proposed to monitor sports activities (Brodie et al., 2008; Waegli and Skaloud, 2009; Zihajehzadeh et al., 2015). However, to address the issue of power consumption and communication losses, IMU-based systems must be able to estimate the speed without or with very limited input from a GNSS device.

Several methods have been proposed to estimate the walking speed using IMU attached to different body-segments (Aminian et al., 2002; Hu et al., 2013; Miyazaki, 1997; Sabatini et al., 2005; Salarian et al., 2013; Zijlstra and Hof, 2003). One solution would be to extend and adapt these methods to running. However, these methods often relied on walking models or on estimating step length, which could not be directly applied to running because of the aerial phases, where accelerometers are erroneous. Other studies have used ML techniques to estimate the walking speed but did not validate the results for running (Fasel et al., 2017c; Zihajehzadeh and Park, 2016).

To the authors' knowledge, few studies proposed an accurate ambulatory method, based on body-worn IMU, to estimate the overground speed of running, and even less did so for instantaneous speed estimation. Two studies used a similar method (integration of the acceleration signal) to calculate the velocity of the shank (Yang et al., 2011) and foot (Chew et al., 2017) segments. However, the system's error was computed over

multiple strides, in a small range of speeds, and for level treadmill running. As mentioned previously, the velocity estimated from the integration of segment acceleration has limitations, mainly when the flight phase varies in a wide range or when various slopes are experienced, as it is the case in the overground running. Another study (Hauswirth et al., 2009) compared in-lab a commercialized speed estimation device with a treadmill's speed and reported a relatively low accuracy considering that the system required a subject-specific calibration. Subject-specific NN was also devised to assess the running speed in free-living conditions using only triaxial accelerometric measurements. However, the model needed a calibration/learning phase for each runner and was validated for the mean speed using a few trials (HERREN et al., 1999). However, one study exploited the personalized calibration and proposed a model based solely on the contact time (De Ruiter et al., 2016). Although the authors obtained a low RMSE (<3%), these results were not instantaneous estimations but rather the average speed over bouts of 125 meters. Besides, a more recent study (Soltani et al., 2019) based on wrist-worn IMU suggested that better results could be achieved by including more features to the model.

The objective of the current study was three-fold. First, we aimed to extend an existing walking algorithm based on strap-down integration of foot acceleration and show its limitation for running speed estimation. Then we proposed a new linear model to predict the running speed at each step and in real-world condition, based on relevant features extracted from feet acceleration and angular velocity. Finally, we investigated how personalization improved the system's performances using additional data, such as occasional GNSS inputs. We compared each method to the GNSS speed, considered as the ground truth, obtained during outdoor measurements of overground running, at different speeds and slopes.

4.7.3 Methods

4.7.3.1 Protocol and instrumentation

33 healthy and active participants, 18 males (age: 38 ± 9 y.o.; size: 180 ± 7 cm; weight: 76 ± 9 kg), 15 females (age: 36 ± 10 y.o.; size: 165 ± 7 cm; weight: 59 ± 7 kg), without any symptomatic musculoskeletal injuries participated to this study. The measurements were performed in real-world conditions with sections of uphill, downhill, and level running. We asked the participants to run the same circuit three times, once at self-adjusted normal, fast, and slow speeds (Figure 4.13, left). The periods of rest and the walking bouts, in between the running segments, were manually removed from the analysis. The local ethics committee approved the present protocol, and we conducted the measurements in agreement with the declaration of Helsinki.

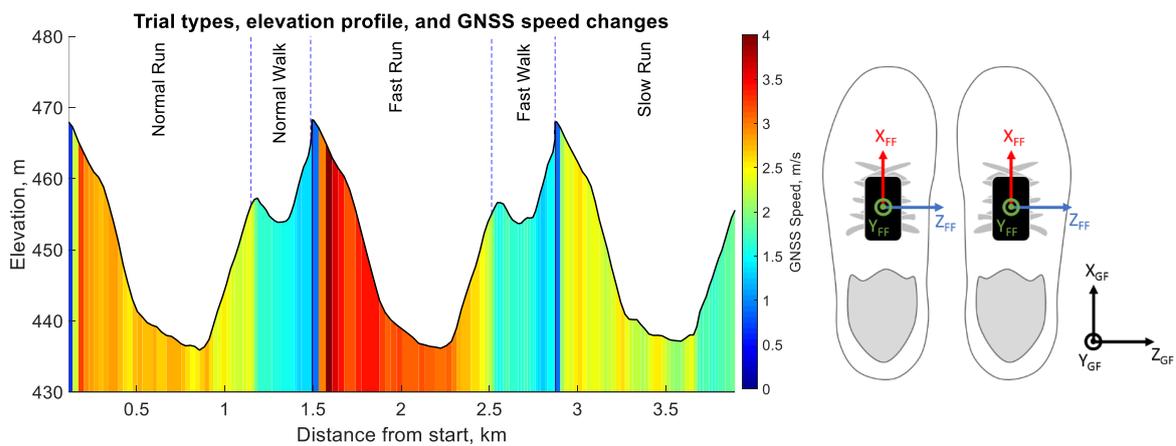

Figure 4.13 – (Left) The elevation and speed of the running circuit. This figure was adapted from (Soltani et al., 2019). (Right) the definition of the foot functional frame (FF) and global frame (GF) used in this study.

Each participant was equipped with two time-synchronized IMU (Physilog 4, Gait Up, Switzerland) strapped on the shoe's dorsum. Each sensor included a triaxial accelerometer, a triaxial gyroscope, and a barometer. The barometer was sampled at 50 Hz. Acceleration (± 16 g) and angular velocity (± 2000 deg/s) were recorded at 500 Hz and were calibrated according to (Ferraris et al., 1995) before each measurement session. Furthermore, a GNSS receiver (CAMM8Q, u-blox, CH) with an external active antenna (ANN-MS, u-blox, CH) was mounted on the head using Velcro attached to a cap. GNSS was used as a reference system for the estimation of the running speed. The GNSS receiver was set to pedestrian mode with a sampling frequency of 10 Hz. With such a configuration, the manufacturer's datasheet reported a median error of 0.05 m/s for instantaneous speed estimation. MATLAB software (R2018b, MathWorks, Natick, MA USA) was used for all the data processing steps without the need for publicly available libraries.

4.7.3.2 Estimation of reference GNSS speed

The reference speed obtained from the GNSS receiver was processed according to (Soltani et al., 2019) and in two steps (Figure 4.14). First, we enhanced the signal by removing the outliers that did not correspond to running; hence, we removed all recorded speed samples outside the 5-20 km/h range. Moreover, the GNSS receiver provided an estimation of the accuracy of each observation; hence we discarded any data-point with an error higher than 0.15 m/s. This process retrieved an unevenly sampled reference speed signal. We applied a moving average of 0.5-second width (in 10 Hz), followed by linear interpolation to obtain an equally-spaced time series at 10 Hz. In the second step, the signal was down-sampled to provide the reference speed (v_{ref}), after a fourth-order low-pass Butterworth filter with the cut-off frequency at 0.25 Hz to reduce the noise.

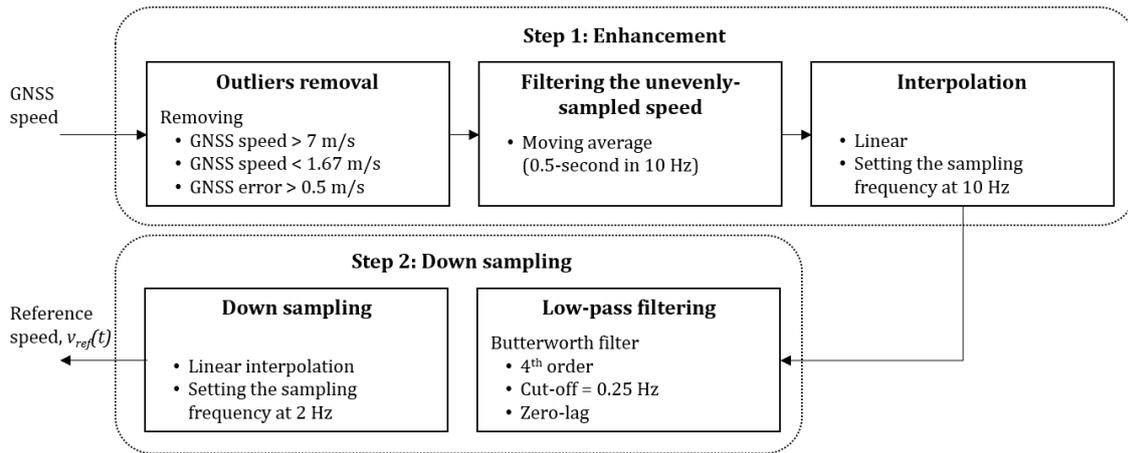

Figure 4.14 – Pre-processing steps applied to the GNSS measurements of speed to obtain the reference speed estimation. This figure was adapted from (Soltani et al., 2019)

4.7.3.3 Speed estimation based on direct integration of foot acceleration

This section describes the sequence of transformations applied to the IMU and barometer data to extract the gait features. The whole process could be summarized in four tasks: pre-processing, temporal analysis, spatial analysis, and foot speed estimation (Figure 4.15).

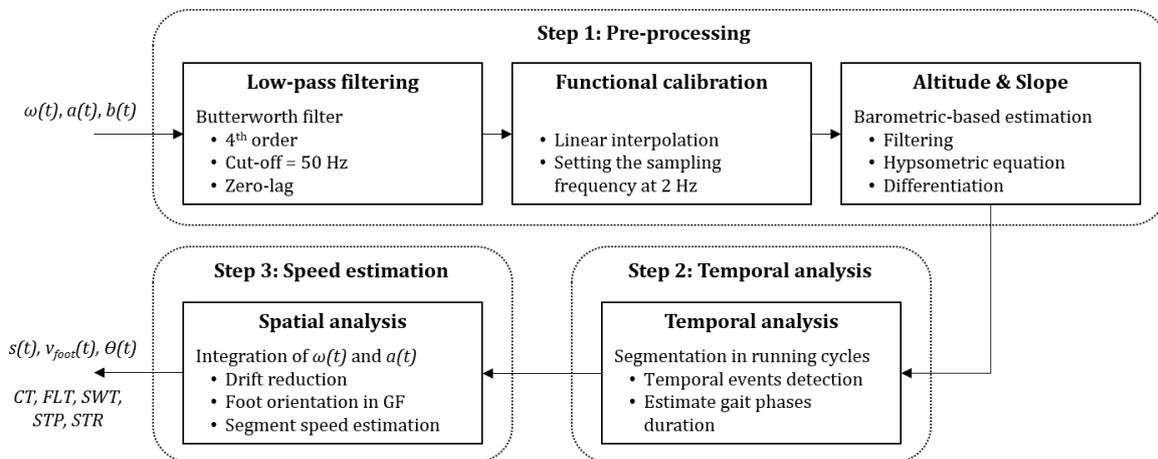

Figure 4.15 – Steps performed on the IMU acceleration $a(t)$, angular velocity $\omega(t)$, and barometric pressure $b(t)$ measurements. The outputs were later used for feature extraction; the slope $s(t)$, the speed of the foot $v_{foot}(t)$, the pitch angle $\theta(t)$, contact time CT , flight time FLT , swing phase duration SWT , step duration STP and stride duration STR .

4.7.3.3.1 Pre-processing

First, a fourth-order low-pass Butterworth filter ($F_c = 50$ Hz) was applied on the raw acceleration, $a(t)$, and angular velocity, $\omega(t)$, signals to reduce the noise. Then the IMU

signals were aligned with the foot segment by computing the rotation matrix that transforms the data recorded in the technical frame of the sensors into the functional frame (FF) of the foot (Figure 4.13, right). For this purpose, we used the measurements of level normal walking (Figure 4.13, left) and a previously reported calibration method (Falbriard et al., 2018). This process aligned the y -axis of the IMU with the vertical axis of the foot, pointing upward, the z -axis to the mediolateral axis, pointing to the right side of the subject, and the x -axis to the longitudinal axis, pointing towards the forefoot. Throughout this study, if not mentioned otherwise, the data are reported in the functional frame of the foot.

The last phase in pre-processing was estimating the overground slope. As the running mechanics differ between level, uphill, and downhill running (Vernillo et al., 2017), we assumed that the elevation difference between successive steps would be a relevant input for the model. Therefore, the barometric pressure was converted by the hypsometric equation to the altitude signal (Bolanakis, 2017), smoothed by applying a 4-seconds moving average filter, and down-sampled to 1 Hz time-series. The slope, $s(t)$, was defined as the altitude difference between two samples spaced by 5 seconds, by assuming that altitude changes shorter than 5 seconds would not significantly affect the running speed.

4.7.3.3.2 Temporal analysis

Temporal events detection was performed as described in (Falbriard et al., 2018) by segmenting the race into midswing-to-midswing cycles and detecting of several temporal events within each cycle. Midswing was detected as the positive peaks observed on the pitch axis (FF z -axis) of the angular velocity measurements. Moreover, we improved the robustness of the peak detection algorithm by applying the YIN auto-correlation method (De Cheveigné and Kawahara, 2002) over a 10-second sliding window (5-seconds overlap) to obtain an approximation of the cadence and set an adequate minimum time difference between the two peaks. The IC , defined as the moment when the foot initiates contact with the ground at landing, and terminal contact (TC), defined as the instant when the toes leave the ground during the pushing phase, were then detected within each cycle using the two minimums of the pitch angular velocity. Moreover, we defined the event MinRot as the time-point where the norm of the angular velocity ($||\omega(t)||$) is minimum within the stance phase (i.e., between IC and TC).

4.7.3.3.3 Spatial analysis and foot speed estimation

This process aimed to measure the foot's orientation in the global frame (GF), remove the Earth's gravitational acceleration from the recorded acceleration, and integrate the corrected acceleration to obtain the speed of the foot. In GF, the x -axis was in the running direction, the z -axis corresponds to the axis perpendicular to the ground surface, and the y -axis was defined by the cross-product of the z and x -axes (Figure 4.13). Using a previously validated technique (Falbriard et al., 2020), foot orientation

was obtained in GF, and foot acceleration in FF was expressed in GF, and the gravitational acceleration ($g = [0 \ 0 \ 9.81]$ m/s²) removed. The resulting acceleration (in GF) was integrated using a trapezoidal rule to get a first estimate of the speed of the foot. We considered the speed of the foot to be zero during the stance phase and, therefore, estimated and removed the integration drift by linearly resetting the speed between MinRot and TC of each stance phase. Note that we preferred MinRot to the IC for drift resting since MinRot corresponds to the time sample when the foot is the closest to a static state, reportedly used as the integration limits in walking gait analysis (Mariani et al., 2010). We finally applied the inverse of the quaternions mentioned above to get the drift-corrected speed of the foot segments ($v_{foot}(t)$) in the FF.

4.7.3.4 Development of a linear model for speed prediction

4.7.3.4.1 Feature extraction, linearization, and outliers removal

First, we extracted several parameters, p_j , for each step, which was later used as inputs for the speed estimation model. As several studies reported on the association between the changes in the duration of the gait phases and the running speed (Högberg, 1952; Nummela et al., 2007; Saito et al., 1974), we computed the ground contact time (CT), the flight time (FLT), the swing time (SWT), the step duration (STP), and the stride duration (STR) for each step i , where $i = 1, \dots, N$, and N is the total number of steps (4.21)-(4.25).

$$CT_i = TC_i - IC_i \quad (4.21)$$

$$FLT_i = IC_{i+1} - TC_i \quad (4.22)$$

$$SWT_i = IC_{i+2} - TC_i \quad (4.23)$$

$$STP_i = IC_{i+1} - IC_i \quad (4.24)$$

$$STR_i = IC_{i+2} - IC_i \quad (4.25)$$

As a few strides suffered from misdetections, outliers were removed according to (1) a valid stride must last between 0.37 and 2.5 seconds, and (2) the flight phase (FLT) must be greater than zero.

Pitch angle, θ , at the IC was extracted as the angle between the longitudinal axis of the foot (FF x -axis) and the ground surface (x and y -axis in GF). A positive pitch angle corresponds to a rear-foot landing (i.e., talus region lower than the toes) and a negative pitch angle to a forefoot strike.

We also extracted several statistics from the acceleration $a(t)$, the angular velocity $\omega(t)$, the foot speed $v_{foot}(t)$, and the slope $s(t)$ time-series. Moreover, since $a(t)$, $\omega(t)$, and $v_{foot}(t)$ were 3D signals, these statistics were computed for each axis (i.e., x , y , and z) and the norm of the signal. Note that the features were captured on the signals of a

single stride (i.e., between IC_i and IC_{i+2} , where $i = 1, \dots, N$) before applying the statistical functions. We opted for a stride-based segmentation instead of the step-based segmentation because a stride corresponds to one period of gait and, therefore, is more likely to capture the complete pattern of a cycle. Besides, the list of selected features (Table 4.3) aimed to collect information on the intensity of the signal (e.g., mean, STD, RMS), the shape of its distribution (e.g., skewness, kurtosis), and its shape in a compressed format (e.g., coefficient of the auto-regressive model). Moreover, as the temporal parameters, (4.21)-(4.25), already hold relevant periodic information, we did not consider features in the frequency domain.

Table 4.3 – List of the features extracted for each stride on the continuous acceleration $a(t)$, angular velocity $\omega(t)$, speed $v_{foot}(t)$, and slope $s(t)$. In the name of the feature, variables $\langle T \rangle$ and $\langle C \rangle$ correspond to the label of the signal and the channel, respectively. Hence $\langle T \rangle$ must be replaced by a , ω , v_{foot} , or s while $\langle C \rangle$ must be replaced by x , y , z , or $norm$.

Type	Feature	Description
Intensity	$mean_{\langle T \rangle_{\langle C \rangle}}$	Mean value
	$std_{\langle T \rangle_{\langle C \rangle}}$	STD
	$med_{\langle T \rangle_{\langle C \rangle}}$	Median
	$iqr_{\langle T \rangle_{\langle C \rangle}}$	IQR
	$max_{\langle T \rangle_{\langle C \rangle}}$	Maximum
	$rms_{\langle T \rangle_{\langle C \rangle}}$	Root-mean-square
Shape	$kurt_{\langle T \rangle_{\langle C \rangle}}$	Kurtosis
	$skew_{\langle T \rangle_{\langle C \rangle}}$	Skewness
Compression	$arm1_{\langle T \rangle_{\langle C \rangle}}$	First coefficient of the auto-regressive model of order 3
	$arm2_{\langle T \rangle_{\langle C \rangle}}$	Second coefficient of the auto-regressive model of order 3
	$arm3_{\langle T \rangle_{\langle C \rangle}}$	Third coefficient of the auto-regressive model of order 3

Before proceeding to the selection of the best features, we visualized the relation between the reference speed $v_{ref}(t)$ and the features individually. Based on our observations, we identified three functions that improved the linear relationship between the reference speed and some of the input features; $f_1(p) = p_2$, $f_2(p) = p_3$, and $f_3(p) = 1/p$. The functions f_1 , f_2 , and f_3 were applied to all the features, and the results were added to the list of features. Finally, we also included several anthropometric parameters to the set of features, such as the size, weight, gender, and age of the participants.

4.7.3.4.2 Data set configuration

We divided the data into three subsets: validation, training, and testing sets. The participants were randomly distributed into the three subsets. It is important to note

that all the steps of a single individual were attributed to only one of the subsets; this removed the performance bias associated with the models trained and tested on measurements originating from the same subjects (Halilaj et al., 2018). Figure 4.16 shows the data from each set with different colors and illustrates their functions.

We used the 10 subjects (30 %) from the validation set for feature selection (in orange in Figure 4.16), and the 23 remaining participants (70 %) were used interchangeably for training (in blue in Figure 4.16) and testing (in green in Figure 4.16) of the model according to the leave-one-subject-out cross-validation method. We emphasize on the fact that the validation set was not included in the evaluation of the model and served exclusively for feature selection. We distinguished the development set from the other sets to lessen the risks of overfitting and preferred a leave-one-subject-out approach to assessing the model’s performance due to the relatively low number of individuals present in this study. Moreover, such a method allowed us to identify potential outliers in the participants and later find collections of subjects with similar biases.

The leave-one-subject-out cross-validation method functioned as followed: we trained the model using the data from 22 subjects (training set) and tested on the data from one individual (testing set). We then repeated this process, such that each participant appeared once in the testing set.

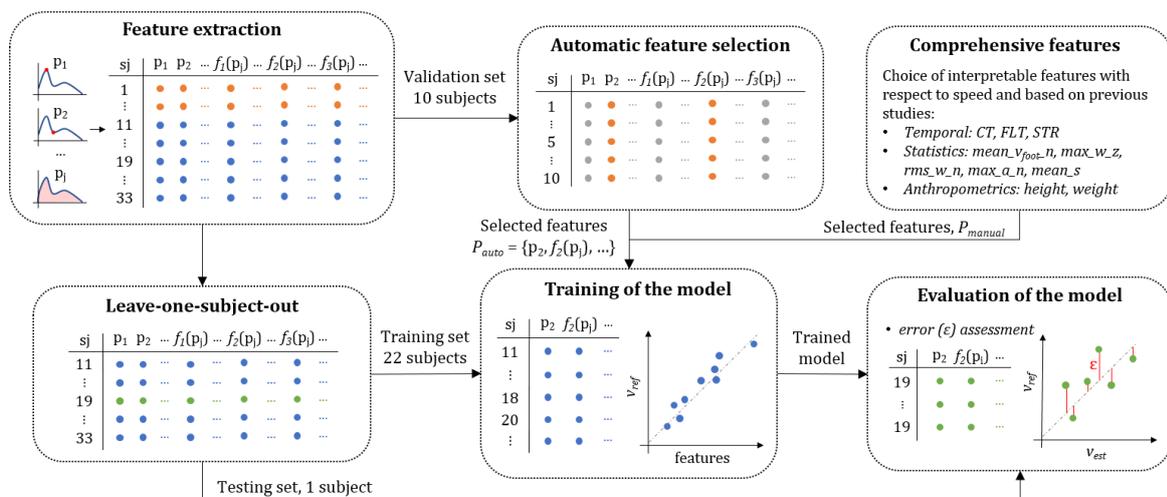

Figure 4.16 – Schematic representation of the data repartition into the validation (blue), training (orange), and testing (green) set. The validation set was used for feature selection, the training set to train the coefficients of the linear model, and the testing set to evaluate the performance of the predictions. The features are represented as p_j and the linearization function as $f_1(p_j)$, $f_2(p_j)$ and $f_3(p_j)$.

4.7.3.4.3 Automatic feature selection

Here, we selected the features (P_{auto}) to minimize the Mean Square Error (MSE) of the speed estimation model using the ordinary least squares method. The leave-one-

subject-out method was applied with 11 subjects for training and one subject to evaluate the error of the predictions (Figure 4.16). The automatic feature selection process started with an empty set of inputs and sequentially added the parameters p_j or their transform (f_1, f_2, f_3) , which minimized the average MSE among all the subjects. This method is known as the forward stepwise selection process and has proven to be reliable on large feature space (John et al., 1994; Kohavi and John, 1997). The algorithm stopped including new parameters if the gain in the average MSE was lower than 1 % of the previous MSE recorded. We deliberately set a low 1 % criterion to obtain a possibly unnecessary large number of inputs knowing that the model is trained using the LASSO method (Tibshirani, 1996) with shrinkage of the redundant features. To ensure that the features contributed equally to the MSE estimation, we rescaled the inputs using a robust z-score normalization method (Jain et al., 2005); after normalization, the feature's mean was equal to zero, and the median absolute deviation equal to one (less sensitive to outliers than the variance of one).

4.7.3.4.4 Comprehensive selected features

Although a supervised and automatic feature selection method might retrieve the subset with the best prediction performance on a given set of parameters, the results are sometimes difficult to interpret. Hence it is generally recommended also to evaluate the performance of a comprehensive set of features selected based on their biomechanical relevance (Halilaj et al., 2018). Based on the findings of previous research in running, we defined a list of features (P_{manual}) known to be affected by variations in the running speed. Similarly to the automatic selection of features, we willingly selected many input features, potentially intercorrelated, knowing that optional inputs will be discarded later in the training stage. In summary, comprehensive features included the following:

- Anthropometric features: the height because taller individuals are likely to have longer step length, thus higher speed, than shorter individuals with similar flight times.
- Temporal features: the *CT*, *FLT*, and *STR* contain relevant information about the stride frequency and were shown to decrease with an increase in the running speed (Chapman et al., 2012; Nummela et al., 2007; Saito et al., 1974).
- Speed and spatial features: the average speed of the foot ($mean_v_{foot_norm}$) obtained with a direct integration; the maximum angular velocity of the foot in the sagittal plane (max_omega_z) assuming faster swing involves higher speed; the RMS value of the angular velocity norm (rms_omega_norm) since higher speed should result in higher dynamic movements; the maximum of the acceleration norm (max_a_norm) as it was demonstrated in previous studies that tibial peak accelerations increased with faster-running velocities (Sheerin et al., 2019); and the average slope ($mean_s$) since uphill and downhill might affect the running speed.

4.7.3.4.5 Training and testing of the model

The linear model was trained and tested with the leave-one-subject-out cross-validation method. For each individual, the performance of the speed prediction was evaluated with the model's coefficients trained on 22 other subjects. This approach was preferred to a traditional split of the data into two datasets (e.g., 70 % training and 30 % testing repartition) due to the restricted number of subjects available after the feature selection phase. Besides, the leave-one-subject-out procedure allowed us to detect potential outliers in the participants and, therefore, possibly identify the sources of poor estimation results.

The least-squares regression coefficients were trained using the LASSO method (Tibshirani, 1996), with scaled inputs to have zero mean and a variance of one, and equally distributed the observations' weights at the initialization stage. To limit overfitting risks, we selected the model with the smallest number of inputs, if any new input would improve the MSE by less than 2 %.

Since we observed some disparity in the dataset (the steps between 2.5-4 m/s were over-represented), we used a random under-sampling (RUS) method to deal with the issue of class imbalance (Pes, 2020). This process started by dividing the range of reference speeds into five equally spaced groups, from 1.4 to 2.2 m/s, 2.2 to 3 m/s, 3 to 3.8 m/s, 3.8 to 4.6 m/s, and 4.6 to 5.4 m/s. We randomly selected the same number of steps from each group based on the group with the least number of steps (i.e., down-sampling of the majority). We repeated this process ten times, generating ten versions of the under-sampled data set and used these subsets independently. In other words, we trained and tested the model ten times for each individual.

Finally, we investigated the changes in the speed prediction when input features were averaged over consecutive steps. Instead of using a single step granularity for running speed, averaging over several steps might conceivably improve the precision (i.e., random error) of the model. We tested this approach on an even number of steps (i.e., 2, 4, 6, 8, and 10), for it equally includes the sensor's information from both feet. In order to avoid grouping non-consecutive steps, we applied this averaging process before under-sampling the inputs.

4.7.3.5 Personalized model

4.7.3.5.1 Running speed estimation algorithm

Recently, online personalization methods have emerged in the field of human movement analysis. For instance, such an approach demonstrated significant improvement in speed estimation performances (Soltani et al., 2019). The objective is to personalize a generic speed estimation model based on the sporadic reference data obtained from a GNSS device. We describe the online-learning procedure used in this study in the following; we define n as the observation (or sample) index used for the

personalization where each sample corresponds to one stride. Therefore, if we have M samples (i.e., strides) for the personalization, then $n \in \{1, 2, 3, \dots, M\}$.

Let's Q be the number of features in each stride. We defined \mathbf{p}_n as the feature vector and sl_n as the reference stride length for the n -th stride according to (4.26) and (4.27). Here, $p_j[n]$ is a symbolic name for the j -th feature of the n -th stride. Moreover, $v_{ref}[n]$ is the GNSS speed of the n -th stride.

$$\mathbf{p}_n = [1 \quad p_1[n] \quad p_2[n] \quad \dots \quad p_Q[n]] \quad (4.26)$$

$$sl_n = v_{ref}[n] \times \frac{1}{STR_n} \quad (4.27)$$

For \mathbf{p}_n we used the selected features in P_{manual} or P_{auto} based on results obtained in the linear model. We first modeled the stride length through RLS and then multiplied that by the stride frequency to obtain the running speed. The RLS is a real-time and computationally effective online learning method, which does not need to have or store all the training data from the beginning of training.

Let P_n and SL_n be the feature matrix and the vector of actual stride length defined in (4.28) and (4.29), respectively.

$$P_n = \begin{bmatrix} \mathbf{p}_1 \\ \vdots \\ \mathbf{p}_n \end{bmatrix} \quad (4.28)$$

$$SL_n = \begin{bmatrix} sl_1 \\ \vdots \\ sl_n \end{bmatrix} \quad (4.29)$$

Using the RLS approach, SL_n could be modeled as in (4.30), where β_n is the coefficient of the model trained using n observations. If P_{n-1} and β_{n-1} are the feature matrix and model coefficients estimated using $n - 1$ samples, then once we obtain a new sample (\mathbf{p}_n and sl_n) for the personalization, β_n could be recursively estimated through (4.30).

$$\beta_n = \beta_{n-1} + D_n \mathbf{p}_n (sl_n - \mathbf{p}_n^T \beta_{n-1}) \quad (4.30)$$

Where D_n , known as the dispersion matrix, itself, is recursively estimated by having only D_{n-1} (i.e., the dispersion matrix estimated using $n - 1$ samples) and the new personalization data (i.e. \mathbf{p}_n and sl_n) according to (4.31). Here, K_n is defined as (4.32).

$$D_n = D_{n-1} (I - \mathbf{p}_n (I + K_n)^{-1} \mathbf{p}_n^T D_{n-1}) \quad (4.31)$$

$$K_n = \mathbf{p}_n^T D_{n-1} \mathbf{p}_n \quad (4.32)$$

For each individual, ten strides from the training set were used to initialize the RLS recursion process.

4.7.3.5.2 Cross-validation

The data set was organized differently for the personalization process to consider each individual's gait style and minimize the training data from GNSS. Data from each individual was divided into bouts of 10 strides, and half of these bouts were assigned randomly to the training set and the other half to the testing set of that same individual. Consequently, we trained and evaluated the models for each individual separately, using the uniquely the data from that same individual.

4.7.3.6 Statistical analysis

We evaluated the performance of the model by computing the error on the training and testing sets. We did so going from a single step to a ten-steps resolution according to the configuration of the inputs. For each of the RUS iteration, the intra-subject accuracy (or bias) and precision were estimated using the mean and STD, respectively. The normality of the speed error was tested using the Lilliefors test, and in the case of non-normal distribution, the mean was replaced by the median and STD by the IQR. To better understand the performance of the system, the intra-subject RMS error was calculated, and the Pearson correlation coefficient was used to assess the linear dependence of the predictions. Since we used the leave-one-subject-out method for training and testing, the results were reported by computing the mean, the STD, the minimum and the maximum on the intra-subject biases, precision, RMS error, and correlation coefficients. Agreement between the reference GNSS speed and the estimated speed was illustrated with Bland-Altman plots (Bland and Altman, 2003). Furthermore, to evaluate the distribution of the errors and possible overfitting, we used the CDF of step absolute error for both training and testing sets.

4.7.4 Results

4.7.4.1 Direct speed estimation

Two subjects were excluded from the data set; because of the poor quality of the GNSS measurements or because of an improper fixation of the IMU on the shoe and high Signal to Noise Ratio of the kinematic data. Since it required no learning, the direct speed estimation method was performed on the 63435 steps available in this study. We observed an inter-subject mean \pm STD (min, max) of 0.08 ± 0.10 (-0.12, 0.27) m/s for the bias, 0.16 ± 0.04 (0.08, 0.25) m/s for the precision, 0.20 ± 0.06 (0.08, 0.34) for the RMSE. The relation between the speed estimation error and the overground velocity is presented in Figure 4.17, and the effect of the slope in Figure 4.18.

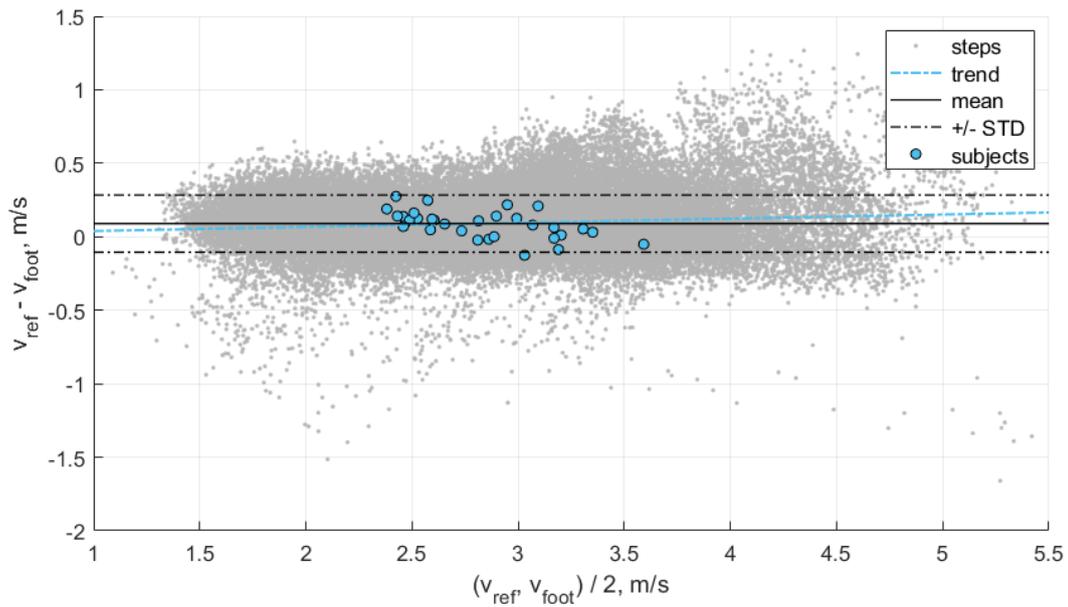

Figure 4.17 – Bland-Altman plot of the agreement between the direct speed estimation method (v_{foot}) and the GNSS reference (v_{ref}). The error was estimated with a granularity of one step.

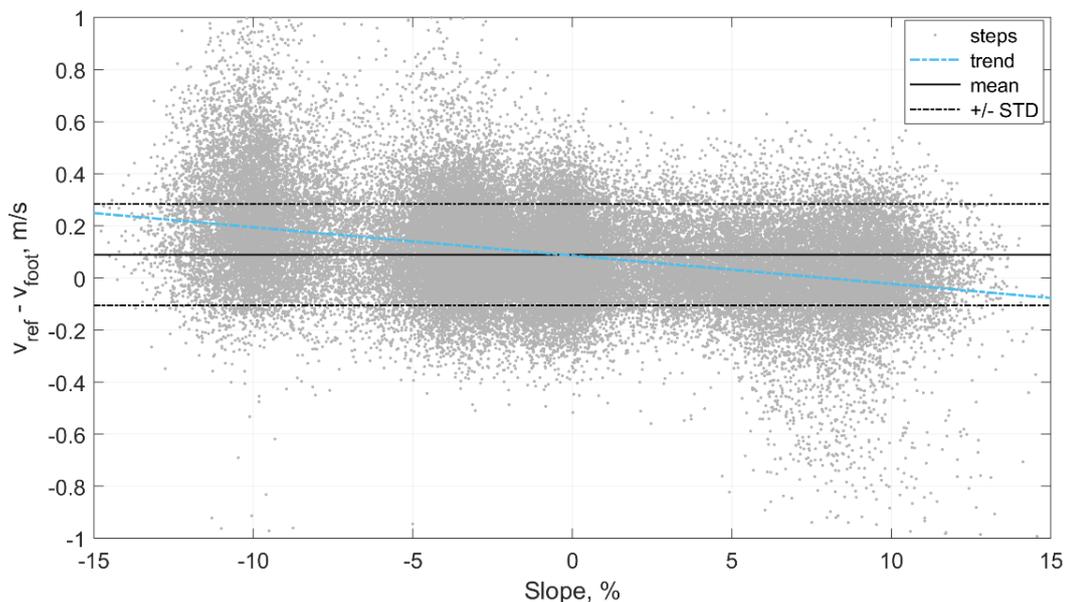

Figure 4.18 – The step by step error of the direct speed estimation method (v_{foot}) in relation to the slope of the ground surface.

4.7.4.2 Automatic feature selection

In total, we used the 20084 strides of the validation set to select 28 features out of the 668 features available. The feature selection process stopped at an average MSE of 0.0057 m/s (Figure 4.19), which corresponded to a 1.12 % improvement compared to the

previous step with 27 features. The selection process was repeated 100 times (i.e., 10 times for each of the 10 subjects) and led to the set of features presented in Table 4.4.

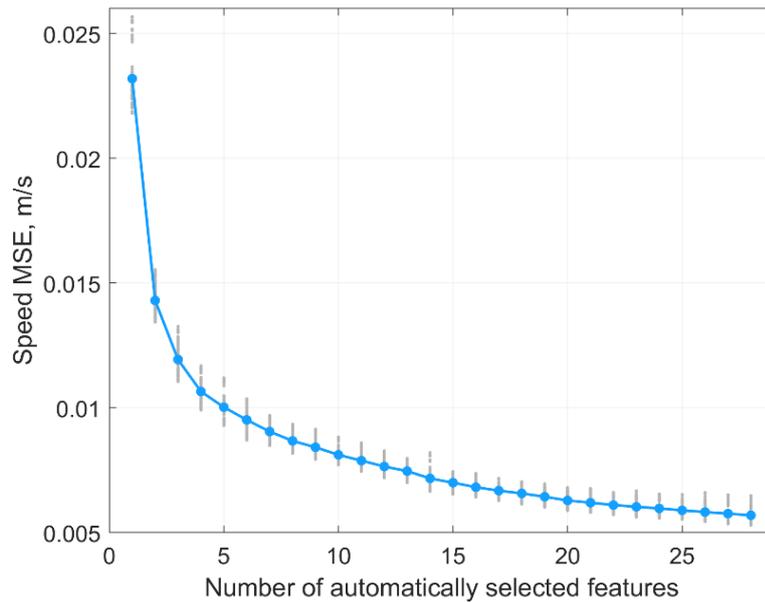

Figure 4.19 – MSE of the speed estimation during the forward stepwise selection process. In grey, the MSE of each subject, and blue the inter-subject average.

Table 4.4 – The ordered list of the features automatically selected by the forward stepwise selection algorithm.

#	Label	$f(p)$	#	Label	$f(p)$
1	<i>mean_a_norm</i>	-	15	<i>mean_v_foot_y</i>	p^2
2	<i>mean_v_foot_norm</i>	-	16	<i>median_omega_norm</i>	p^{-1}
3	<i>iqr_a_norm</i>	-	17	<i>median_omega_x</i>	-
4	θ	-	18	<i>skew_v_foot_norm</i>	-
5	<i>mean_s</i>	p^2	19	<i>iqr_v_foot_norm</i>	p^{-1}
6	<i>STR</i>	p^{-1}	20	<i>max_v_foot_y</i>	p^{-1}
7	<i>median_a_x</i>	p^3	21	<i>mean_omega_y</i>	-
8	<i>median_omega_z</i>	p^3	22	<i>rms_a_x</i>	p^3
9	<i>max_v_foot_norm</i>	-	23	<i>median_v_foot_x</i>	-
10	<i>median_a_y</i>	p^3	24	<i>std_a_norm</i>	p^{-1}
11	<i>mean_v_foot_x</i>	p^2	25	<i>skew_omega_norm</i>	-
12	<i>skew_v_foot_y</i>	p^{-1}	26	<i>skew_omega_z</i>	p^2
13	<i>median_v_foot_y</i>	-	27	<i>std_a_x</i>	p^{-1}
14	<i>std_omega_z</i>	-	28	<i>arm3_v_foot_y</i>	p^{-1}

Out of the 28 features selected, 16 (57 %) resulted from one of the three linearization functions (f_1 , f_2 , f_3), one feature from the temporal analysis (STR), one from the orientation estimation (θ). The other features are statistics extracted from the different time series (i.e., acceleration $a(t)$, angular velocity $\omega(t)$, the velocity of the foot segment $v_{foot}(t)$, and the slope $s(t)$).

4.7.4.3 Linear model

In total, 43351 steps were used to train and test the linear model. Due to the subdivision of the data associated with the leave-one-subject-out method, we used, for each individual, a mean \pm STD (min, max) of 41287 ± 188 (41032, 41642) steps for training and 2064 ± 188 (1709, 2319) steps for testing.

When the P_{auto} feature set was used for training, the LASSO method always favored the same 7 inputs ($P_{auto,best}$) among the 28 features previously selected (Table 4.4):

$$P_{auto,best} [mean_a_norm, f_1(mean_s), f_3(STR), f_2(median_omega_z), \\ max_v_{foot_norm}, f_1(mean_v_{foot_y}), f_3(median_omega_norm)]$$

In comparison, with P_{manual} the LASSO method selected 4 inputs ($P_{manual,best}$):

$$P_{manual,best} = [rms_omega_norm, mean_v_{foot_norm}, mean_s, CT]$$

The linear predictor performances over the testing set are shown in Table 4.5; the inter-subject mean, STD, minimum, and maximum are presented for the bias, the precision, the RMSE, and the correlation coefficients. The running speed estimation results are presented for single-step resolution and where the inputs were averaged over 2, 4, 6, 8, and 10 steps before being used by the linear model.

In comparison, when we used a moving average (4 steps) on the output of the speed estimation model (i.e., not the inputs as in Table 4.5), then we obtained an inter-subject mean \pm STD (min, max) bias of 0.00 ± 0.10 (-0.17, 0.17) m/s, precision of 0.13 ± 0.05 (0.06, 0.23) m/s, RMSE of 0.14 ± 0.05 (0.08, 0.28) m/s, and correlation coefficients of 0.985 ± 0.010 (0.956, 0.997). The agreement between the speed estimation using $P_{auto,best}$ (v_{est}) and the reference GNSS system is presented for each stride (grey dots) and each individual (blue circles) in Figure 4.20.

Table 4.5 – Inter-subject mean, STD, minimum, and maximum of the system’s bias, precision, RMSE, and the linear correlation coefficient (R). The results are presented for each configuration of inputs ($P_{auto,best}$ and $P_{manual,best}$). Here, “Feat.” means features.

Feat. Step	Bias, m/s				Precision, m/s				RMSE, m/s				R

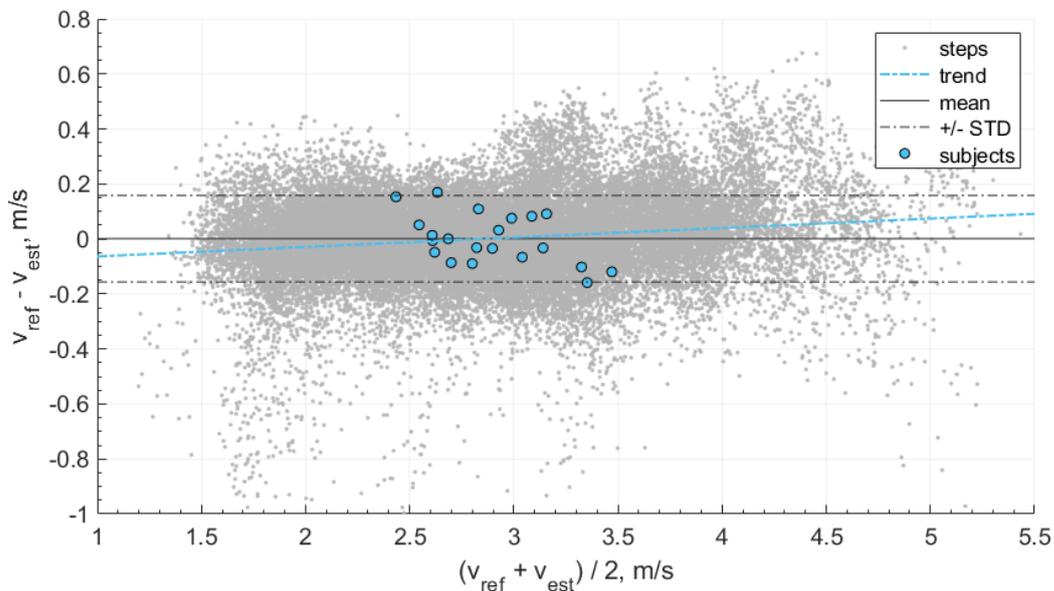

Figure 4.20 – Bland-Altman plot of the speed estimation (v_{est}) obtained with the features automatically selected ($P_{auto,best}$) and compared with the reference GNSS speed (v_{ref}). The grey dots represent the steps, the blue circle the average results of each subject, the solid black line the mean of the steps, the dashed black lines the STD of the steps, and the dashed blue line the linear trend of the steps.

Figure 4.21 (left) shows the CDF of the speed estimation error for each subject (grey lines) and the subjects aggregated (blue line). In total, 56 % of the recorded steps have an error below 0.1 m/s and 86 % below 0.2 m/s. Finally, as an illustration of overground measurement of speed over a various range of self-adjusted speed, the speed obtained with the reference GNSS system was compared for a typical subject with the speed estimation at step level ($v_{est,1}$), and the estimation when averaged over four steps ($v_{est,4}$) in Figure 4.21 (right).

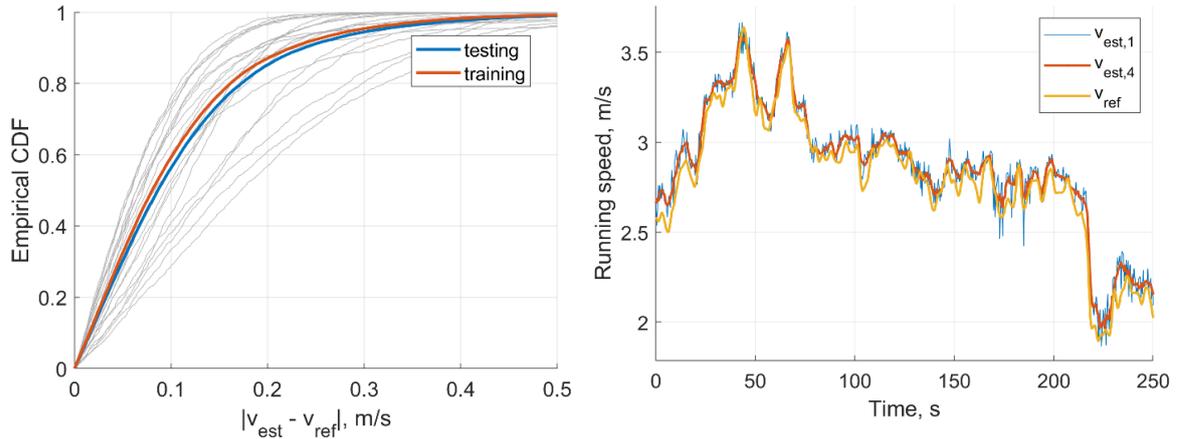

Figure 4.21 – (Left) CDF of the speed estimation error of each step ($|v_{est} - v_{ref}|$). The speed was estimated using the automatically selected inputs ($P_{auto,best}$). The grey curves represent the CDF of each individual in the testing set, the blue line the inter-subject CDF of the testing set, and the orange line the inter-subject CDF of the training set. (Right) Comparison between the speed estimation of each step ($v_{est,1}$), the speed estimation averaged over four steps ($v_{est,4}$), and the reference GNSS speed (v_{ref}).

4.7.4.4 Personalization

We used the features in P_{manual} to train and test the personalized model since the results of the generic model show little differences between $P_{auto,best}$ and $P_{manual,best}$, and because, with P_{manual} , we could include the 10 subjects from the validation set in the training and testing process without any risk of overfitting. For each subject, the training samples (i.e., half of the subject's data, randomly selected) were fed one-by-one to the RLS, and the speed was estimated with the complete test set of the subject. Figure 4.22 shows this process for the first 150 strides used to personalize the model; the solid line and the shaded area represent the inter-subject mean and STD of the RMSE. Also, the evaluation error for the first 10 strides is not displayed in Figure 4.22; these strides were used to initialize the RLS algorithm.

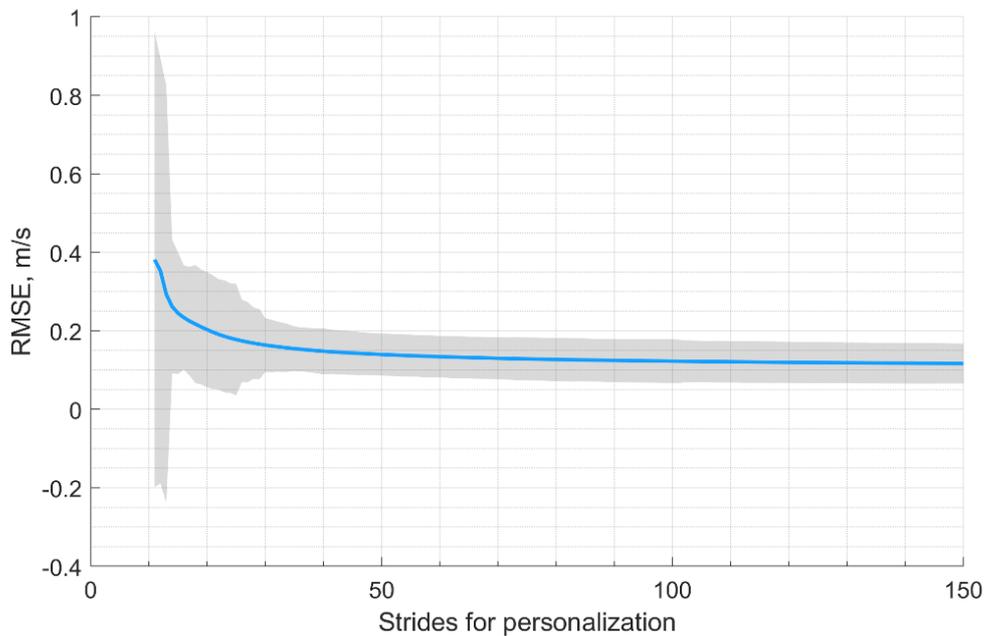

Figure 4.22 – Evolution of the RMSE error during the personalization of the speed model. Here, the solid line and the shaded area represent the inter-subject mean and STD of the RMSE. The x -axis corresponds to the number of strides used for the personalization. To better visualize the error evolution, the figure is zoomed only on the first 150 samples used for personalization.

In total, we used 1139 ± 149 strides for training and 1132 ± 149 strides for testing for each individual. Table 4.6 reports the bias, precision, and RMSE of the personalized model.

Table 4.6 – Inter-subject median and IQR error of the personalized model.

Error	Median	IQR
Bias, m/s	0.00	0.01
Precision, m/s	0.09	0.03
RMSE, m/s	0.09	0.06

Figure 4.23 also shows the Bland-Altman plot of the personalized model where the mean and STD of the error is displayed by the dark and dotted lines, respectively. Moreover, the Spearman’s test showed a high correlation of 0.97 between the estimated and the reference values of running speed.

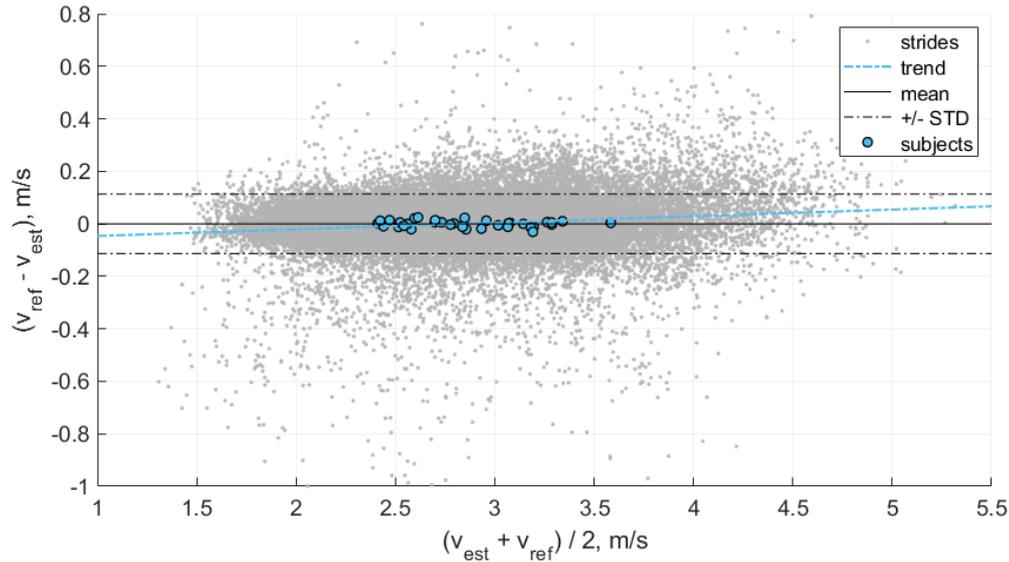

Figure 4.23 – Bland-Altman plot of the proposed personalized model. Here, the points represent samples in the testing of all subjects. The dark and dotted and lines show a mean and STD of the error, respectively.

4.7.5 Discussion

In this study, we proposed three methods to estimate overground running speed using feet worn sensors. First, we estimated the overground speed using solely the foot's velocity obtained through the direct integration of the acceleration. We evaluated this direct method to test our hypothesis that the accelerometer fails to provide the correct value during the flight phase due to the combination of rotational and translational accelerations. Nevertheless, the foot's velocity, with other relevant features, was selected as the input of the second method based on a linear model to predict the running speed. Thanks to an exhaustive features selection procedure and cross-validation approach, the model predicted the running speed with better accuracy. Finally, we assumed that the running technique varies among individuals, but it should be well correlated with individual gait features. Therefore, we showed that running speed estimation could be improved using an online-personalization method with sporadic access to some GNSS data. It is important to note that the same method could be extended to less complicated instrumentation (e.g., a stopwatch over a fixed distance).

The speed estimation result for the method based on v_{foot} only confirmed our hypothesis that the direct integration of the acceleration, as proposed for walking, cannot be generalized to running due to the presence of aerial phases. The inter-individual mean bias (0.08 m/s) we observed indicates that the direct integration method underestimates the speed during the phase of flight. This underestimation confirms the inexact measure of the translational movement by the accelerometer during the flight phase. Moreover, the trend displayed in the Bland-Altman plot

(Figure 4.17) that the system underestimates the velocity more at faster speeds. This observation is coherent with our hypothesis; the higher the speed, the greater the distance covered during the phase of flight (i.e., longer step length) (Nummela et al., 2007). Slope also seems to be a confounding factor of the error (Figure 4.18), with higher errors obtained during downhill running. In conclusion, v_{foot} itself does not characterize the speed of the subject as it cannot measure the distance covered during the period of the flight, but v_{foot} was a good proxy for speed and was one of the main features for speed prediction based on the linear model.

The selection of relevant features in the linear model was a crucial phase. Feature selection was carried over 20084 steps and aimed to retrieve the most relevant features among the 668 variables available. Although we used a high-dimensional feature space, the curse of dimensionality issue did not apply as we used approximately 30 times more observations for feature selection. The feature selection process results show that the cost function (i.e., MSE) decreased quickly with the first few inputs and then stabilized as additional features were included (Figure 4.19). We set the stopping criteria intentionally low (i.e., 1 % improvement in the MSE), knowing that the LASSO method used for training the model would ignore the inputs with redundant information. Interestingly, several of the features manually selected (P_{manual}) were among the first to be selected by the automatic process (P_{auto}); however, using different linearization functions (Table 4.5).

The linear model required inputs parameters from the temporal and spatial domain, as well as overground slopes. Hence a precise estimation of related parameters is paramount to optimize the precision of the speed estimation. The methods used to obtain these parameters should always be carefully reported and, ideally, previously validated. Interestingly, the model did not select the *FLY* parameter and instead favored the inverse of the stride duration (i.e., the stride frequency); hence none of the features selected required a bipedal configuration of the sensors allowing us to use the model with a single foot-worn IMU in the future. Also, none of the anthropometric parameters was necessary for the estimation of the running speed. This result is somewhat surprising, as we expected the height to be an essential input.

Apart from its computation time greediness, one reported issue of the forward selection algorithm is that decisions made early in the process cannot be changed, therefore potentially affecting its performance when the inputs are correlated (Derksen and Keselman, 1992). Although we observed some correlation in the inputs, we presumed that the two-fold selection process (i.e., stepwise selection and LASSO) would not be significantly affected by that matter. Moreover, the linearization of the feature-space was an essential component of this study. We selected f_1 , f_2 , and f_3 functions based on visual inspection of the data, and out of the 28 pre-selected features, 16 (57 %) resulted from these linearization functions.

Although the performance of the automatically selected set of features ($P_{auto,best}$) performed slightly better than the comprehensive set of features ($P_{manual,best}$), the differences remain in the order of a few centimeters per second (Table 4.5). Indeed, the estimations based on $P_{auto,best}$, with a granularity of 1, over-performed the ones using $P_{manual,best}$ by 0.01 m/s in the inter-subjects STD of the bias, 0.01 m/s in average precision, and display a slightly lower RMSE. These differences are relatively little since several elements in $P_{manual,best}$ were among the most relevant features selected by the LASSO regression method in $P_{auto,best}$, or at least were highly correlated. The results also show that averaging the inputs over several steps had a moderate effect on the performance of the system; it reduced the random error of the system with mean precision values consistently decreasing from 0.14 m/s for the step level estimation to 0.11 m/s when the granularity decreased to 10 steps. When the output of step level estimated speed was averaged over four steps, the precision slightly improved (0.13 ± 0.05 m/s). Hence, whether the inputs or the outputs are averaged does not seem to affect the model's performances.

Overall, the linear method showed good prediction results across a wide range of speed and slope, observed in real-world conditions (Figure 4.21, right). It principally removed the mean bias of the method based on v_{foot} only and slightly improved the precision. The Bland-Altman plot in Figure 4.20 shows a good agreement between the linear model and the reference GNSS system. The linear trend of the error (dashed blue line) is almost horizontal ($y = 0.0034x + 0.098$), suggesting that the running speed has little effect on the error. These results support using the RUS technique on the training data; the model ensured that all the ranges of speeds observed were equally represented. Although procedures more sophisticated than the RUS method have been proposed, they do not always provide a clear advantage in the results (Japkowicz, 2000). Moreover, the CDF curves of the training and testing sets do not indicate clear overfitting of the training data (Figure 4.21, left) as the training set attains better performance than the testing set, but these are within an acceptable range.

It seems challenging to reduce further the STD of the bias using such a linear model since it depends on the inter-subject differences. It has previously been reported that individuals use different spatiotemporal adaptations at similar speeds. For instance, previous studies have shown that the relationship between stride frequency and stride length was specific to each subject (Nummela et al., 2007; Saito et al., 1974). Previous studies also encountered these limitations that aimed to estimate the running speed based on body-worn IMU. In (Yang et al., 2011), the authors used a shank-worn IMU to measure the shank's velocity and compared it with the speed of a motored treadmill. The study was conducted at five predefined speeds (2.5, 2.75, 3, 3.25, 3.54 m/s), with seven participants, and the error was calculated as the difference between the average estimated speed over 30 strides and the constant speed of the treadmill (i.e., the bias). The results show inter-trial mean and STD of the bias of 0.11 ± 0.03 m/s at 2.5 m/s, 0.10 ± 0.03 m/s at 2.75 m/s, 0.08 ± 0.02 m/s at 3 and 3.25 m/s, and 0.09 ± 0.02 at 3.5 m/s. The biases reported in (Yang et al., 2011) are in range with those obtained in our study.

However, the measurements were performed on a leveled treadmill at a discrete and limited number of running speeds, and the results were averaged over 30 strides (i.e., 60 steps). By considering the foot and shank as a single rigid body, the authors in (Chew et al., 2017) used foot-worn IMU with ten participants and a similar approach as in (Yang et al., 2011). Based on the errors reported at each speed (8, 9, 10, 11 km/h), our method outperformed the one proposed in (Chew et al., 2017). Aiming to evaluate the accuracy and the repeatability of a commercialized foot-worn running assessment system (RS800sd, Polar, Kempele, Finland), the authors in (Hauswirth et al., 2009) performed 30-seconds measurements at multiple speeds (from 12 to 18km/h) and compared the speed estimations with the speed of the treadmill. Even though the commercialized system required a subject-specific calibration, the reported mean \pm STD bias of -0.03 ± 0.14 m/s indicates a slightly less accurate estimation of the running speed than the method proposed in this study. In a study (HERREN et al., 1999) conducted in outdoor conditions, the authors explored whether triaxial accelerometric measurements could be combined with subject-specific NN to assess the speed and incline of running accurately. The authors reported an RMSE of 0.12 m/s for average speed the whole running trial, which is similar to our linear model estimations when the inputs are averaged at least four steps.

In a recent effort to reduce the inter-subject differences in the bias, researchers in (De Ruiter et al., 2016) proposed a personalized speed estimation model based solely on the measurement of the contact time (CT). They obtained the CT using shoe-worn IMU and conducted the measurements on an outdoor 2 km long tarmac. First, they personalized a model ($speed = \alpha CTd$) for each of the 14 participants based on the average speed over several bouts of 125 meters. Then, they compared the personalized estimation results with those obtained with a stopwatch over a fixed 120-meters distance ($N = 35$ bouts) and reported a median RMSE of 2.9 and 2.1 % (two runs). In comparison, our linear model method obtained a mean RMSE of 5.1 % at step level estimation, and the personalized method a median RMSE of 3.1 %. This slightly higher RMSE in our study partly reflects the variety of slopes in our measurements compared to the level running in (De Ruiter et al., 2016).

A recent study (Soltani et al., 2019) proposed a real-world speed estimation method based on wrist-worn IMU. The authors obtained a median [IQR] bias of -0.02 [-0.2 0.18] m/s and precision of 0.31 [0.26 0.39] m/s for the non-personalized method. These results improved using a personalization technique similar to this study, with 0.00 [-0.01 0.02] m/s and 0.18 [0.14 0.23] m/s for the bias and precision. Hence, for both the personalized and non-personalized methods, this study out-performed the wrist-based estimation of the running speed.

The linear model is accurate for “*average people*” (i.e., individuals with typical running patterns), and individuals with an atypical running technique will give rise to higher speed estimation errors (Figure 4.20). In comparison, the personalized model adapts to

the movements of each individual; thus, it ensures a bounded error for “*average*” and “*atypical*” individuals (Figure 4.23).

The proposed personalization demonstrates significant improvements in the performance of the real-world running speed estimation. As reported in Table 4.6, the personalization process improved the IQR of the bias by at least a factor of 10 and the median precision by roughly 30 % by employing approximately 35 times less training data than the non-personalized linear model. The personalized model bypasses the bias caused by the intrinsic variation of individuals during real-world running. This observation is best characterized by Figure 4.22, which demonstrates the relatively fast convergence of the proposed RLS-based personalization; after roughly 50 strides, the model stabilized. As a consequence, the personalized model does not require continuous GNSS value to be updated. Once a good performance is reached, GNSS switch to off to save batteries. Moreover, the proposed personalized method is based on an online learning technique that does not require a database; hence it saves time and energy. It allows real-time speed estimation, computationally optimized, and does not need to store training data.

4.7.6 Conclusion

In this study, we proposed and evaluated three different methods for real-world speed estimation in the running: direct speed estimation, training based linear model, and a personalized model. The direct estimation of the foot velocity confirmed the hypothesis that accelerometers inaccurately measure an individual’s translational motion during the flight phase; therefore, techniques developed for walking analysis could not be generalized to running. We evaluated the linear model for two sets of features: automatically selected (i.e., optimized) or manually selected (i.e., comprehensive features). The model performed best when we averaged its output over a few steps and showed that 4 steps (i.e., two left strides and two right strides) provided an acceptable trade-off between performance (bias: 0.00 ± 0.11 m/s; precision: 0.12 ± 0.06 m/s) and time-resolution. The personalized method tested in this study used an online-learning technique based on recursive least-squares to personalize each individual’s speed estimations. Our results indicate that such an approach primarily reduces the inter-subject bias (0.01 m/s) and improves the average random error by more than 30 %.

Based on this study’s results, we recommend using the linear model for speed estimation when the recordings of other accurate devices are temporarily unavailable and personalized the model when these recordings are available. For instance, the system could be used as a complement to a GNSS device experiencing sparse communication, either due to a reduced transmission bandwidth (e.g., indoor running, city centers) or because of electrical power limitations (e.g., low power systems).

4.7.7 Acknowledgment

The authors thank M. Ziqi Zhao for his participation in the data analysis of the personalized model.

5 Walking speed estimation by an LB sensor: A cross-validation on speed ranges¹

5.1 Abstract

Walking speed is a key measure for daily mobility characterization. Various algorithms were developed to estimate walking speed in real-world situations using an IMU worn on the LB, which is considered a proper sensor location for monitoring in daily life. However, these algorithms were rarely compared and validated on the same datasets, including people with different preferred speed. This study implemented several original, improved, and new LB-based algorithms for estimating cadence, step length, and eventually speed (9, 12, and 16 algorithms, respectively). We designed comprehensive cross-validation to compare the algorithms on slow, normal, fast, and walking-aids walkers. We used two datasets (40 subjects with an instrumented mat and 88 subjects with the shanks-worn IMU references), including both healthy and patients. The results showed that the proposed improvements were useful (up to 50%). Training on all people with different preferred speed led to better performance. For the slow walkers, an average RMSE of 2.5 steps/min, 0.04 m, and 0.10 m/s were respectively achieved for cadence, step length, and speed estimation. For normal walkers, the errors were 3.5 steps/min, 0.08 m, and 0.12 m/s. An average RMSE of 1.3 steps/min, 0.05 m, and 0.10 m/s were also observed on fast walkers. For people with walking-aids, the error significantly increased up to an RMSE of 14 steps/min, 0.18 m, and 0.27 m/s. The results demonstrated the robustness of the proposed combined speed estimation approach for different speed ranges. It achieved an RMSE of 0.10, 0.18, 0.15, and 0.32 m/s for slow, normal, fast, and walking-aids walkers.

Keywords: walking speed, step length, cadence, inertial sensors, slow walkers, walking-aids.

Contributions are as follows: study design; data collection; algorithms design and implementation; contribution to data analysis, performance evaluation, and writing the manuscript.

5.2 Introduction

Walking speed has recently emerged as an essential indicator of human functional ability, recognized as the sixth vital sign, and a key factor for healthy aging (Choi et al., 2011; Del Din et al., 2016a, 2016b; Elble et al., 1991; Fritz and Lusardi, 2009; Harada et al., 1995; van Iersel et al., 2008; Rydwick et al., 2012; Steffen et al., 2002; WHO, 2015). In clinical/epidemiological studies, walking speed has become an essential measure in characterizing movement-related pathologies, the design and assessment of interventions, and the early detection of functional decline (Castell et al., 2013; Fritz and Lusardi, 2009; Maki, 1997; Middleton et al., 2015; Perera et al., 2015; Quach et al., 2011; Rochat et al., 2010; Salarian et al., 2004; Studenski et al., 2011; Weiss et al., 2014).

Studies have recently demonstrated that people walk differently during unsupervised real-world situations than supervised ones such as a laboratory. Daily-life gait is usually self-triggered, purposeful (e.g., catching a bus, shopping), and happening in a multitasking context (e.g., walking and texting). Several psychological and psychological factors (e.g., white coat effect setting (Warmerdam et al., 2020), Hawthorne effect (Paradis and Sutkin, 2017; Robles-García et al., 2015), pain, stress) also contribute to the difference between daily-life and in-lab gaits. One might have longer step length (traveled distance during one step), higher cadence (number of steps per unit time), hence, higher speed during long-distance walking in real-world situations (Bonato, 2005; Brodie et al., 2016; Dobkin and Dorsch, 2011; Hillel et al., 2019; Kawai et al., 2020; Takayanagi et al., 2019; Warmerdam et al., 2020). Therefore, it is crucial to design portable systems capable of estimating speed and related parameters in every-day life conditions.

GNSS offers the most straightforward solution for measuring walking speed in daily life (Fasel et al., 2017a; Terrier et al., 2000; Witte and Wilson, 2004). However, it suffers from two major issues: a high power consumption, limiting the duration of measurements, and the need for communication with satellites, which restricts measurements only to outdoor environments. In order to overcome these issues, an alternative solution is to develop speed estimation algorithms based on IMU (i.e., accelerometer, gyroscope, and possibly barometer) mounted on various body segments. Among the different sensor configurations and locations, a single sensor, worn on the upper body (e.g., LB, sternum, waist, and wrist), has attracted more attention by providing a user-friendly and straightforward measurement setup for real-world and long-term monitoring (Paraschiv-Ionescu et al., 2004; Yang and Li, 2012).

Wrist-based algorithms have been shown to be successful in monitoring walking in healthy populations because of the clear repetitive pattern in the acceleration signal as well as being free from a fixed sensor position, which is ideal for handheld electronic gadgets (Duong and Suh, 2017a; Fasel et al., 2017a; Park et al., 2012; Soltani et al.,

2019; Zihajehzadeh and Park, 2016). However, further studies aimed at validating the wrist algorithms on populations with gait disorders are required.

Another widely used solution is to mount a single IMU on the LB. This sensor's location offers several advantages. Typically, IMU is tightly fixed on the body, which reduces the artifacts and provides the possibility to align the sensor's axes with the body or global coordinate systems. Second, an LB-worn IMU is close enough to the body CoM ensures a robust gait pattern in the acceleration signal, even in the presence of abnormal gait. These advantages provide the opportunity to develop biomechanical and physical models (Zijlstra and Hof, 2003) for estimating a wide range of gait parameters, from primary outcomes such as cadence, step length, and speed to the secondary ones like gait variability and symmetry (Aminian et al., 1995a; Bylemans et al., 2009; Kim et al., 2004; Köse et al., 2012; Lee et al., 2010; McCamley et al., 2012; McGinnis et al., 2017; Paraschiv-Ionescu et al., 2019; Pham et al., 2017; Shin and Park, 2011; Weinberg, 2002; Zhang et al., 2018; Zhao et al., 2017; Zijlstra and Hof, 2003).

For speed estimation based on an LB-mounted IMU, a common approach is to estimate cadence and step length separately, whose multiplication results in speed. For cadence estimation, several approaches have been proposed, including both time and frequency domain algorithms. Briefly, TD algorithms are based on the detection of step-related temporal events (e.g., IC), using signal processing techniques for peak enhancement and detection (Lee et al., 2010; McCamley et al., 2012; Paraschiv-Ionescu et al., 2019; Pham et al., 2017; Shin and Park, 2011; Zijlstra and Hof, 2003). The second type of the algorithms work in FD and try to estimate the acceleration signal's dominant frequency, associated with step or stride frequencies (Fasel et al., 2017a).

Regarding the step length estimation, this could be estimated through BM (e.g., inverted pendulum model or empirical intensity-based models (Bylemans et al., 2009; Kim et al., 2004; Weinberg, 2002; Zhao et al., 2017; Zijlstra and Hof, 2003)), DI (Köse et al., 2012), and recently by deploying ML methods (e.g., linear regression, Gaussian process regression, SVM, NN (Aminian et al., 1995a; Soltani et al., 2019; Tibshirani, 1996; Zihajehzadeh and Park, 2017)).

Recent research studies have revealed that people with movement-related disorders such as MS, PD (Disease, 2003), Hemiparesis (HE, (Holden et al., 1984)), Huntington's disease (HD, (Kiebertz et al., 2001)), or even healthy older adults, generally have a lower range of walking speed (slow walkers) than healthy populations (normal and/or fast walkers). Based on these previous findings, it is well known that algorithms' performances might decrease when analyzing impaired and/or slow gait with/without walking-aids due to changes in the acceleration patterns and amplitudes. Therefore, in the light of the abovementioned considerations, it is crucial for the development of evidence-based clinical gait analysis applications to assess algorithms validity across both healthy and pathological populations and to understand to which extent algorithms performances are influenced by changes in acceleration patterns due to different speeds and gait patterns (Bryant et al., 2011; Combs et al., 2014; Dean et al.,

2001; Dobkin et al., 2011; Hebenstreit et al., 2015; Kim and Eng, 2004; Kim and Oh, 2019; Kirtley et al., 1985; Reisman et al., 2009; Rochester et al., 2008).

This study pursues a comprehensive cross-validation analysis to investigate speed estimation performance and related parameters when a single IMU is mounted on the LB. This performance was evaluated in a different range of speeds with data recorded in healthy and patient populations. To this end, we developed and improved various algorithms according to methodologies adapted from the existing literature. We also propose new algorithms as well as a new concept to combine various algorithms with taking advantage of all approaches into one unique solution towards optimizing the performance. Cross-validation was conducted to investigate the performance of algorithms when test and training datasets corresponded to various partitions of walking patterns/speed (i.e., slow, normal, fast, all ranges as well as using walking-aids). The algorithms have been evaluated on two datasets recorded in both healthy and mobility-impaired populations. In addition to the LB-worn IMU data, these datasets included reference values for relevant gait parameters.

5.3 Methods

5.3.1 Materials and measurement protocols

Two datasets have been employed in this study; Dataset M1 with a reference system based on an instrumented walkway and dataset M2 with a reference system based on the IMU mounted on the shanks.

5.3.1.1 Dataset M1

Instrumentation: A single IMU (Opal™, APDM) was attached to the subject's lumbar spine (between L4 and S2) using an elastic waist belt. The IMU contained a 3D accelerometer (± 6 g) and a gyroscope, and the device recorded the sensor signals at a sampling frequency of 128 Hz (Allseits et al., 2019). A 7-meter instrumented mat (GAITRite™ Electronic Walkway, CIR System Inc.) was employed as the reference for temporal and spatial gait parameters (sampling at 120 Hz, with spatial and temporal accuracies of 12.7 mm and 1 sample, respectively). A cable was used to synchronize the instrumented mat with the IMU with an accuracy of ± 1 sample.

Participants: 40 subjects (24 women, 16 men, age 62 ± 8 , height 165.8 ± 7.0 cm, weight 68.6 ± 10.7 kg) from four clinical populations of older adults, PD (with a Unified PD Rating Scale (Disease, 2003) of 62.7 ± 19.1), HE (as a consequence of stroke with a Functional Ambulatory Category score (Holden et al., 1984) of 3.3 ± 1.5), and HD (with a Unified HD Rating Scale (Kiebertz et al., 2001) of 34.9 ± 16.9) have been included in this dataset (ten subjects from each category). The participants were enrolled at the Movement Disorders Clinic of the University of Genoa. Informed written consent was

collected from all participants, and a local ethics committee approved the measurement protocol (Trojaniello et al., 2014, 2015).

Protocol: Participants walked back and forth along a 12-meter path (7-meter instrumented mat was placed 2 meters from the starting point) for around 1 minute at their self-selected comfortable speed. They were also allowed to use walking-aids such as tripods.

5.3.1.2 Dataset M2

Instrumentation: Three time-synchronized IMU (Opal™, APDM) were mounted on each subject (one on the lumbar spine (around L5, (Spain et al., 2012)), and one on each shank, close to the ankle) through adjustable Velcro straps, featuring 3D accelerometer (± 6 g) and gyroscope, sampled at 128 Hz. The algorithm described in (Aminian et al., 2002; Salarian et al., 2013), based on the shanks-attached IMU, was used to provide reference values for the temporal and spatial gait parameters. Compared to the motion capture system, an error (mean \pm STD) of 0.002 ± 0.023 s, 0.038 ± 0.066 m, and 0.038 ± 0.056 m/s for estimating stride time, stride length, and stride velocity by the reference system was reported in (Aminian et al., 2002; Salarian et al., 2013).

Participants: 88 subjects (59 women, 29 men, age 54 ± 9) from two populations of Healthy Control (HC, 24 subjects), and patients with MS (64 subjects) were included in this dataset. Their disability status was evaluated by the Expanded Disability Status Scale (EDSS), where a median (range) score of 5.5 (3.0–6.5) was observed for the MS population. The participants were chosen either from the Sheffield MS Clinic at the Royal Hallamshire Hospital or the Sheffield Clinical trial Unit (both in Sheffield, United Kingdom) (Angelini et al., 2020), with ethics approval granted by the NRES Committee Yorkshire & The Humber-Bradford Leeds, (reference 15/YH/0300) and by the North of Scotland Research Ethics Committee (IRAS project ID: 224422).

Protocol: Each participant walked straight back and forth over a 10-meter path for around 6 minutes at their self-selected comfortable speed. They were allowed to use walking-aids and to end the measurement at any time based on their exhaustion. This protocol also includes several turns for each subject. We employed the algorithm proposed in (El-Gohary et al., 2014) to detect and remove the turning periods from the database M2. In (El-Gohary et al., 2014), sensitivity and specificity of 0.9 and 0.75 were reported to detect turns.

5.3.2 Reference values

Reference systems of both datasets M1 and M2 provided the cadence, stride length, and speed in stride granularity. In order to compare the results of the reference systems with the LB-based approaches, the average values of cadence, stride length, and speed over each walking bout (i.e., walking period consists of consecutive strides, detected by

the reference systems) were computed. In a walking bout, the average stride length divided by 2 was considered as the average step length over the bout.

5.3.3 Single sensor algorithms

In order to estimate walking speed using an LB-mounted single sensor, we estimated the cadence and step length, separately, whose multiplication resulted in the speed. This simplification reduces the nonlinearity and complexity of the developed algorithms, which might improve the performance (Soltani et al., 2019). All the algorithms have been validated under the condition of continuous straight-line walking. It is worth mentioning that, for both cadence and step length estimation, we only focused on the most popular and original algorithms in the literature rather than their variations.

5.3.3.1 Preprocessing

State-of-the-art algorithms based on LB sensor location generally use a 3D accelerometer (a_x , a_y , a_z), and as inputs, the acceleration along unidirectional axes (vertical or AP), or the acceleration norm, a_{norm} , computed according to (5.1).

$$a_{norm}(t) = \sqrt{a_x(t)^2 + a_y(t)^2 + a_z(t)^2} \quad (5.1)$$

The algorithms assume that the accelerometer axes (x , y , z) are aligned with the global reference system and/or the measurement setup includes functional calibration procedures. However, this assumption/technique is not practical for the real-world measurement setup. The alternative solution is to take advantage of a 3D gyroscope available in the IMU devices and correct the sensor orientation using complementary filters and other signal-processing approaches. Therefore, we proposed a preprocessing stage including the Madgwick filter (Madgwick, 2010) to correct the orientation of vertical acceleration, $a_v(t)$, and the PCA during each walking bout to align the AP acceleration, $a_{ap}(t)$, with the direction of movement/walking.

5.3.3.2 Cadence estimation

We developed seven cadence estimation algorithms (CAD1-7, adapted from the existing literature according to their popularity and originality) and two new combined methods (cTime and cALL). For all algorithms, the mean cadence over each walking bout was computed and compared to the reference value. The algorithms were categorized into three methodological approaches as TD, FD, and combined. In the following, the cadence algorithms are briefly explained.

5.3.3.2.1 TD approach

We implemented and improved six TD cadence estimation algorithms (CAD1-6) with the ideas adapted from the existing literature. All the algorithms were based on the detection of IC of both feet during walking. Step duration was defined as the period between two consecutive IC of different feet. Then, the instantaneous cadence was estimated as the inverse function of the step duration (in the minute unit to have steps/min unit for the cadence). Eventually, for each algorithm, the mean value of the cadence over each walking bout was computed.

For the algorithms sensitive to the step-related peaks in the input signals (CAD2, CAD3, and CAD6), we employed a peak enhancement method adapted from (Paraschiv-Ionescu et al., 2019). To this end, a combination of de-trending, zero-phase low pass filtering (FIR, $f_c \approx 3.2$ Hz), followed by a continuous wavelet transform (CWT) smoothing and differentiation procedure (scale 10, “*gauss2*”), and a Savitzky-Golay filtering were applied to reduce high-frequency noises (movement artifacts) as well as enhancing the step-related peaks.

CAD1: The first algorithm was adopted from (Zijlstra and Hof, 2003), where we first low-pass filtered $a_{ap}(t)$ (FIR, $f_c \approx 3.2$ Hz) according to (Paraschiv-Ionescu et al., 2019). Then, the peaks of $a_{ap}(t)$ preceding a change of sign of the signal were detected as IC.

CAD2: This algorithm was based on (Shin and Park, 2011) where the smoothed acceleration $SWS(k)$ was obtained from $a_{norm}(t)$ using a sliding window of size W equivalent to 0.2 s, as stated in (5.2).

$$SWS(k) = \sum_{t=k-W+1}^k a_{norm}(t) \quad (5.2)$$

Then, the acceleration differential according to (5.3), $a_{diff}(k)$, was used for identifying IC as zero-crossing of the negative-to-positive signal slope.

$$a_{diff}(k) = SWS(k + W) - SWS(k) \quad (5.3)$$

CAD3: This algorithm was developed as a combination of the processing techniques described in (McCamley et al., 2012) and (Paraschiv-Ionescu et al., 2019). The vertical acceleration $a_v(t)$ was filtered by integration and differentiation using the CWT (scale 9, “*gauss2*”). Then, IC were determined by the detection of the minima of the smoothed signal. Before applying the CWT, the $a_v(t)$ signal was de-trended and low-pass filtered (FIR, $f_c \approx 3.2$ Hz).

CAD4: This algorithm was according to (Paraschiv-Ionescu et al., 2019) where, first, the peak enhancement method was applied on $a_{norm}(t)$ to compute the filtered acceleration ($a_f(t)$). Then, for further enhancement of the step-related peaks, a peak sharpening method (O’Haver, 1997) was applied on $a_{sharpen}$ corresponding to the Taylor

series expansion of $a_f(t)$ where only the second (a_f'') and fourth (a_f'''') derivatives are considered as stated in (5.4).

$$a_{sharpen}(t) = a_f(t) - K_2 a_f''(t) + K_4 a_f''''(t) \quad (5.4)$$

Here, K_2 and K_4 are adjustable factors, empirically found set as 20 and 2, respectively, to optimize the performance on the training data. Eventually, an adaptive threshold was applied on $a_{sharpen}(t)$ to determine the step-related peaks as IC.

CAD5: According to (Pham et al., 2017), $a_{ap}(t)$ was linearly de-trended and low-pass filtered using a second-order Butterworth filter ($f_c = 10$ Hz). Then, the signal was integrated and differentiated using CWT (an estimated scale according to (Pham et al., 2017)). Finally, the minima of the processed signal were reported as IC.

CAD6: According to (Lee et al., 2010), opening and closing morphological filters (nonlinear signal transformations that reshapes information of a signal (Chu and Delp, 1989)) were applied to $a_{norm}(t)$ in order to highlight the step-related peaks. Then, the peaks higher than a specified threshold were selected as IC. In order to improve this algorithm, $a_{norm}(t)$ went through the proposed peak enhancement method, described in (Paraschiv-Ionescu et al., 2019), before applying the morphological filters.

5.3.3.2.2 FD approach

CAD7: The FD approach included one algorithm according to (Fasel et al., 2017a), which is based on detecting the dominant peak of the spectrum of the acceleration norm. To this end, a comb function has been applied to the estimated spectrum to sharpen the dominant frequency related to step or stride. This comb function helps to detect correct peaks and be able to distinguish between the step and the stride frequencies. Then, a maximum likelihood technique was used to estimate the cadence. The algorithm presented in (Fasel et al., 2017a) employs the Euclidean norm, $a_{norm}(t)$, which is a non-linear operation and it might distort the acceleration signal. Therefore, we improved this algorithm using (5.5) by estimating the *Overall Spectrum* as the sum of spectrum of each channel of acceleration.

$$Overall\ Spectrum = AX(f) + AY(f) + AZ(f) \quad (5.5)$$

Here, AX , AY , and AZ are respectively the spectrum of a_x , a_y , a_z , and f is the frequency variable. Like (Fasel et al., 2017a), we used a 256-point FFT with a Hann window to compute the spectrum of acceleration signals. Like the other algorithms, the mean cadence over each walking bout was computed.

5.3.3.2.3 Combined approach

We proposed the combined approach (Figure 5.1), where the output of different algorithms was averaged with equal weights to generate a combined solution. Through

this procedure, we proposed two combined cadence estimation algorithms called cTime and cALL, which were respectively the average the TD (CAD1-6) and all (CAD1-7) algorithms. Since we had only one algorithm (CAD7) for the FD approach, we did not define a combined solution for this approach.

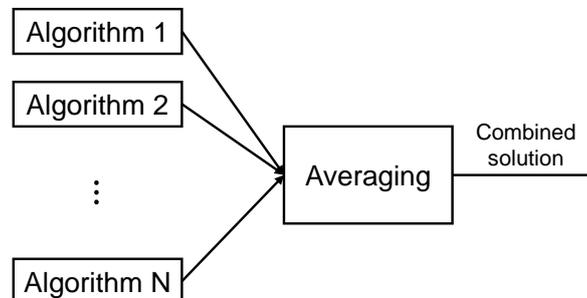

Figure 5.1 – Proposed combination strategy. An equally-weighted averaging is applied on the output of algorithms 1 to N in order to provide a more robust combined solution.

5.3.3.3 Step length estimation

We developed a total number of 12 step length algorithms (STPL1-12) plus four combined algorithms (cBM, cDI, cML, and cALL), which have been categorized into four main approaches (i.e., BM, DI, ML, Combined). For each algorithm, the mean value of the step length during each walking bout was calculated. Besides, in order to isolate the error of the step length algorithms from the error of cadence estimation (IC detection), here, we used IC detected by the reference systems ($ic(m)$, where m is the step's number/index within a walking bout). Besides, the IC was used to derive the reference cadence, $CAD_{step}(m)$, to be used as a parameter by some of the step length algorithms. Since several algorithms required the cadence in per-second granularity, we applied a moving window with the length of one second on $CAD_{step}(m)$ to estimate the instantaneous cadence $CAD_{second}(t)$. Moreover, in this section, variables A and B are the tuning coefficients, computed during the training sessions to optimize the performance. In the following, the step length estimation approaches are explained.

5.3.3.3.1 BM-based approach

This approach included four algorithms (STPL1-4) adapted from the existing literature and based on models that describe the biomechanics of human body segments (such as legs and trunk) during walking.

STPL1: This algorithm was based on the inverted pendulum model according to (Zijlstra and Hof, 2003) and (Zijlstra and Hof, 1997), where the step length was computed through (5.6). Here, $d_{step}[m]$ is the vertical displacement of the body CoM (i.e., LB in this study) during m -th step, and l is the pendulum length (i.e., the leg length).

$$STPL1[m] = A \left(2 \sqrt{2 l d_{step}[m] - d_{step}[m]^2} \right) + B \quad (5.6)$$

To calculate the vertical displacement of the CoM in the original method (Zijlstra and Hof, 1997), the $a_v(t)$ was double integrated and high-pass filtered with a fourth-order Butterworth filter with a cut-off frequency of 0.1 Hz to obtain the vertical position, $d_v(t)$. Then, $d_{step}[m]$ was computed according to (5.7), within two neighboring IC.

$$d_{step}[m] = \frac{|\max(d_v(t)) - \min(d_v(t))|}{ic(m) \leq t \leq ic(m+1)} \quad (5.7)$$

This method was modified as follow (Figure 5.2): the high-pass filtered $a_v(t)$ (fourth-order Butterworth, $f_c = 0.1$ Hz) was integrated to obtain the vertical speed, $V_v(t)$. Then, $V_v(t)$ was high-pass filtered (fourth-order Butterworth, $f_c = 1$ Hz, empirically chosen) and integrated (by MATLAB function “*cumsum*”) to compute the vertical displacement, $d_v(t)$. Eventually, we estimated $d_{step}[m]$ using the same equation as (5.7).

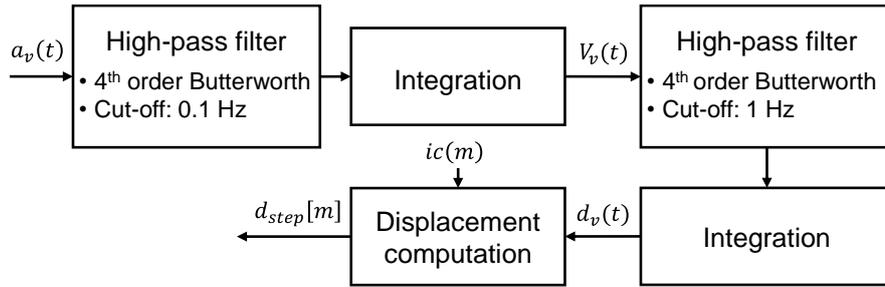

Figure 5.2 – Block diagram of estimating the vertical displacement of LB during each step, $d_{step}[m]$. After filtering and integrating $a_v(t)$, the vertical speed, $V_v(t)$, was high-passed and integrated to obtain the vertical displacement, $d_v(t)$. Then, the effect of drift was removed by computing the difference between maximum and minimum of $d_v(t)$ between each neighboring IC, $ic(m)$.

STPL2: We developed the second algorithm according to (Weinberg, 2002), where the step length was estimated using a geometrical acceleration-intensity-based model (see (5.8)).

$$STPL2[m] = A \left(\sqrt[4]{a_{maxmin}(m)} \right) + B \quad (5.8)$$

Here, $a_{maxmin}(m)$ is the difference between maximum and minimum of $a_v(t)$ during m -th step as defined in (5.9). We modified this algorithm by filtering $a_v(t)$ with a fourth-order low-pass Butterworth ($f_c = 3$ Hz) before using it in (5.9).

$$a_{maxmin}(m) = \frac{|\max(a_v(t)) - \min(a_v(t))|}{ic(m) \leq t \leq ic(m+1)} \quad (5.9)$$

STPL3: This algorithm was designed according to (Kim et al., 2004) and (Zhao et al., 2017), where the mean absolute value of $a_v(t)$ during a step duration ($a_{vMean}(m)$ in (5.10)) was employed to estimate the step length, as shown in (5.11).

$$a_{vMean}(m) = \text{mean}_{ic(m) \leq t \leq ic(m+1)} |a_v(t)| \quad (5.10)$$

$$STPL3[m] = A \left(\sqrt[3]{a_{vMean}(m)} \right) + B \quad (5.11)$$

It should be noted that, in the original algorithm, the vertical acceleration is derived from a shank-mounted IMU. However, we used the vertical acceleration obtained from the LB-mounted IMU that is valid for the algorithm since both vertical accelerations were in the global frame.

STPL4: This algorithm was based on (Bylemans et al., 2009), where the step length was modeled according to (5.12). Here, $T(m)$ is the duration of the m -th step, which was computed according to (5.13), and $a_{maxmin}(m)$, $a_{vMean}(m)$ were calculated through (5.9), (5.10), respectively. It should be noted that, before using (5.12), $a_v(t)$ was smoothed using a moving average with a length of 0.125 s.

$$STPL4[m] = A \left(\sqrt[2.7]{(a_{vMean}(m)) \times \sqrt{\frac{1}{\sqrt{T(m)} \times a_{maxmin}(m)}}}} \right) + B \quad (5.12)$$

$$T[m] = ic(m+1) - ic(m) \quad (5.13)$$

5.3.3.3.2 DI-based approach

One straightforward way to estimate the step length is to double integrate the forward acceleration, $a_{ap}(t)$, in the global frame. The difficulty with this approach, especially for a single LB sensor, is to assure an accurate estimation of AP acceleration and remove the accumulated integration drift using an appropriate technique. Only a few methods have been proposed in the literature, such as (Köse et al., 2012), which needed some requirements like the initial values for the AP speed and an expected position of CoM at specific gait events (e.g., IC). Therefore, we adapted the main ideas and proposed three new algorithms (STPL5-7) where for each algorithm, the mean step length during each walking bout was computed.

STPL5: First, the acceleration $a_{ap}(t)$ was filtered using a second-order high-pass Butterworth filter ($f_c = 0.5$ Hz). Then, the filtered signal was double integrated to obtain the AP position, $p(t)$. Finally, to reduce the effect of the drift, the step length was computed according to (5.14) where $a_{apMean}(m)$ is the mean value of $a_{ap}(t)$ during the m -th step calculated in (5.15).

$$STPL5[m] = A \left(\frac{|\max(p(t)) - \min(p(t))|}{ic(m) \leq t \leq ic(m+1)} \times a_{apMean}(m) \right) + B \quad (5.14)$$

$$a_{apMean}(m) = \text{mean}_{ic(m) \leq t \leq ic(m+1)} (a_{ap}(t)) \quad (5.15)$$

STPL6: This algorithm is based on a data-adaptive estimation of the integration drift and more effective removal using the EMD (Flandrin et al., 2004; Zhao et al., 2017). As illustrated in Figure 5.3, after removing the mean value of $a_{ap}(t)$, the signal was integrated, then, the EMD was applied where only the first four intrinsic modes were used for the reconstruction. Next, the resulted signal was again integrated, and the EMD applied to remove the drift and to reconstruct the AP position, $p(t)$, by keeping only the first three modes. Finally, similar to STPL5, $p(t)$ was fed into (5.14) to obtain the step length.

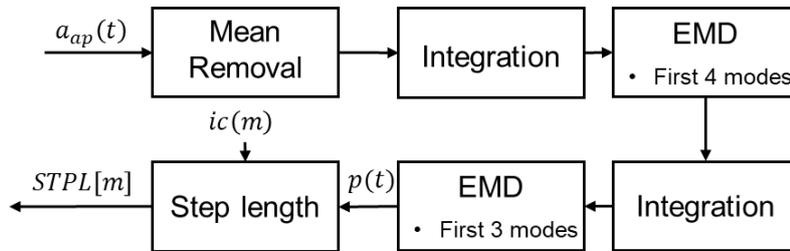

Figure 5.3 – Block diagram of the step length estimation method according to EMD (STPL6). After removing the mean of $a_{ap}(t)$ and integrating the zero-mean signal, an EMD was used to keep the four first modes of the signal. Then, another integration and EMD were applied to the resulted signal to generate $p(t)$ by first three modes. Finally, (5.14) and (5.15) were used to compute the step length.

STPL7: Another effective approach for removing the integration drift is to reset the integration by an initial value at each gait cycle. For sensors mounted on the lower limbs, especially on the feet, the assumption of the ZUPT at the beginning of each gait cycle has been widely used (Mannini and Sabatini, 2014; Peruzzi et al., 2011). However, for the IMU mounted on the upper body (such as LB), this assumption is not valid since the upper body could move even when the foot is on the ground. In STPL7, we proposed to correct the mean value of the linear speed (i.e., integrated acceleration) by the speed estimated using $STPL1(m)$ and $STPL2(m)$. To this end, as it is shown in Figure 5.4, first, $a_{ap}(t)$ was integrated with the ZUPT assumption at each IC to obtain the linear velocity, $V_{linear}(t)$. In parallel, in the Mean Velocity Computation block, we calculated the mean value of speed at each step according to (5.16). Then, the mean value of $V_{linear}(t)$ at each gait cycle was removed and replaced by $V_{mean}[m]$ to obtain $V_{corrected}(t)$. Next, $V_{corrected}(t)$ was integrated to compute the position, $p(t)$. Finally, we employed (5.17) to estimate the step length.

$$V_{mean}[m] = \left(\frac{STPL1(m) + STPL2(m)}{2} \right) \times CAD(m) \quad (5.16)$$

$$STPL7[m] = A \left(\max_{ic(m) \leq t \leq ic(m+1)} (p(t)) \right) + B \quad (5.17)$$

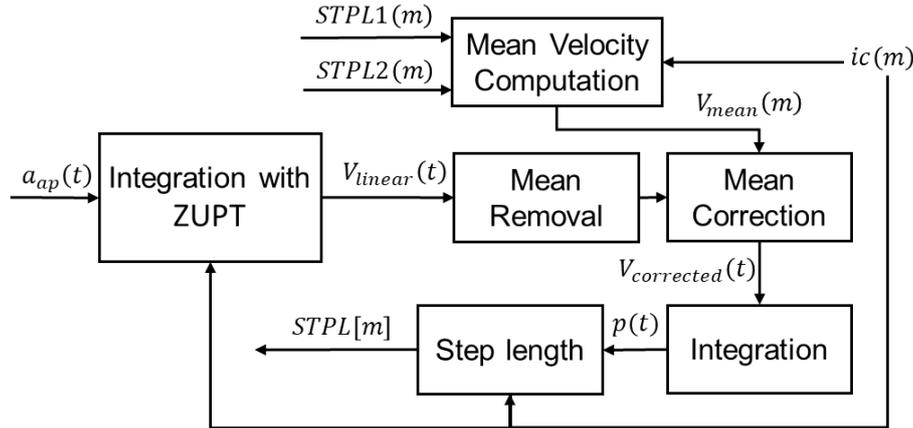

Figure 5.4 – Block diagram of STPL7. Here, after the integration of $a_{ap}(t)$ with zero-velocity update assumption, the mean value of $V_{linear}(t)$ at each gait cycle was replaced with a new mean, $V_{mean}(m)$, computed according to (5.16) to obtain $V_{corrected}(t)$. Then, the resulted signal was integrated and (5.17) was used to compute the step length.

5.3.3.3.3 ML-based approach

We selected and implemented 6 step length estimation algorithms (STPL8-13) based on the ML technique. STPL8-11 were developed and improved according to the existing literature, while STPL12 was newly developed. For STPL9-12, a moving window with a one-second shift was used to extract their corresponding features (explained later in this subsection). The length of this window was set according to the minimum value between the length of each walking bout and 5 seconds. For STPL8, the features were extracted during each step duration. For each algorithm, the mean step length over each walking bout was computed. The ML-based algorithms are as follow:

STPL8: In this algorithm (Aminian et al., 1995a), several statistical features such as mean, median, and STD of $a_v(t)$ and $a_{ap}(t)$ during each step, as well as demographic information like height and gender were fed into a feedforward NN with 5 hidden layers.

STPL9: This algorithm was developed according to (Zihajehzadeh and Park, 2017) where features such as mean, mode, median, STD, the sum of absolute values, the sum of square values, and number of zero crossings of $a_{norm}(t)$, along with height and gender information were fed into a Gaussian process regression model.

STPL10: In this algorithm, a SVM-based regression was deployed to model the step length (McGinnis et al., 2017). Mean, range, kurtosis, and the cross-correlation of the filtered $a_v(t)$ and $a_{ap}(t)$ (second-order low-pass Butterworth, $f_c = 12$ Hz) were extracted as a part of features. In addition, the amplitude of the spectrum of the filtered $a_v(t)$ at dominant frequency was computed as a feature. Moreover, the cadence ($CAD_{second}(t)$), the height and the gender were also included as features.

STPL11: This algorithm was proposed to adapt the non-personalized version of the algorithm, described in (Soltani et al., 2019), to be suitable for the LB-mounted IMU. Features like mean of $a_{norm}(t)$, STD of $a_v(t)$, STD of $a_{ap}(t)$, the mean absolute derivative of $a_{norm}(t)$ (called as the jerk in (Soltani et al., 2019)), the cadence ($CAD_{second}(t)$), the height, and the gender were used in a linear least square regression to model the step length. It is worth mentioning that the original algorithm required the slope of the path derived from a barometer, which was discarded in this adapted model.

STPL12: This is one of the new algorithms we proposed. Features like the vertical displacement of CoM (see (5.7)) median, range, and kurtosis of $a_{ap}(t)$, mean and STD of $a_{norm}(t)$, mean of $a_v(t)$, cadence ($CAD_{second}(t)$), the height, and the gender were used in a linear regression model with the well-known LASSO regularization, which guaranteed a non-singular solution, and also had an intrinsic feature selection behavior (Tibshirani, 1996).

5.3.3.3.4 Combined approach

Similar to the cadence estimation, here, the combined approach for step length estimation was proposed. Four combined algorithms, cBM, cDI, cML, and cALL were derived as the average of the outputs of BM (STPL1-4), DI (STPL5-7), ML (STPL8-12), and all (STPL1-12) algorithms, respectively.

5.3.4 Implementation, cross-validation, and statistical analysis

We implemented all the abovementioned algorithms in MATLAB. Comprehensive cross-validation was also performed separately for dataset M1 (with the instrumented mat) and M2 (with an IMU-based reference system). In each cross-validation, first, the mean speed of each subject ($V_{refMean}(s)$, where s is the subject index) was computed using the reference speed values. Second, in order to evaluate the effect of speed range and the usage of walking-aids, subjects were categorized into four groups as follows: slow ($V_{refMean} < 1$ m/s), normal ($1 \leq V_{refMean} \leq 1.3$ m/s), fast ($V_{refMean} > 1.3$ m/s), and walking-aids (subjects who used walking-aids during the measurements). Then, the subjects within each speed category (except the walking-aids group) were divided into two equal subgroups (i.e., 50-50 %) as training and testing data. Since the subjects with walking-aids were not the focus of this study, we included this group only in testing data. Besides, we built ALL_train (for training) and ALL_test (for testing)

subcategories, which were respectively the aggregation of the training and testing data of slow, normal, and fast walkers. In order to evaluate the implemented algorithms, the RMSE between the reference values and the LB-based algorithms for cadence, step length, and speed estimation was computed on the test dataset.

5.4 Results

5.4.1 Participants

Table 5.1 shows the number of subjects within each speed category used for the proposed cross-validation analysis. As indicated, there is a proper balance of the number of subjects in the different groups. Note that the walking-aids groups were used only for testing. Moreover, since height information was missing in dataset M2, we consider a typical height value of 170 cm in the algorithms which need height information.

Table 5.1 – Distribution of participants in the proposed cross-validation. For instance, the column “*Slow*” reports the number of slow walkers included in the training and test data within each dataset.

Datasets	Session	Slow	Normal	Fast	ALL	Walking-aids
M1	Train	6	7	6	19	0
	Test	5	6	5	16	5
M2	Train	12	11	8	31	0
	Test	12	11	7	30	27

5.4.2 Performance improvements

Figure 5.5 compared the performance of the modified algorithms before (blue) and after (orange) the improvements for the estimation of cadence (right) and the step length (left) in both dataset M1 (top) and M2 (down). After enhancements, the RMSE mostly decreases. The algorithms were trained (if required) and tested on the “*ALL*” category of train and test sets of each dataset.

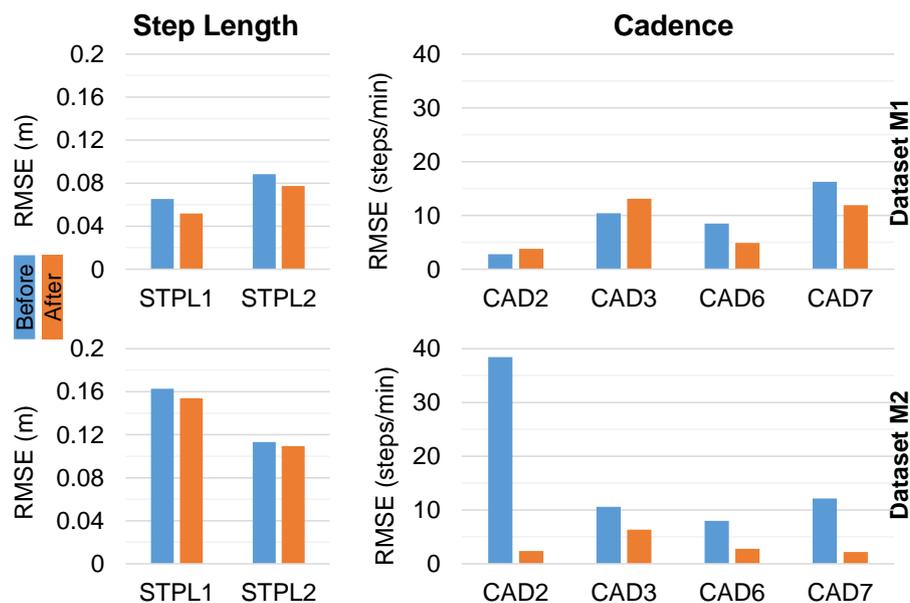

Figure 5.5 – RMSE of the algorithms before (blue) and after (orange) improvement. The left side is for the step length and the right side for the cadence. The upper side is the results of dataset M1 and the lower one for M2. The algorithms were trained (if required) and tested on the “*ALL*” category of the train and test sets of each dataset.

5.4.3 Cadence estimation

Table 5.2 reports the RMSE of the cadence estimation algorithms tested on both datasets M1 and M2 for different speed ranges. The algorithms are categorized by their conceptual groups as Time, Frequency, cTime, and cALL. The status of the algorithms determines whether the algorithms are original from the literature, modified, or newly proposed in this study. Besides, the performance of the algorithms tested on subjects with walking-aids is reported.

5.4.4 Step length estimation

The cross-validation results of step length estimation algorithms are presented in Table 5.3. The algorithms are categorized according to their corresponding conceptual approach as BM, DI, ML, cBM, cML, cDI, and cALL.

5.4.5 Walking speed estimation

Table 5.4 compares the speed estimation results by multiplying different step length and the cadence estimation approaches (each row is one solution). Here, to reduce the number of solutions between the cadence and the stride length algorithms, we only considered the combined approaches representing their corresponding conceptual groups.

Table 5.2 – Performance of the cadence estimation algorithms tested on different speed ranges for both datasets M1 and M2. Here, cTime and cALL are combined approaches. Column “*Status*” indicates if the algorithms are original, modified, or new. All Values are also RMSE in steps/min.

	Approach	Algorithm	Status	Slow	Normal	Fast	ALL	Walking-aids
Dataset M1	Time	CAD1	Original	13.1	5.1	7.2	8.3	19.9
		CAD2	Modified	2.1	5.4	1.9	3.8	12.1

Table 5.3 – Cross-validation results for the step length algorithms. Here, cBM, cML, cDI, and cALL are combined approaches. Columns separated by the vertical lines correspond to the training conditions. “S”, “N”, “F”, “A”, and “WA” report RMSE (in m) of testing on Slow, Normal, Fast, ALL, and with walking-aids walkers. Column “Stat” shows if the algorithms are original, modified, or new in this study. “App” means Application. Column “Alg” refers to Algorithm, showing the number of each algorithm (CADX).

Training condition			Slow walkers					Normal walkers					Fast walkers					ALL

5.5 Discussion

In this study, we implemented, improved, and compared several LB sensor-based algorithms to estimate cadence, step length, and walking speed. We analyzed data from two datasets, M1 (with the instrumented walkway) and M2 (with the IMU-based reference system), containing both healthy and diseased populations (i.e., PD, MS, HE, HD, OA). As shown in Table 5.1, the participants of both datasets have been distributed uniformly among different speed ranges for both training and test sets. While the patients fell mainly in slow and normal categories, the healthy ones were mainly in normal and fast groups. Several people with walking-aids (32 subjects) were included to test the algorithms' performance under this unique situation.

Figure 5.5 illustrates that the proposed enhancements led to improved cadence and step length estimation on both datasets M1 and M2. For the algorithms CAD2 and CAD3 (both TD), while RMSE substantially decreased on dataset M2 (by at least 50 %), a slight increase (maximum 25 %) was observed on dataset M1. One possible reason for this observation is that the step-related peaks in M2 were generally weaker than in M1 (probably due to MS disease). That is why the proposed peak enhancement method was generally more effective on the M2 dataset than M1. Moreover, the FD algorithm (CAD7) reached a considerable improvement (minimum 30 %) on both datasets. For the step length algorithms (STPL1 and STPL2, both based on BM), the error has been consistently reduced on both datasets M1 (minimum 16 %) and M2 (minimum 10 %).

Referring to Table 5.2, for the normal walkers, almost all cadence algorithms worked properly and similar (an average RMSE of 3.5 and 3.8 steps/min on M1 and M2). However, for the slow walkers, the TD algorithms showed a severe degradation of the performance (up to an error of 13 and 23 steps/min on M1 and M2, respectively) probably due to weakened step-related peaks in the acceleration signal. On the other hand, the FD algorithm (CAD7) achieved an excellent error of 2.5 steps/min for slow walkers on both datasets, possibly because this approach depends mainly on the gait-related repetitive patterns than the peaks in the time domain signal.

Furthermore, for the fast walkers, while both approaches provided perfect results on the M2 dataset (maximum error of 2 steps/min), a significant increase of the error (up to 18 steps/min) was observed for the FD algorithm on M1. One explanation is that, compared to the slow and normal walking, the fast walking might generate more harmonics in the spectrum of the acceleration, which could confuse the FD cadence algorithm to find the correct dominant frequency. For walking-aids people, the RMSE considerably increases up to an average RMSE of 14 and 20 steps/min on M1 and M2.

Considering all circumstances for the cadence estimation, every algorithm showed several advantages and limitations, so that it is difficult and unreliable to choose only one. Nevertheless, it was interesting to observe that the combined approaches provided a stable and high performance in all conditions. For instance, the cALL achieved an

RMSE of 3.4, 3.5, 3.4, and 13.7 steps/min for slow, normal, fast, walking-aids walkers on the M1 dataset. On M2 datasets, the results are as 5.8, 3.8, 1.1, 19.8 steps/min, respectively.

Only a few previous studies have reported cadence estimation error. In (Paraschiv-Ionescu et al., 2019), the cadence estimation has been evaluated on typically developed and cerebral palsy children where mean and STD absolute errors vary between [0.5-2] and [1.3-7.2] steps/min, respectively. The study (Fasel et al., 2017a) also has reported a median [IQR] of 0.15 [-1.95 2.27] steps/min for the estimation of cadence on healthy subjects and using wrist sensors. It should be noted that the performance of cadence estimation could be affected by target populations, in-lab or real-world situations, the definition of cadence, and the definition of error, which is different in every study.

Regarding the different training conditions (training for ML and tuning for the other approaches) in Table 5.3, we realized that training on a specific range of speed might not be necessarily the best choice even when testing was performed on the same speed range (e.g., training on slow walkers and testing on the same group). The results demonstrated that training on “*ALL*” (i.e., including people from all speed ranges) led to better performance than other training conditions. One main reason might be that more data with higher diversity were fed into the algorithms during training on “*ALL*”, resulting in more generalized models.

Considering the column “*training on ALL*” of Table 5.3, for the slow walkers, the BM-based algorithms showed slightly better performance (RMSE around 0.04 m on M1 and 0.13 m on M2). One reason might be that they are more dependent on biomechanically-derived models than the intensity or gait-related-patterns of the acceleration signal (as ML or DI). Therefore, even when the acceleration signal is weak or distorted due to the slow walking, they could still accurately estimate the step length. While DI algorithms seemed to perform slightly better for the normal walkers, all approaches provided good performances (RMSE around 0.08 m). No big difference was observed among different approaches for the fast walkers (RMSE around 0.07 m and 0.05 m on M1 and M2). For the walking-aids walkers, we noticed a significant performance drop in all approaches (RMSE around of 0.18 m). Nevertheless, ML and BM seemed to be more appropriate for this type of walking since they offer a high generalization ability, making them robust against the body's atypical movement. Like cadence estimation, the combined step length estimation approaches (cALL) appeared to be more accurate and robust for all speed categories as well as the walking-aids group. On the M1 dataset, the combined approach (i.e., cALL) achieved RMSE of 0.05, 0.08, 0.07, and 0.18 m for slow, normal, fast, and walking-aids walkers, respectively. On M2 datasets its results are as 0.13, 0.07, 0.05, and 0.16 m, respectively.

Table 5.4 shows promising results for the estimation of walking speed. Like the step length estimation, training on “*ALL*” walkers generally resulted in a better performance. For slow walkers of dataset M1, the choice of cBM (BM-based combined algorithm) or cALL with any cadence algorithms (i.e., cTime, Frequency, or cALL)

achieved a better estimation of the speed (RMSE around 0.10 m/s). However, on M2, all possible solutions resulted in the same RMSE around 0.22 m/s.

Furthermore, for the normal walkers of M1, the combination of cDI or cBM with any cadence algorithms led to better performance (RMSE around 0.12 m/s). On M2, however, the selection of cDI or cML with any cadence algorithms resulted in better performance (RMSE around 0.12 m/s). Moreover, for the fast walkers, excluding the combination of the FD cadence approach with any step length algorithms in M1, the rest of the possibilities showed the same performance (RMSE around 0.14 m/s and 0.10 m/s on M1 and M2).

For the walking-aids group of M1, except the combination of DI with any cadence algorithms, other combinations led to a similar RMSE around 0.32 m/s. However, on M2, the combination of cBM with any cadence algorithms showed better performance (RMSE around 0.27 m/s). Finally, Table 5.4 demonstrates that the choice of cALL for both step length and cadence led to a more robust and acceptable estimation of the speed in all conditions. This solution achieved an RMSE of 0.10, 0.18, 0.15, and 0.32 m/s for slow, normal, fast, and walking-aids walkers, respectively, on the M1 dataset. Besides, it reached RMSE of 0.22, 0.13, 0.10, and 0.32 m/s on M2 dataset.

Looking at the literature, (McGinnis et al., 2017) achieved an RMSE of [0.12-0.15] m/s to estimate speed on healthy and MS populations. A median absolute error of 0.3 m/s was also reported in (Park et al., 2012) to estimate walking speed on a healthy population. In (Soltani et al., 2019), a median [IQR] error of 0.10 [0.07 0.12] m/s was obtained for the non-personalized wrist-based speed estimation on healthy population in real-life situations.

For cadence, step length, and walking speed estimation, a slight difference was observed between the results obtained on dataset M1 (with the instrumented walkway) and M2 (with the IMU-based reference system). Generally speaking, dataset M2 seemed to be more challenging for the algorithms than M1. One reason might be that the IMU-based reference system of M2 had higher error than the instrumented walkway in M1. Another error source might be using a fixed height value (i.e., 170 cm) in dataset M2, which is needed for some algorithms. Besides, detecting walking bouts of M1 is more reliable than M2 (due to using the instrumented mat as reference).

The same analysis could be performed on bigger datasets recorded for long-durations in daily-life situations as future work. This real-world analysis could prepare a wide variety of challenging situations (self-triggered, purposeful, and multitasking walking in a rich behavioral context) to test and judge the algorithms' performance. For further improvement, one possibility is to deploy a weighted average instead of an equally-weighted one to optimize the performance of the combined algorithms by tuning the weights (giving more weights to more accurate algorithms). For instance, it would be possible to use the linear least square method to compute the optimal weights on a

tuning dataset. Moreover, comparing the error between healthy and pathological populations could be another potential future work.

Furthermore, some of the TD cadence algorithms could be used for step demarcation (timing of IC) in a fully autonomous LB-based speed estimation pipeline. This study focused on evaluating speed estimation and its related parameters (i.e., cadence and step length). However, a prospective study could be performed to evaluate the step demarcation error to complete previous studies like the one presented in (Iijima and Takahashi, 2020).

5.6 Conclusion

In this study, we developed several LB-worn IMU-based algorithms to estimate cadence, step length, and, eventually, the walking speed. In most cases, the proposed enhancements were useful for cadence (30-50 %) and step length (10-16 %) estimation. The results showed that training on all people with different preferred speed led to better performance.

For the slow walkers, the FD cadence estimation (RMSE of 2.5 steps/min), the BM-based step length estimation (RMSE around 0.04 m on M1 and 0.13 m on M2), and speed estimation by choosing cBM or cALL with any cadence algorithms (RMSE around 0.10 m/s on M1 and 0.22 m/s on M2) offered better performance. For normal walkers, both cadence approaches (RMSE around 3.5 and 3.8 steps/min on M1 and M2) and all the step length approaches (RMSE around 0.08 m) were preferred. For the speed estimation on M1, selecting cDI or cBM with any cadence algorithms led to better performance (RMSE around 0.12 m/s). On M2, however, opting cDI or cML with any cadence algorithms showed more promising results (RMSE around 0.12 m/s).

Furthermore, for fast walkers, the TD cadence estimation (RMSE around 2.3 and 1.3 steps/min on M1 and M2), all the step length approaches (RMSE around 0.07 m and 0.05 m on M1 and M2), and all possible speed solutions, excluding the selection of FD approach with any step length algorithms on M1, (RMSE around 0.14 m/s and 0.10 m/s on M1 and M2), were suggested. The error significantly increased for people with walking-aids where an RMSE around 14 steps/min, 0.18 m, and 0.27 m/s were observed for estimating cadence, step length, and speed. The results demonstrated that the combined approaches offer more robust solutions under various circumstances. For instance, the combined speed estimation approach (cALL) achieved an RMSE of 0.10, 0.18, 0.15, and 0.32 m/s for slow, normal, fast, and walking-aids walkers, respectively, on the M1 dataset. Besides, the results were 0.22, 0.13, 0.10, and 0.32 m/s on M2 dataset.

5.7 Acknowledgments

The present study was performed in the framework of project Mobilise-D funding from the Innovative Medicines Initiative 2 Joint Undertaking under grant agreement No 820820. This Joint Undertaking receives support from the European Union’s Horizon 2020 research and innovation program and EFPIA. We would like to thank all consortium members, especially the technical validation work package (WP2). We also thank Elisa Pelosin (from the University of Genova) for sharing the dataset M1. Finally, we appreciate all the participants and medical centers’ staff for taking part in our measurements.

Part III – Real-world Application

6 Real-world gait speed estimation in a large cohort: frailty and handgrip strength¹

6.1 Abstract

Real-world gait speed (GS²) is recognized as “the sixth vital sign” and is a key to characterize people’s health status. A few previous studies used IMU in large clinical cohort studies, but they mainly analyzed PA intensity (e.g., low, medium, vigorous) rather than GS. One reason might be the difficulties of accurate estimation of GS in real-world situations. Therefore, in this study, we demonstrated 1) the feasibility of deploying a wrist-worn IMU-based system to assess GS in free-living situations; 2) the meaningfulness of using GS in frailty/handgrip strength estimation. This study included 2809 (1508 women; +45 y) participants. PA was measured using a wrist-worn accelerometer. GB were stratified into three duration categories (<30; [30-120]; >120 seconds). Different GS measures of each category were used for analyses. Univariate analysis was performed to investigate the effect of sociodemographic and lifestyle factors on GS. Besides, we performed multivariate analyses to demonstrate the advantage of adding GS as an independent prediction of frailty/handgrip strength estimation. Compared to normative reference values in literature, similar speed values and trends were observed. Using GS significantly improved frailty prediction and handgrip strength estimation. The 95th PCT of GS and 30-120s duration provided the highest discrimination power to distinguish subjects stratified by frailty or handgrip strength. The methodology might be valuable in analyzing cohort datasets, and real-world GS could be used as a reliable indicator of health and age-related functional decline.

¹ To be submitted as Soltani, A., Abolhassani, N., Marques-Vidal, P., Aminian, K., Vollenweider, P., Paraschiv-Ionescu, A., (2020), Real-world gait speed estimation and frailty/handgrip strength: a cohort-based study, to *American Journal of Epidemiology*. Contributions are as follows: study design; data cleaning; contribution to data analysis, performance evaluation and drafting the manuscript.

² The abbreviation “GS” is used exclusively in chapter 6

Keywords: gait speed, cohort studies, wearable systems, frailty, aging, obesity, PA, GB duration.

6.2 Introduction

GS, recognized as the “6th vital sign” (Fritz and Lusardi, 2009; Middleton et al., 2015), is a valid, reliable, and sensitive measure of people’s functional ability, closely associated with well-being, healthy aging, and survival in elderly populations (Choi et al., 2011; Del Din et al., 2016a; Elble et al., 1991; Harada et al., 1995; van Iersel et al., 2008; Rydwick et al., 2012; Steffen et al., 2002). GS allows for monitoring overall health, assessing functional status, early detection of disease and age-related functional decline (e.g., frailty status (Cesari et al., 2016)), and for objectively quantifying the impact of treatments and interventions (Castell et al., 2013; Fritz and Lusardi, 2009; Maki, 1997; Middleton et al., 2015; Perera et al., 2015; Quach et al., 2011; Rochat et al., 2010; Salarian et al., 2004; Studenski et al., 2011; Weiss et al., 2014). Most studies that have contributed to the accumulated evidence about the reliability of GS as the predictor of adverse health outcomes among community-dwelling adults were based on measurements in the laboratory or clinical settings. However, mounting evidence has indicated that the GS assessed in a laboratory setting does not fully reflect the GS of the individuals in their everyday life context. Therefore, there is growing consensus to develop a better way to assess gait in real-world conditions (Kawai et al., 2020; Takayanagi et al., 2019; Van Ancum et al., 2019).

GS could be estimated in real-life situations by algorithms developed using multiple or single IMU worn on different body segments (Paraschiv-Ionescu et al., 2004; Yang and Li, 2012). PA in everyday life has multiple dimensions. Therefore, innovative approaches have been developed and validated to extract metrics related to the type (e.g., walking/running, body postures), duration of bouts, and intensity (e.g., GS, accelerometer counts, metabolic equivalent of task) of PA. The most common sensor locations for long-term monitoring are the trunk (e.g., waist, chest, hip, LB) or the wrist. While the classification of multiple dimensions of PA (type, intensity, duration) using the wrist-recorded data (e.g., acceleration) is technically challenging, recent research focused on the development and validation of robust algorithms (Godfrey et al., 2008; Lee et al., 2019; Rosenberger et al., 2016; Soltani et al., 2019, 2020; Troiano et al., 2014).

Given the difficulty of an accurate estimation of GS in real-world situations, most existing commercial wearable devices deploy a more straightforward classical approach for PA assessment by providing only an estimation of PA intensity levels (time spent in sedentary, light, moderate, and vigorous intensities). Here, the issue is that the processing of raw data (acceleration signal) and the definition of the thresholds used to classify PA intensity levels differ between devices. Therefore, comparing PA-outcome measures across different studies is not very trivial (Ward et al., 2005).

Assessing PA by GS might overcome this issue since the gait characterized by the speed is an “*invariant*” component of PA. Nevertheless, additional aspects should be considered when using real-world GS as a PA outcome measure (Graham et al., 2008; Kim et al., 2016). One important aspect is that the statistical metrics (e.g., mean, median, mode, STD), derived from GS within different GB durations (e.g., short, medium, long), have been rarely investigated in large clinical cohort studies (Pradeep Kumar et al., 2020). However, identifying GB durations, probably corresponding to various “*purposeful*” daily activities that represent a person’s physical capacity, is an essential topic for outcome evaluation in population-based studies. Additional aspects are the potential influence of external/contextual factors on GS, increasing the intra/inter subjects’ variability. For instance, although PA features are subject to ultradian and circadian changes so that they should be studied during the whole 24 hours activity cycle (Carlson et al., 2012; Firmann et al., 2008; Rosenberger et al., 2016), only a few studies addressed this aspect (Cabanas-Sánchez et al., 2020; Hillel et al., 2019). Another critical aspect is the small sample size of many studies, limiting the statistical analyses power and reliability to generalize the results for large populations. Finally, the complexity of the systems for PA objective assessment (e.g., multiple body-worn IMU) could affect people’s daily habits, reducing compliance for participating in long-term monitoring protocols (Buchser et al., 2005). The complexity also necessitates additional technical considerations (e.g., synchronization of devices) which could impose time and money costs.

This study pursues two main goals. First, we aim at the feasibility of assessing GS using an accurate, easy-to-use wrist-worn IMU-based system (Soltani et al., 2019, 2020) in a large population (more than 2800 participants) for a long-duration measurement (13 consecutive days, 24 hours per day) in free-living conditions. Second, we seek the added values of including the real-world GS to estimate clinical outcomes such as frailty and handgrip strength. Also, we investigate the association between the GS and subjects’ characteristics (e.g., demographic information). As a secondary outcome, we report what GS metric and in what GB duration provides the highest discrimination power to distinguish between different groups of people stratified by clinical indexes such as frailty and handgrip strength.

6.3 Methods

6.3.1 Study population

Subjects were enrolled in the framework of the CoLaus³ cohort study. The Colaustudy is an ongoing prospective survey, investigating the biological and genetic determinants of cardiovascular risk factors and cardiovascular disease in the population of Lausanne, Switzerland. The detailed description of the CoLaus study and its follow-ups has been

³ <https://www.colaus-psycolaus.ch/>

reported elsewhere (Fried et al., 2001). A simple, non-stratified random sample of the Lausanne population aged between 35 and 75 years was chosen based on the following inclusion criteria: (i) written informed consent and (ii) willingness to take part in the examination and to provide blood samples. The baseline survey was conducted between 2003 and 2006, the first follow-up between 2009 and 2012, and the second follow-up between 2014 and 2017. The baseline and subsequent follow-ups included an interview, a physical exam, blood sampling, and questionnaires. In the second follow-up (4881 participants), daily PA was also assessed by accelerometry. Hence, data from the second follow-up was used. It should also be noted that we excluded the participants whose GS metrics or other covariates data were missing.

6.3.2 PA measurement

Participants wore a 3-axial accelerometer (GENEActiv Original, ActivInsights Ltd, United Kingdom) on the right wrist for 13 successive full days in their free-living situations without any supervision or intervention. The GENEActiv device is lightweight (16 g), waterproof, and allows continuous measurement for a maximum of 45 days. The acceleration was recorded with a range of ± 8 g and a sampling frequency of 50 Hz (high enough to avoid ailiasing during gait analysis (Van Hees et al., 2014)), where the accelerometer was calibrated based on (Sabia et al., 2014). After recording, the raw acceleration data were transferred into a computer for analysis to identify the GB and estimate GS using algorithms validated in chapters 3 and 4 of this thesis (Soltani et al., 2019, 2020).

6.3.3 Real-world GB detection and speed estimation

Figure 6.1 illustrates the block diagram of the system deployed for the real-world GS estimation using wrist acceleration signals.

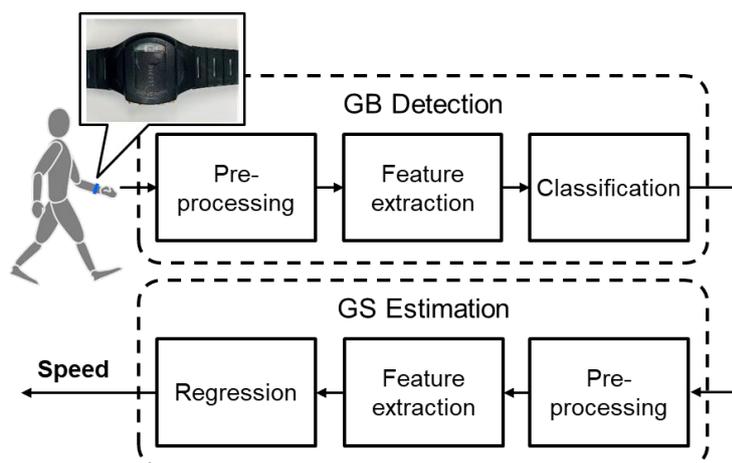

Figure 6.1 – Block diagram of the system used for real-world GS estimation. Two validated algorithms were used, one for GB detection (chapter 3, (Soltani et al., 2020)) and the second for GS estimation (chapter 4, (Soltani et al., 2019)).

6.3.3.1 GB detection

The algorithm presented in chapter 3 (Soltani et al., 2020) was employed to detect GB. In this algorithm, after decreasing noise by preprocessing the wrist acceleration, several biomechanically meaningful features (defined based on intensity, periodicity, posture, and noisiness) were extracted. The features were then fed into a classification procedure consisting of a Bayes classifier followed by two smart post-classification blocks. The output of this algorithm was per-second labels for continuous GB without any breaks. A median sensitivity, specificity, accuracy, precision, and F1-score of 90.2, 97.2, 96.6, 80.0, and 82.6 are reported (all values in %, highest possible value for these classification performance metrics is 100, corresponding to a full agreement between the validated algorithm and the ground truth).

6.3.3.2 GS estimation

We used the non-personalized version of the algorithm proposed in (Soltani et al., 2019) to estimate the GS of the GB detected in the previous step. In this algorithm, first, the wrist acceleration signal was passed through a preprocessing stage to enhance the meaningful features. Then, relevant features such as energy, cadence (step frequency), mean of acceleration, mean of the jerk, intensity of wrist swing were extracted and fed into a linear regression model to estimate the instantaneous speed (per second) of each detected GB. A median RMSE of 0.10 and 0.31 m/s are reported for the instantaneous walking and running speed estimation, respectively, using the non-personalized version.

For each subject in this study, detected GB were stratified into three categories according to their durations (<30s; [30-120]s; >120s). The main idea behind this grouping was the fact that the short (<30s) bouts occur mostly indoors and are mainly context-dependent, whereas the long (>120s) bouts happen mostly outdoors (Hickey et al., 2016). The other category ([30-120]s) could be a mixture of indoor and outdoor activities (Hickey et al., 2016). For each subject, we computed a set of speed metrics derived from the statistical distribution of GS (average, mode, median, 75th, 90th, and 95th PCT, STD, and maximum) of each GB duration category.

6.3.3.3 Other covariates

We collected gender and age by questionnaire. Age was categorized into four groups: [45-54], [55-64], [65-74] and [75 years. Height and weight were assessed by a Seca® scale (Seca Gmb, Hamburg, Germany) with the participants in light clothes and without shoes. BMI was categorized as normal ($18.5 < \text{BMI} < 25 \text{ kg/m}^2$), overweight ($25 \leq \text{BMI} < 30 \text{ kg/m}^2$) and obese ($\geq 30 \text{ kg/m}^2$). As the percentage of underweight ($\text{BMI} \leq 18.5 \text{ kg/m}^2$) participants was small (<2 %), they were included in the normal weight group.

Handgrip strength was assessed using the Baseline® Hydraulic Hand Dynamometer (Fabrication Enterprises Inc, Elmsford, NY, USA) with the subject seated, shoulders

adducted, and neutrally rotated, elbow flexed at 90°, forearm in a neutral position, and wrist between 0 and 30° of dorsiflexion. Three measurements were performed consecutively with the right hand, and the highest value was included in the analyses. Frailty condition was defined using gender, BMI, and handgrip strength (kg) and categorized as frail and non-frail according to Fried et al. (Fried et al., 2001). Therefore, the frailty condition was identified as follows; for men: if $BMI \leq 24$ and handgrip strength ≤ 29 or $24 < BMI \leq 28$ and handgrip strength ≤ 30 or $BMI > 28$ and handgrip strength ≤ 32 ; and for women: if $BMI \leq 23$ and handgrip strength ≤ 17 or $23 < BMI \leq 26$ and handgrip strength ≤ 17.3 or $26 < BMI \leq 29$ and handgrip strength ≤ 18 or $BMI > 29$ and handgrip strength ≤ 21 .

PA intensity levels were estimated from the raw acceleration data using the R-package GGIR⁴ (Sabia et al., 2014; Van Hees et al., 2014) and the criteria of White et al. (Tom White, 2018) to define moderate and vigorous PA. PA levels were further categorized into inactive (< 150 min/week) and active (≥ 150 min/week) of moderate and vigorous PA, respectively.

6.3.3.4 Ethical statement

The institutional Ethics Committee of the University of Lausanne, which afterward became the Ethics Commission of Canton Vaud⁵, approved the baseline CoLaus study (reference 16/03). The approval was renewed for the first (reference 33/09) and the second (reference 26/14) follow-ups. The study was performed in agreement with the Helsinki declaration and its former amendments, and under the applicable Swiss legislation. All participants gave their signed informed consent before entering the study.

6.3.3.5 Statistical analysis

Statistical analysis was performed using Stata software version 16.0 (Stata Corp, College Station, TX, USA) and MATLAB (MathWorks, USA). First, we performed univariate analysis to investigate the effect of each factor (gender, age, BMI, and PA levels) on the GS and to demonstrate the consistency between the speed values estimated in this study and the normative values in the literature. A comprehensive multivariate analysis was then designed to show the advantage of adding real-world GS to predict frailty condition and handgrip strength estimation. Both analyses are briefly described as follows:

6.3.3.5.1 Univariate Analysis

We computed the average number of GB detected within each duration category for different age groups to ensure having enough sample size within each group. Then, the

⁴ <http://cran.r-project.org>

⁵ www.cer-vd.ch

subject's preferred GS, for all GB as well as for GB in each duration category, was estimated as the mode (peak) of PDF using the Kernel Smoothing Function (MATLAB function "*ksdensity*"). Besides, the distributions of the preferred GS of subjects stratified by gender, age, BMI, and PA levels were compared through boxplots to highlight the effect of each factor on the preferred speed.

6.3.3.5.2 Multivariate Analysis

Two logistic regression models (A and B) were built to assess the importance of including GS in predicting frailty condition. Model A included gender, age, BMI, and PA intensity levels, as these covariates are associated with frailty (Fried et al., 2001). Model B used the same covariates as model A, plus the GS metrics. Two linear regression models assessed the association with handgrip strength: model A included gender, age, BMI, and PA levels, and model B was the same as model A plus the GS metrics. For both analyses, the results were expressed as the Area Under the ROC (AUC) and Akaike's and Bayesian information criteria (AIC and BIC, respectively). The improvement in predicting frailty, as well as estimating handgrip strength, was assessed by comparing model B with model A using the likelihood ratio test (LR) as well as the AUC. Eventually, to confirm the results of the previous analyses, a stepwise logistic regression (forward method) with a p-value for the entry of 0.05 was deployed to select the speed metric(s) with the most vital relation with the non-frail condition. The same analysis was performed for the handgrip strength with a stepwise linear regression instead. Due to the large number of tests performed, statistical significance was arbitrarily assessed for a two-sided test with $p < 0.001$.

6.3.3.5.3 Sensitivity analyses

The system deployed in this study for GB detection and GS estimation (Figure 6.1) could not distinguish between walking and running. Therefore, we excluded the participants whose 95th PCT of speed was above the maximum value of walking speed reported in (Bohannon, 1997). We then repeated the multivariate analysis as described above. We used the 95th PCT of speed since, statistically, it is more reliable than the maximum value.

6.4 Results

6.4.1 Selection of participants

Of the initial 4881 participants, 1982 (no walking speed data) and 90 (missing covariates) were excluded, and 2809 (46.3 % men, 53.7 % women, mean age 62.4 ± 9.9 years) were included in this study. After analysis, each participant's data was verified to check the number of days with detected GB (valid days); days with no detected GB were discarded. From the 2809 subjects, ~98 % of subjects had at least eight valid days, including weekly and weekend days. This number was large enough to estimate

preferred GS and related gait metrics (Soltani et al., 2017). Supplementary Table 6.1 reports the characteristics of the participants included and excluded in this study.

6.4.2 Real-world GS estimation

Figure 6.2 illustrates an example of the wrist acceleration-based GS estimation for one participant of this study. Panel A displays the wrist acceleration norm and the GS estimated during 13 continuous days in free-living situations. Panel B is a zoom on Panel A to show the analysis results in a typical day (24h) in real-world situations. Figure 6.2 demonstrates that the wrist-based method successfully estimated a consistent GB sequence and their corresponding speed in regular daily life activity. There is a clear repetitive pattern of GB among successive days. Each day starts with a non-active period, likely related to sleep time, followed by two active periods in the morning and the afternoon (probably associated with a daily routine). Moreover, sometimes, a few GB could be observed in the evening. In many cases, the GS (i.e., the intensity of activities) is higher in the morning and gradually decreases.

6.4.3 Univariate analysis

Figure 6.3 shows the GB distribution (mean and STD) for each age group within each duration category, expressed as the percentage of the total number of GB detected for each subject in each age group. The distributions of the GB appeared relatively similar between the age groups. Figure 6.4 illustrates the preferred GS distribution for each bout duration, using the pooled data from all subjects. The effect of subject-specific factors (gender, age, BMI, PA level) on the preferred GS is graphically illustrated with the boxplots in Figure 6.5.

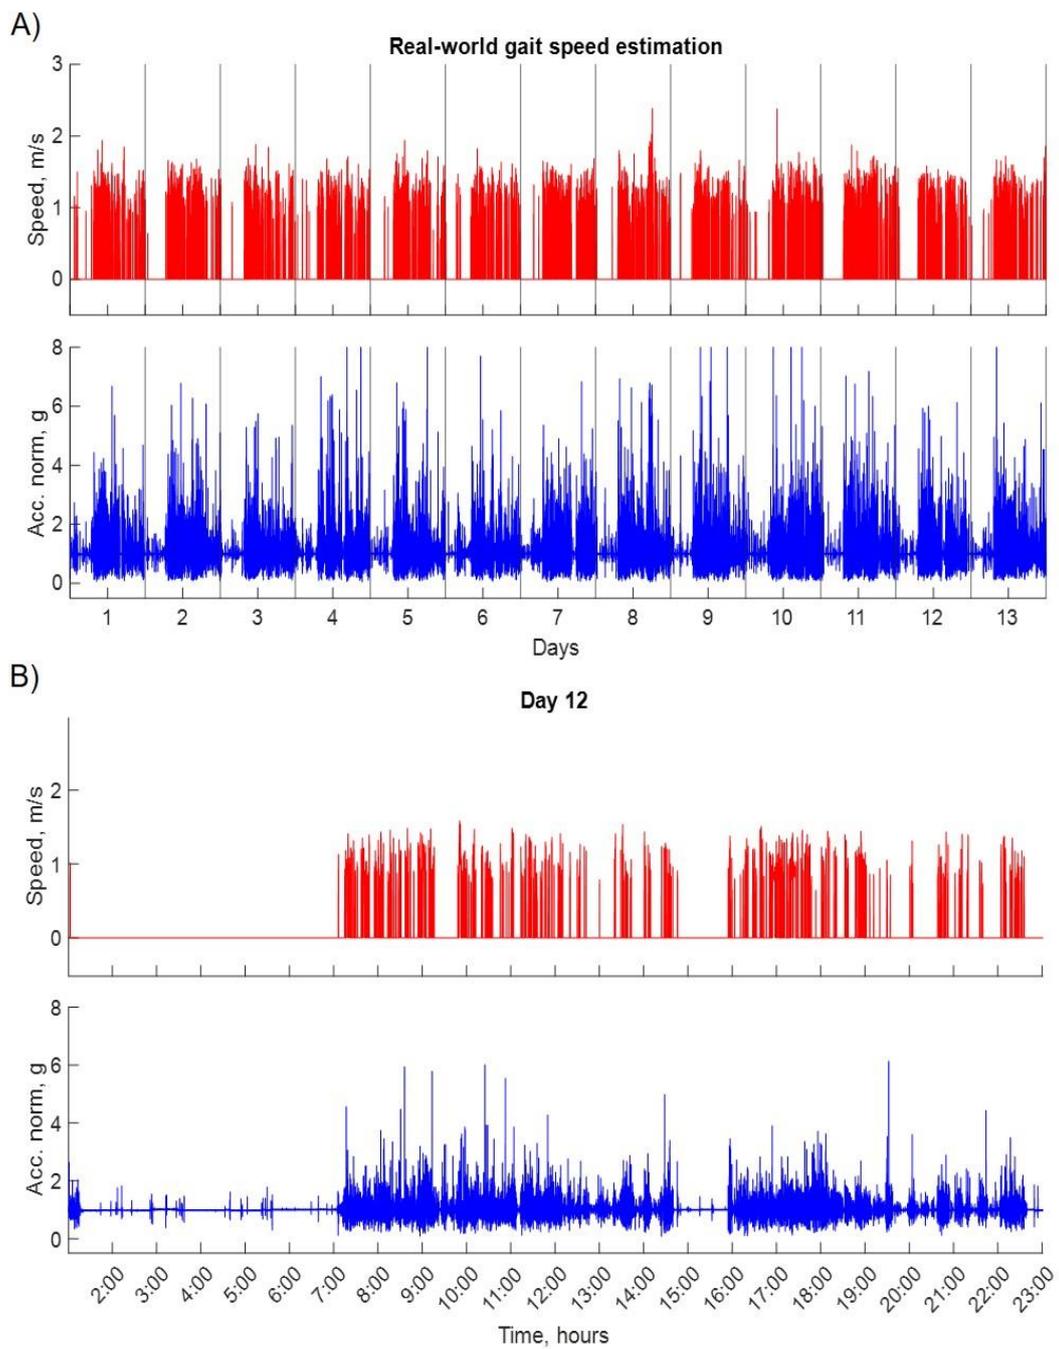

Figure 6.2 – An illustrative example of a real-world GS estimation for a representative subject monitored in daily life situations. A) Estimated speed of detected GB (red) and wrist acceleration norm (blue) during 13 continuous days. B) One typical day (day #12).

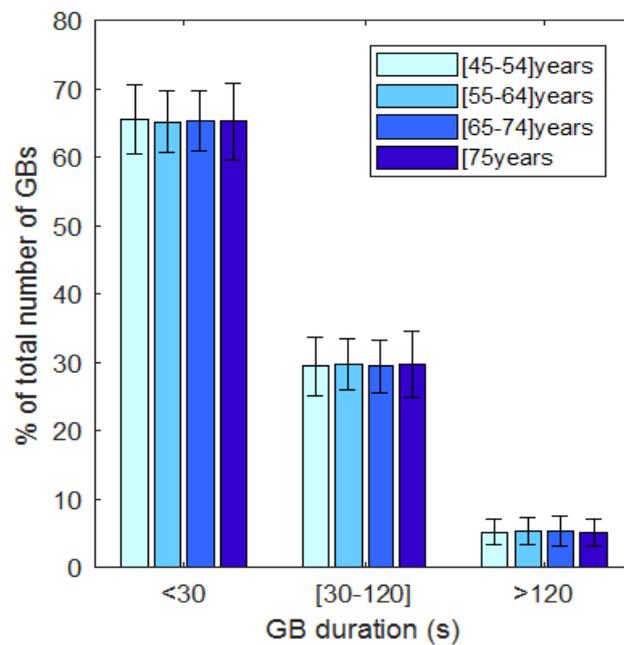

Figure 6.3 – Distribution of the GB within each duration category, stratified by age groups. Each bar and the corresponding error bar report the mean and STD of GB within each duration category and each age group. The values were calculated as percentages of their total number of GB for each individual in each age group.

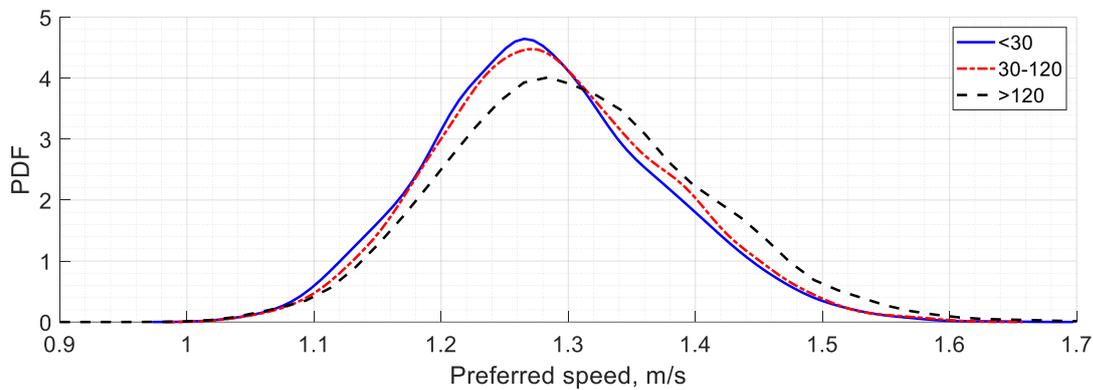

Figure 6.4 – PDF of the preferred GS values for each GB duration, including data from all subjects. First, the preferred speed of each subject for each bout duration was computed. Then the PDF was estimated by the Kernel Smoothing Function (function “*ksdensity*” in MATLAB).

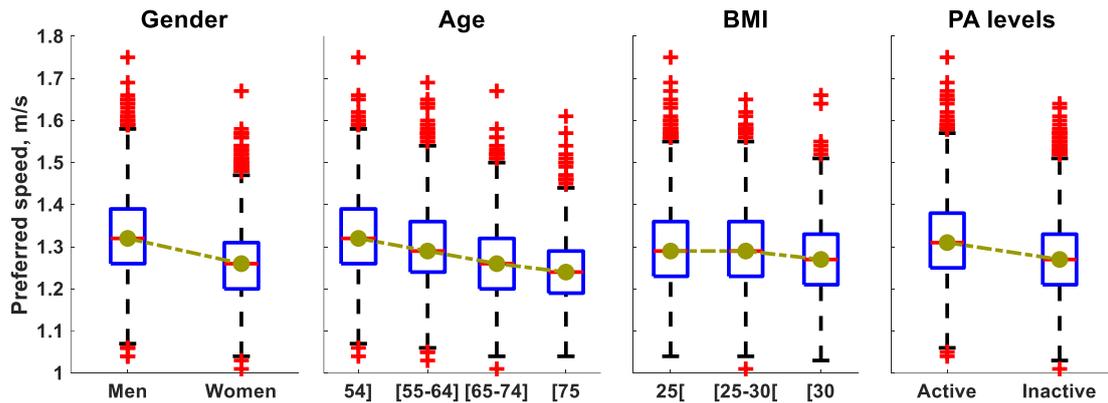

Figure 6.5 – Boxplots of the preferred (mode value of) speed of different groups stratified by gender, age, BMI, and PA levels. Here, the green line connects each group’s median value.

6.4.4 Multivariate analysis: frailty and handgrip strength estimation

The logistic regression model A (without GS metrics) and model B (with GS metrics) for prediction of frailty were analyzed (Table 6.1). As indicated by a lower AIC/BIC and a significant LR test, model B provides a substantial improvement in the prediction of frailty condition by taking advantage of any speed metrics in all GB durations. Compared to model A, the AUC, AIC, and BIC of model B were enhanced in all conditions, where an average improvement of 3.1, 3.1, and 2.7 % are respectively observed for all GS metrics in all GB durations (Table 6.1). However, the improvements for the duration of 30-120s are slightly greater than the other periods. Moreover, the LR test suggests GS’s 95th PCT as a proper speed metric in all GB durations to predict frailty. Similar outcomes could be observed for estimating the handgrip strength (Table 6.2). Estimating the handgrip strength by model B, including any GS metrics in all GB durations, leads to a significant improvement compared to model A. Similarly, the 95th PCT of GS and GB duration 30-120s showed more promising results.

In order to visualize the difference between models A and B for the prediction of frailty, the ROC curves of both models are presented (Figure 6.6). Here, we separated the results in each GB duration, and only the baseline (model A) and three speed metrics (mean, 90th, and 95th PCT) are displayed. Figure 6 also visually confirms these results where the AUC of baseline (model A) in all GB durations is less than model B.

The results of the stepwise regression models using different GS metrics within different GB duration categories in predicting non-frailty and handgrip strength are presented in Table 6.3. The stepwise regression analysis results also support the previous findings where the 95th PCT of the GS entered into the model in all GB durations.

Table 6.1 – Effect of adding speed metrics to predict frailty. Model A includes gender, age, BMI, and PA. Model B consists of all variables from model A plus the variable of interest (the speed metric specified in each row). “NaN” corresponds to the values which were not possible to be computed.

Name	Duration (s)	Speed metrics	AUC	LR	p-value	AIC	BIC

6.4.5 Sensitivity analysis

The exclusion of participants with high speed (assumed as running) excludes 753 out of 2809 subjects. The result of the repeated multivariate analysis for the remainder of participants (2056 subjects) could be found in the Supplementary Table 6.1, Supplementary Table 6.2, and Supplementary Table 6.3. The exclusion of running data had no significant impact on the multivariate analyses; consequently, the same outcomes can still be outlined.

6.5 Discussion

The results of this study demonstrated the feasibility of using a wrist acceleration-based method for long-term monitoring of real-world GS in a large cohort of community-dwelling adults. Moreover, the statistical analysis demonstrated that the real-world GS' distribution, estimated from the wrist-worn device, was consistent with normative values published in the literature, when subjects were stratified by demographic data such as gender, age, BMI, and daily PA levels (Bohannon, 1997; Bohannon and Williams Andrews, 2011). Moreover, it also highlights that the statistical metrics (mode, median, mean, 75th, 90th, 95th PCT, maximum, and STD) derived from the distribution of GS within different bout durations improved the discriminative power of regression models built for the prediction of frailty, and handgrip strength. The large sample size (2809 subjects) and the uniform distributions of the subjects within each category identified by gender, age, BMI, and PA allowed a comprehensive, valid statistical analysis of the GS metrics.

6.5.1 Univariate analysis

As illustrated in Figure 6.4, the range of [1-1.6] m/s for the preferred GS (estimated as the mode/peak of PDF), for each range of bout duration, is consistent with the values reported by several previous studies (Bohannon and Williams Andrews, 2011). Interestingly, the trend observed with age and gender is similar to recent data on a big Japanese population-based cohort study, where the daily-life GS was assessed using smartphone-integrated GNSS (Obuchi et al., 2020). Nevertheless, this technology might raise privacy issues and might not be accepted by the ethical committee in clinical research. Similarly, the percentage of the total GB number within each duration range (see Figure 6.3) appeared to be similar to the previous studies (Del Din et al., 2016a; Orendurff et al., 2008). It indicated an exponential reduction of the number of GB for longer durations. From Figure 6.3, it could be observed that about 65 % were short (<30s), 30 % were medium duration (30-120s), and only 5 % were long (>120s), and this trend was similar for all age categories. It was also observed that longer GB had a higher variation of GS. One explanation for this behavior would be that the long GB was probably related to outdoor activities, which are more influenced by contextual factors (e.g., quick utilitarian walk to a shop, or peaceful recreational walk in a park).

An exact effect of gender, age, BMI, and PA levels on the preferred GS was observed. The trends in Figure 6.5 are also consistent with the literature (Schimpl et al., 2011b) and show the importance of real-world GS for monitoring and assessing functional decline caused by factors such as aging and obesity.

6.5.2 Multivariate analysis

Our study demonstrated a significant improvement in predicting frailty and estimating handgrip strength by taking advantage of any speed metrics in any GB durations. However, the improvements appear slightly higher within the GB duration between [30-120]s than the other durations. The possible explanation is that the short bouts (<30s) are usually related to indoor activity, such as stepping in a constrained environment during daily tasks. Hence, individuals are not necessarily challenged by their walking ability. On the other side, the long bouts (>120s) represent only a small percentage of daily GB. Therefore, their limited number of samples might reduce statistical power. The medium-duration GB (30-120s) appear optimal for estimating robust speed metrics because their number is sufficiently high (about 30 %), and the duration long enough to correspond to a stable gait pattern.

Furthermore, the 95th PCT of the GS seems to be the best speed metric in all GB durations to predict frailty. A Canadian study on older adults found that GS alone was sensitive and specific as a proxy for the Fried frailty phenotype. However, the dual-trait measure of GS with grip strength was more sensitive than individual traits and other possible dual-factor combinations (Lee et al., 2017). A systematic review also concluded that GS alone was as good as other composite tools in predicting the risk of adverse outcomes. There was sufficient evidence to support the GS as a single-item assessment tool for frailty screening in community-dwelling older adults (Abellan van Kan et al., 2009). In our study, the significant difference between models A and B and increased AUC for 95th PCT of GS in predicting the frailty revealed that this speed metric could serve a better as a proxy for the frailty than other GS metrics. The explanation is that the 95th PCT is an estimation of the upper-bound of GS distribution. Therefore this metric is more likely to reflect the physical/physiological reserve of the person. Real-world GS metrics also predicted handgrip strength. Clinically, these results were expected and agreed with the existing studies (Alley et al., 2014; Nagamatsu et al., 2019). Indeed, a reduction of both GS and handgrip strength might appear due to muscle weakness, which is one of the cardinal signs of frailty/transition to frailty.

6.5.3 Strengths and limitations

The main strengths of this study are the assessment of GS in a long-duration monitoring protocol (i.e., 13 successive full days), in a large (2809 participants) and diverse cohort (i.e., gender, age, BMD), and under entirely free-living situations using acceleration data from a wrist-worn device. The comprehensive statistical analyses on such a rich database with a wide range of GS led to a better and more reliable

understanding of the importance of GS in clinical applications. Furthermore, the methodology presented could help analyze massive existing databases, recorded with GENEActiv device or any other wrist-worn tools that record raw acceleration data (Cabanas-Sánchez et al., 2020; Cassidy et al., 2018; Doherty et al., 2017; da Silva et al., 2014). The technique could be valuable for assessment or screening of adverse conditions in both clinical and epidemiological studies.

This study also has some limitations. First, it was conducted in a community-dwelling population that could be considered mostly healthy. Therefore, the results might not apply to hospitalized and impaired people. Second, frailty was defined using a small set of criteria. There were an imbalanced number of subjects in the fit and frail groups; the results might change if the definitions based on other criteria would be used. Nevertheless, the definition of frailty used in this study is reliable in functional performance (Fried et al., 2001). Third, this study was conducted in Lausanne, a steep city, and the results might not be generalizable to other settings. Furthermore, the gait definition included walking and eventually running activity; however, the sensitivity analysis confirmed the same results. Finally, this study was cross-sectional where causality between PA and frailty or handgrip strength cannot be established; the ongoing follow-up of the CoLaus cohort will allow such assessment.

6.6 Conclusions

The current study demonstrated the feasibility of assessing real-world GS in extensive cohort studies using a simple, unobtrusive wrist-worn device recording raw acceleration data and algorithms developed and validated for this configuration. The methodology could be valuable for analyzing existing cohort datasets. The results showed that real-world GS could be a reliable indicator of health and age-related functional declines. It could effectively improve the evaluation of frailty condition.

6.7 Acknowledgment

This study has been supported by the research grants from GlaxoSmithKline, the Faculty of Biology and Medicine of Lausanne, and the Swiss National Science Foundation (grants 33CSCO-122661, 33CS30-139468, and 33CS30-148401). We would like to thank all participants and medical center staff who took part in our measurements.

Part IV - Conclusions

7 Conclusions, limitations, and future work

7.1 Main contributions

This thesis's ultimate goal was to design and validate accurate speed estimation and GB detection algorithms using data recorded with a single wearable sensor in real-world conditions. We dealt with the challenges of using only a single sensor unit worn on the LB or wrist (e.g., data deficiency, a high degree of freedom of the wrist movements). Another difficulty was validating accurate algorithms in challenging real-life situations, where the GB might be relatively short, non-stationary, unstable, and context-dependent. In order to provide a useful tool for long-term monitoring of gait in free-living situations, we were restricted to use only low-power sensors (e.g., accelerometer, barometer) rather than high-power ones (like GNSS), making it tough to extract accurate gait parameters. We also attempted to design the algorithms which were usable for both healthy and diseased populations such as PD and MS. The current chapter summarizes the main contributions of this thesis, limitations, and possible future work.

7.1.1 Part I - Introduction and Background

The first part of this thesis (chapters 1 and 2) highlighted the importance of gait analysis, especially gait speed and its related parameters in daily life situations. It also introduced the monitoring using a single inertial sensor, worn on LB or wrist, as suitable sensor locations in free-living situations. A review of the state of the art demonstrated that:

- iv. The existing wrist-based speed estimation and GB detection algorithms were mostly validated in supervised or semi-supervised situations, and they possibly lost performance in real-world situations. Therefore, there was a need to design and validate algorithms that remain accurate even in free-living conditions?

- v. An appropriate sensor location for both healthy and diseased populations was LB. While there were several LB-based speed estimation algorithms in the literature, it was not determined what algorithm and under what criteria (slow, normal, and fast walkers) lead to the best performance.
- vi. A few studies attempted to deploy IMU to monitor PA in large cohort studies. Their effort could be completed by adding gait analysis to these studies and assessing its added values.

7.1.2 Part II - Algorithms Design and Validation

The second part of this thesis provided a detailed description of all algorithms designed, implemented, and validated to answer the first (chapters 3 and 4) and second (chapter 5) research questions of section 7.1.1.

In chapter 3, an accurate wrist-based GB detection algorithm was devised and validated in everyday situations. We dealt with the difficulties of wrist-based gait patterns in real-world contexts by proposing biomechanically meaningful features based on the wrist posture, as well as the intensity, periodicity, and noisiness of the wrist acceleration. Besides, the Bayes classifier was deployed to recognize the GB. We also proposed two physically meaningful post-classification stages (i.e., temporal-based probability modification and smart decision making) to improve the Bayes' decisions. While the existing methods were rarely validated in unsupervised real-world conditions, we validated the proposed algorithm in entirely free-living situations, without any supervision or imposed sequence of activities, on two relatively big datasets (29 young and 37 elderly healthy subjects, 1-2 days per person). High median sensitivity, specificity, accuracy, precision, and F1-score (90.2, 97.2, 96.6, 80.0, and 82.6 %, respectively) were achieved in detecting GB. Besides, the total duration of GB of each person was successfully estimated ($R^2 = 0.95$). It should also be noted that a hardware implementation of the proposed method was designed as a low-power and real-time prototype, which could be used for long-duration measurement in everyday situations.

Chapter 4 was dedicated to designing and validating an accurate wrist-based algorithm for speed estimation in daily-life situations. We demonstrated that, due to inter-subject variability in daily life, a general model (i.e., trained on a group of people) might face important performance limitations for data recorded in some people. Therefore, an online personalization procedure was devised in which the GNSS was sporadically used to capture a few speed data of a person's gait to personalize the speed estimation model. We deployed the RLS technique for the online adaptation of the speed model to each subject's gait pattern. Although previous works mainly validated their algorithms in controlled and supervised laboratory settings, we validated the proposed algorithm against GNSS and in free-living situations on 30 healthy participants (around 2 hours per person) revealed a median [IQR] of RMSE of 0.05 [0.04-0.06] m/s and 0.14 [0.11

0.17] m/s for walking and running, respectively. The personalized method, compared to the non-personalized version, illustrated a significant performance improvement. The non-personalized approach achieved an RMSE of 0.10 [0.07 0.12] m/s, and 0.31 [0.25 0.42] m/s for walking and running, respectively. Apart from the performance, the personalized method did not need any database preparation; hence, it could save a lot of money and time. It was also low-power (by minimizing the GNSS usage), where the autonomy of one year was estimated for the algorithm using a primary battery cell (approximately 135.5 mAh per year). Moreover, it was perfectly adapted for real-time, long-duration, indoor/outdoor speed estimation in free-living situations.

Furthermore, the annex of chapter 4 illustrated how the proposed personalization model could be deployed in other sensor locations to improve real-world speed estimation, for instance, in the running using the feet-mounted IMU. When validated against the GNSS on the same dataset used in chapter 4, the personalized model achieved accuracy and precision of 0.00 ± 0.01 m/s and 0.09 ± 0.06 m/s, respectively. The non-personalized approach, however, obtained a 0.00 ± 0.11 m/s accuracy and 0.11 ± 0.05 m/s precision. The results demonstrated that the proposed personalization model provided a great capability to reduce the variance of the bias error, which was technically associated with gait's inter-subject variability. As a prospective work, the personalization model could also be applied to other sensor positions such as the LB. The GNSS of smartphones could be potentially used to collect data for the personalization model.

Since there were already several existing LB sensor-based gait speed estimation in the literature, we did not attempt to design an entirely new one. Instead, we took advantage of the existing algorithms and tried to improve them. Chapter 5 analyzed and compared the relevant speed (and its related parameters like cadence and step length) estimation algorithms to determine those showing the best performances for slow, normal, and fast walkers. To this end, after a technical review, the selected existing algorithms were organized in a conceptual framework for speed estimation. Then, algorithms based on BM, DI, and ML were developed and implemented. A novel concept based on the combination of the output of user-selected algorithms was also proposed to obtain one unique optimal solution. The comprehensive cross-validation revealed that the FD approach for slow walkers (a minimum RMSE of 2.3 steps/min) and the TD approach for fast walkers (a minimum RMSE of 0.6 steps/min) led to a better cadence estimation. For normal walkers, both approaches showed similar performance (a minimum RMSE of 1.3 steps/min).

Moreover, the results show that training the algorithms on a specific speed range (i.e., slow, normal, fast walkers) might not necessarily be the best option. Another alternative which showed more robust results was training on all speed ranges. Overall, the BM-based approach achieved better performance for estimating slow walkers' step length (the best RMSE of 0.05 m). However, all approaches (i.e., BM, DI, and ML) showed similar results for normal and fast walkers (a minimum RMSE of 0.04 m). The

combined approaches offered a more robust solution for both the cadence and the step length.

Furthermore, the choice of the cBM (i.e., the approach by combining the BM-based algorithms) or the cALL (i.e., the approach by combining all the algorithms) with any cadence algorithms revealed more accurate speed estimation for slow walkers (a minimum RMSE of 0.09 m/s). Besides, the cDI (i.e., the approach by combining all DI-based algorithms) with any cadence algorithms showed better speed estimation for normal walkers (a minimum RMSE of 0.11 m/s). For fast walkers, all approaches, except the FD one, led to similar speed estimation (a minimum RMSE of 0.10 m/s). For cadence, step length, and speed estimation of people with walking-aids, a considerable increase of error (up to 10 times) was observed. Considering all the results, the combined approaches (e.g., cALL) might be preferable for practical usage due to more robust and promising performance in all conditions. It should be noted that the algorithms were tested on laboratory datasets in this chapter. They might be tested on big real-world datasets in the future before real-life usage.

7.1.3 Part III - Real-world Application

The third part of the thesis (chapter 6) presented an application of the proposed wrist-based algorithms (chapters 3 and 4) in a long-term cohort study (around 3000 people) to monitor and assess real-world gait speed. A few previous studies used IMU in large cohort studies, but they mainly provide the intensity of PA (e.g., low, medium, vigorous) rather than gait speed. Chapter 6 demonstrated that, compared to GNSS and other complex systems like cameras, such an easy-to-use and user-friendly monitoring tool could obtain a similar distribution of speed and notable trends (caused by aging, obesity, and gender). Since the wrist-based method needs only on the accelerometer, this system could be used in many accelerometry devices and studies.

More importantly, this study revealed the significance of using the gait speed in predicting clinical outcomes like frailty detection or handgrip strength estimation. According to the results, the 95th PCT of the speed of the GB with a duration between 30-120 seconds showed the highest discrimination power. This study was an application example, providing evidence that the methodology could be used to take advantage of gait speed and its related parameters (e.g., cadence and step length) in analyzing data available in other cohorts.

7.2 The proposed systems in the industry and academia

The algorithms proposed in chapters 3 and 4 were designed in close collaboration with the Swiss watch industry in the framework of a CTI (Commission for Technology and Innovation) grant. This collaboration provided the possibility to recognize practical issues related to a portable activity tracker (e.g., limited computational power, memory,

and battery life) and to seek realistic and feasible solutions (e.g., avoiding computationally complicated approaches (e.g., deep NN), recursive training, minimal GNSS usage). It also gave a unique opportunity to transfer this thesis's outcomes to the industry for public usage. During this collaboration, three patents^{1,2,3} were prepared for the wrist-based gait speed estimation and GB detection algorithms.

Furthermore, in chapter 5, the algorithms were developed and implemented in the framework of the Innovative Medicines Initiative (IMI) European project Mobilise-D⁴ that brings more than 30 academic, clinical, and industrial partners. The main objective of this project is to connect digital mobility assessment, particularly gait speed, to clinical outcomes. Therefore, the first phase of this project (technical validation) is about developing, implementing, comparing, and validating performant algorithms to estimate gait parameters (especially speed as the primary outcome). The validation is being carried on both in-lab and real-world data of healthy and diseased people such as MS, PD, chronic obstructive pulmonary disease, and hip fracture recovery. The second phase of this project is a clinical validation to provide evidence that the gait outcomes, particularly speed, accurately measure and monitor disability and predict clinical outcomes in the mentioned populations. Currently, the project is finishing the technical validation. The clinical validation would be pursuing within three more years.

Eventually, the study presented in chapter 6 was performed in collaboration with the CHUV hospital as a part of the CoLaus⁵ (Cohort of Lausanne, Switzerland) study. This study is an ongoing prospective survey investigating the biological and genetic determinants of cardiovascular risk factors and cardiovascular disease in the population of Lausanne, Switzerland. The outcomes of this thesis could be beneficial for the CoLaus study, as shown in Chapter 6, by providing long-term gait speed, as an essential dimension of PA, using only a single accelerometer.

7.3 Limitations

This section briefly explains the limitations of the outcomes of this thesis. The proposed wrist-based (chapters 3 and 4) and a part of the LB-based (chapter 5) algorithms are designed based on the ML technique that imposes a few restrictions. First, they are based on analyzing successive temporal windows (typically overlapping) of 4-6 seconds. Therefore, they need to have at least a window of data (i.e., 4-6 seconds) to be able to begin their analysis. The window analysis also imposes the edge effect due to cutting

⁵ <https://www.colaus-psycolaus.ch/>

the signals by a sharp rectangular window, which might be problematic for feature extraction (e.g., FD features). It also limits the time resolution of the output (i.e., one output per each window) and might cause missing short activities (e.g., missing 3-second GB when the window is 6 seconds). Besides, the interpretation of the output is not always trivial since it corresponds to a whole window. For instance, when a window is detected as the gait, it is unclear what part of the window contains the gait. In another example, the output of the speed estimation is the average speed over a window. Therefore, the outputs of the wrist-based methods are in window granularity rather than in the usual gait granularity (steps/strides).

Another limitation of ML-based approaches (i.e., the proposed wrist-based methods) is that they usually require to be retrained for each new population, especially for diseased ones, to optimize the performance. This retraining needs collecting new datasets and an expert to rerun the algorithms (as performed in chapters 3 and 5). Besides, it is not always easy to determine how much training is enough to avoid underfitting or overfitting. Typically, several tests are necessary after each training. Consequently, ML-based approaches' maintenance might need additional work to be performed by an expert. We dealt with the database preparation issue in chapter 4 by proposing an online training procedure. However, it needs the GNSS and a smart strategy to collect necessary training data.

Another limitation is related to validating the proposed wrist-based algorithms (chapters 3 and 4), which has been performed only on healthy people. Applying these algorithms to diseased populations might result in a degradation of performance. The LB-based algorithms (chapter 5) have been validated on both healthy and diseased populations, but in laboratory conditions. Therefore, additional validation in real-world conditions is needed to confirm the current results. This validation is one of the project Mobilise-D objectives, where a multiple-sensor-based system will be used as a reference.

The outcome of the cohort study also faced some limitations. First, the dataset was imbalanced, where the number of fit people was much higher than the non-fit (i.e., frail) ones. Second, we defined the frailty according to a small set of criteria. Therefore, the results might slightly change if we introduce additional criteria in the definition. Next, we carried this study in a steep city like Lausanne so that the results might not be the same for flat cities. For instance, people might have longer gait periods with higher speed in flat cities. Eventually, the wrist-based system that we employed in this study could not distinguish between walking and running. While we attempted to remove the majority of running periods by applying a threshold to the speed, a part of them (e.g., slow running) remained, affecting the outcomes in the sense that speed outcomes were assessed during walking and potentially during slow running periods. Another alternative is to detect running periods by building an ML model on some accelerometer-based features such as intensity (running acceleration has probably

more intensity than walking) and cadence (running has usually higher cadence than walking).

7.4 Future work

One important perspective work of the developments performed in this thesis could be to validate the wrist-based algorithms (proposed in chapters 3 and 4) for diseased populations, especially those with affected arm movements like PD.

In addition, as discussed previously, the proposed personalized wrist-based speed estimation algorithm requires a smart strategy to collect the best GNSS speed samples for personalization. For instance, a histogram of features used to personalize the model could be tracked to decide which area of the feature space requires personalization. Another additional work could be performed to personalize the proposed wrist-based GB detection. For instance, it might be possible to ask users to provide a few self-assessed regular GB in their everyday life contexts and then use it to personalize the models.

For the LB-based algorithms (chapter 5), a valuable future work would be carrying the same evaluation, but on big datasets collected in real-life situations. This evaluation would provide more reliable conclusions about the speed estimation algorithms. Apart from this, since the LB-mounted sensor is in the proximity of the body CoM, it might be possible to design accurate algorithms to estimate secondary gait outcomes like symmetry. Therefore, other related prospective work could be to design and validate such algorithms.

Moreover, a complementary study could be conducted to investigate which one of the wrist or LB sensor locations are better for real-world gait analysis. For example, both sensors could be worn during long-duration measurements in free-living situations. The speed could then be estimated by the wrist-based and the LB-based algorithms and compared to a reference such as GNSS.

Furthermore, the cohort study in chapter 6 revealed a great potential of the proposed algorithms to be employed in real-world clinical applications to monitor the gait. As introduced in chapter 6, there are a growing number of large cohort datasets (Cabanas-Sánchez et al., 2020; Cassidy et al., 2018; Doherty et al., 2017; da Silva et al., 2014) all over the world that could be analyzed by the proposed algorithms and methodology. Another perspective could be adding the barometer sensor in the cohort studies and investigating its effects on the large populations' gait speed. Finally, some interesting studies could be performed to investigate how much the speed estimation could promote a more active lifestyle towards healthier populations.

Curriculum Vitae

06 / Oct / 1990

Abolfazl Soltani Biomedical engineer / Data scientist

- ❖ Expert in advanced signal processing and machine learning
- ❖ Expert in biomedical data science
- ❖ Experiences in designing embedded systems

Contact

- ◆ Private: Av. du 24-Janvier 28, Renens 1020, Switzerland
- ◆ Work: EPFL-LMAM, Station 9, Lausanne 1015, Switzerland
- ◆ Email: abolfazl.soltani@epfl.ch
- ◆ in: [linkedin.com/in/abolfazl-soltani-942a7877](https://www.linkedin.com/in/abolfazl-soltani-942a7877)

Professional Experiences

2016 – Present
EPFL,
[Laboratory of
Movement
Analysis and
Measurement
\(LMAM\)](#)

Project management

- ◆ Supervising master and bachelor students
- ◆ Developing fundamental research questions and outlining the main direction of the projects

Research assistant

- ◆ Collecting, processing, and fusing data captured from various wearable sensors (e.g., accelerometer, gyroscope, barometer)
- ◆ Modeling human physical activities (e.g., speed and steps estimation, walking and running detection) using biomechanical and machine learning techniques for healthy and patients
- ◆ Algorithm developer for the European project Mobilise-D (<https://www.mobilise-d.eu/>), aiming to estimate the gait speed using a single wearable sensor.
- ◆ Collaboration with many medical, academic, and industrial partners (e.g., Swatch group, Novartis, CHUV)

Teacher assistantship

- ◆ M.Sc. course Sensors in medical instrumentation

2013 – 2015 AUT, <i>Speech Processing Lab</i>	Research assistant <ul style="list-style-type: none"> ◆ Data analysis (Audio, particularly speech) ◆ Signal quality enhancement (signal-to-noise ratio) ◆ Advanced pattern recognition
	Teacher assistantship <ul style="list-style-type: none"> ◆ Courses Digital Signal Processing, Engineering Mathematics, and Microprocessor Systems

Education

2016 – Present EPFL, Laboratory of Movement Analysis and Measurement (LMAM)	Candidate Ph.D. in electrical engineering <ul style="list-style-type: none"> ◆ Modeling human's physical activity (e.g., gait detection and speed estimation) for healthy and patient populations in real-life situations by a single wearable sensor ◆ Outlining a conceptual framework for real-world gait speed estimation ◆ Using advanced signal processing (e.g., filter design, PCA, Kalman, Madgwick, CWT, EMD) and machine learning (e.g., online Recursive Least Square, Bayes, SVM, Decision trees, deep CNN) empowered by biomechanical rules ◆ Using Artificial-Intelligence to design auto-adaptive personalized solutions, implemented inside a wristwatch ◆ Optimizing power consumption and computational loads ◆ Data mining to assess the feasibility and usefulness of gait analysis in big data of cohort studies ◆ Designing measurement protocols and implementing analysis software
2013 – 2015 AUT, Tehran Polytechnique	M.Sc. in electrical engineering <ul style="list-style-type: none"> ◆ Machine learning techniques for audio pattern recognition ◆ Audio signal enhancement and noise cancellation ◆ Main Courses: Statistical pattern recognition, signal processing, robust speech recognition, AI.
2009 – 2013 AUT, Tehran Polytechnique	B.Sc. in electrical engineering <ul style="list-style-type: none"> ◆ Designing and hardware implementing of embedded systems using microprocessors and FPGAs

Languages	<ul style="list-style-type: none"> ◆ English (fluent) ◆ French (Intermediate) ◆ Persian (Mother tongue)
------------------	--

Technical skills

Programming	Devices	Software
<ul style="list-style-type: none"> ◆ Matlab ◆ Python ◆ C/C++ ◆ VHDL ◆ Assembly 	<ul style="list-style-type: none"> ◆ Accelerometer, gyroscope, GNSS, barometer, magnetometer, ◆ VICON, force plate, ◆ FPGA, ARM, AVR, DSP 	<ul style="list-style-type: none"> ◆ Matlab, Jupyter notebook, Spyder, Visual studio ◆ Libraries: Pandas, Numpy, Scipy, Matplotlib, TensorFlow, PyTorch ◆ LabVIEW, Xilinx ISE, Keil uVision
Team-working	<ul style="list-style-type: none"> ◆ Gitlab, ◆ Sharepoint, Projects, TeamViewer ◆ Zoom, Skype 	

Honors	<ul style="list-style-type: none"> ◆ First ranks among Electronics students in master and bachelor studies ◆ Member of National Elites Foundation of Iran (2013-Present)
Significant Projects	<p><i>Personalized gait speed estimation in daily life by a single sensor</i></p> <ul style="list-style-type: none"> ◆ Devising an auto-adaptive personalized speed estimation model using a wrist accelerometer (in a smartwatch) ◆ The smart AI-based algorithm automatically learns a user's gait patterns by online learning to achieve the best-personalized model <hr/> <p><i>Gait bouts detection in free-living situations by a single sensor</i></p> <ul style="list-style-type: none"> ◆ Detecting gait bouts in real-life situations using a single wrist-mounted inertial sensor unit ◆ Devising biomechanically-derived features such as intensity, periodicity, noisiness, and the wrist posture ◆ Applying biomechanical constraints on machine-learning models <hr/> <p><i>Gait speed estimation in patient populations by a single sensor</i></p> <ul style="list-style-type: none"> ◆ Outlining a conceptual framework for gait speed estimation by a single wearable sensor ◆ Improving and implementing existing methods ◆ Unifying biomechanical and machine learning techniques to design a unique, robust solution in different conditions (slow walkers, walking-aids) <hr/> <p><i>Monitoring gait in big data of clinical cohort studies</i></p> <ul style="list-style-type: none"> ◆ Investigate the feasibility of using a handy wrist-worn system to monitor gait in real-life of a large cohort ◆ Data mining to explore the usefulness of adding gait parameters to clinical cohort studies to predict clinical outcomes such as frailty <hr/> <p><i>Database development for analyzing human physical activities</i></p> <ul style="list-style-type: none"> ◆ Developing and maintaining several databases containing real data of physical activities recorded through multiple sensors (e.g., accelerometer, gyroscope) worn by a large number of people (3000 >) <hr/> <p><i>Data classification and pattern recognition</i></p> <ul style="list-style-type: none"> ◆ Designing a heuristic supervised learning approach to distinguish between different classes of data (e.g., object recognition). Genetic programming in the framework of Matlab was used <hr/> <p><i>Ultra-fast implementation of data coding</i></p> <p>Devising an ultra-high throughput and fully pipelined implementation of Advance Encryption Standard algorithm on FPGA (Xilinx family) using VHDL</p>
Patents	<ul style="list-style-type: none"> ◆ Soltani, A., Dejnabadi, H., and Aminian, K. 2020. Methods for computing a real-time step length and speed of a running or walking individual. US 2020/0000374 A1. ◆ Soltani, A., Cabeza, J., Savary, M., Dejnabadi, H. and Aminian, K. 2019. Activity monitoring watch for sport and wellness with personalized and auto-adaptive measurement and feedback. Submitted in 2019. ◆ Soltani, A., Savary, M., Dejnabadi, H. and Aminian, K. 2019. Method and system for gait detection of a person. Submitted in 2019.
