70 **1** Introduction

Plasma can sustain high electric fields and can be used to produce accelerating gradients larger than 71 in conventional particle accelerators [1-5]. The Advanced Wakefield Experiment (AWAKE) [6] is 72 an experiment located at CERN that investigates proton-driven plasma wakefield acceleration [7]. 73 AWAKE uses proton bunches from the CERN Super Proton Synchrotron (SPS) with the energy of 74 400 GeV to accelerate a witness bunch of electrons in a ten-meter-long rubidium plasma source. 75 The seeded self-modulation mechanism [8, 9] is used to divide the long driver bunch into a group 76 of shorter bunches that can resonantly drive wakefields [10, 11]. 77 A detailed understanding of the parameters of the incoming proton bunches is important for 78 the understanding of the experimental data. The bunch and plasma parameters define the wakefield 79 structure, and a comparison of experimental observations to simulations requires correct bunch 80 parameters. It has been shown [12] that results of plasma modeling are sensitive to the parameters 81 of the driver bunch, and uncertainty in the input bunch parameters complicates the comparison of 82 the simulation results and experimental measurements. 83 In this paper, we present a determination of the parameters of the unmodulated proton bunch 84

⁸⁵ by combining the data from multiple beam imaging systems. We test our analysis using simulated

data and then apply it to experimental data to study variations of the parameters over a large number
 of events.

The paper is structured in the following way. In section 2, a short overview of the AWAKE experiment is given with a focus on the proton bunch, as it plays the central role in our study. In section 3, the experimental setup used in our analysis is described, an overview of the acquired data is given and preliminary investigations are discussed. A statistical model is presented and tested on simulated data in section 4. This is followed by section 5, in which parameters and their prior probabilities are discussed, and results are presented. Finally, conclusions are presented in section 6.

95 2 Proton Bunch in the AWAKE experiment

The proton bunches used in the AWAKE experiment are produced in the CERN accelerator complex. They are accelerated in the Linac 4, Proton Synchrotron Booster, and Proton Synchrotron accelerating stages and reach the required energy of 400 GeV in the SPS. After this, they are sent to the AWAKE facility with intervals of 15 – 30 s. Extraction of a proton bunch to the AWAKE facility will be further denoted as an 'event'.

In AWAKE, the proton bunch enters a ten-meter-long rubidium vapor section [14, 15] together with the co-propagating laser pulse (see Fig. 1). According to the Run 1 baseline [16], the bunch is focused at $z_w = (5 \pm 3)$ cm after the entrance to the rubidium section. The radial size is $\sigma_{x,y} = (0.20 \pm 0.04)$ mm, longitudinal size is $\sigma_z = 6 - 8$ cm and angular divergence is $\sigma'_{x,y} = (4 \pm 2) \times 10^{-5}$ rad, where σ represents a Gaussian standard deviation. The parameters of proton bunches, such as the bunch centroid and population, fluctuate from event to event.

Figure 2. The standard deviation of the transverse proton bunch profile versus the beamline position for nominal bunch parameters without plasma. Gray solid lines show positions of four beam observation systems. The position of the plasma section is shown by red dotted lines.

The laser pulse [17] with a maximum energy of 450 mJ and a central wavelength of 780 nm ionizes the rubidium vapor, creating a relativistic ionization front that co-propagates with the proton bunch. The relativistic ionization front is much shorter than the typical period of the wakefields (> 3 ps) and it is used to seed the controlled self-modulation instability of the proton bunch. The resulting microbunches then act resonantly to drive large wakefields during the plasma section.

In the SPS accelerating ring, wire scanners are used to measure the transverse and longitudinal bunch emittances with an accuracy of 20% [6, 18, 19]. The Beam Quality Monitors [20, 21] are used to measure longitudinal bunch profiles, and Beam Current Transformers (BCT) [22] are used to determine the bunch intensity during the whole accelerating cycle.

In the AWAKE experiment, transverse and longitudinal structures of the bunch can be observed before and after the plasma section using diagnostics based on Optical Transition Radiation (OTR) or scintillating light, which is produced when the bunch crosses light-emitting screens placed at 45° to the beamline [6].

Table 1. Description of the beam imaging systems (denoted as Cam. 1-4) used in the measurements. The position along the beamline is denoted as z, and it is measured from the position of the first camera.

3 Measurements and Data

Four beam imaging systems that capture images of the transverse profile of the unmodulated proton 121 bunch before and after the rubidium vapor section were used in our analysis. Parameters of the 122 beam imaging systems are summarized in Table 1. The first three stations have CCD cameras with 123 OTR screens, and the last station has a digital CMOS camera with a scintillating screen. Fig. 2 124 illustrates the relative positions of the measurement stations, the plasma section, and the envelope 125 trajectory of the unmodulated bunch for the baseline parameters. It can be seen that the first two 126 stations are located very close to the waist position, so they mainly carry information about the 127 size of the bunch close to the focus. The last two stations are located much farther from the waist 128 position, and they are primarily sensitive to the angular divergence of the bunch. 129

We performed measurements on October 10, 2018, during which a dataset that consists of 672 130 events was collected. By 'event data' we denote 4 images from the beam imaging systems and the 131 proton bunch population measured in the SPS using the BCT. Four types of proton bunches were 132 requested from the SPS operators with the parameters summarized in Table 2. The first two types 133 correspond to the bunches with small, $(7.77 - 10.30) \times 10^{10} p^+$, and large, $(23.20 - 28.00) \times 10^{10} p^+$, 134 populations. These events are intended to study the impact of the bunch population on the bunch 135 emittance and focal size. The second two types represent bunches with or without longitudinal 136 compression. The bunch compression is achieved via a rotation in longitudinal phase space using a 137 voltage step with a fast rise time [23, 24]. The typical longitudinal bunch length (rms) without the 138 bunch rotation is ≈ 9.6 cm and with the bunch rotation ≈ 7.9 cm. The acquired dataset represents 139 proton bunches commonly used in the later stages of Run 1 data-taking period. 140

An example of the event data with a population of $n = 24.04 \times 10^{10} p^+$ is shown in Fig. 3. The central part of the images represents the OTR light on the first three screens and the scintillating light on the last screen produced by the proton bunch. The background noise is produced primarily by secondary particles that are generated upstream of AWAKE.

145 3.1 Preliminary Investigations

The analysis relies on knowledge of calibration factors and resolution scales for the devices used.
 These are described briefly.

148 3.1.1 Pixel Calibration Factor

¹⁴⁹ To determine the calibration factor of the pixel sizes, we use calibration frames that are engraved on

¹⁵⁰ the surface of each light-emitting screen. Parameters of the frames, such as width, height, and sizes

Table 2. Summary of the datasets.	Events are divided into 4 categories, i.e.,	small and large bunch population
and bunch rotation ON and OFF.		

Symbol	$n [10^{10}, p^+]$	Rotation	# Events
D_{11}	7.77 - 10.30	ON	181
D_{12}	7.77 - 10.30	OFF	160
D_{21}	23.20 - 28.00	ON	139
$D_{22}.$	23.20 - 28.00	OFF	192

Figure 3. Images from one event with the proton bunch population $n = 24.04 \times 10^{10} p^+$. Subplots correspond to the four beam imaging systems specified in Table 1. Signal amplitude represents the value recorded by the camera pixel, and it is in the range [0, 4095].

of the engraving lines, are known to high precision. The screens are placed at an angle of 45° with respect to the beamline and rotated on the horizontal axis. To calculate the horizontal calibration factor, we divide the absolute size of the frame by the number of pixels that correspond to it. To determine the vertical calibration factor, the absolute size of the frame is multiplied by $\cos(\pi/4)$ and then divided by the number of corresponding pixels. In the following, we assume that the pixel size includes the correct calibration factors. The resulting pixel sizes for each camera are specified in Table 3.

158 3.1.2 Resolution Function

There are two types of resolution effects present in the measurements. The first is the resolution of the optical system of the camera. The second is the resolution of the light-emitting screen. We assume that they both are convolutions with Gaussian kernels and their superposing effect is also represented by Gaussian convolution with the variance given by the quadrature sum of these two components.

Figure 4. Background distributions from different regions of Cam. 1. The frequency represents the number of counts present in each bin normalized such that the sum of frequencies from each bin is equal to one. The pixels enclosed by the white dotted lines are used to determine the parameters of the proton bunch. The background distributions from four rectangular regions enclosed by the dashed lines are shown in the right subplot. The dashed line in the right subplot shows the truncation threshold. The filled region represent the distribution of the signal (enclosed by the white dotted line).

We estimate the optical camera resolution using the images of the calibration frame previously discussed in the pixel calibration. For this, we assume that the engravings have sharp edges and can be represented as a product of Heaviside step functions. The images of the frames captured by the corresponding cameras are used to determine the unknown optical resolution parameters.

The study [25] performed at the CERN HiRadMat test facility indicates that scintillating screens are characterized by a worse resolution compared to the OTR screens. We include the additional smearing from the scintillating screen in our analysis using nuisance variables and consider constant resolution parameters for 3 cameras with OTR screens. The detailed values of resolution parameters are specified in Table 3.

173 3.1.3 Background Distribution

We divide the image from each camera into different regions (see Fig. 4). Those pixels located 174 in the central region — which is approximately 4-5 standard deviations around the bunch centroid 175 — are used to infer the parameters of the proton bunch. The remaining pixels are combined from 176 multiple events to approximate the background distribution via binned histograms. We use separate 177 background distributions for each camera and datasets with small and large bunch populations. An 178 example of the background distributions from four different regions of one camera is shown in 179 Fig. 4. It can be seen that all histograms significantly overlap, demonstrating that the background 180 follows a similar distribution in different parts of the camera. 181

Figure 5. Background distributions corresponding to the dataset with a large bunch population. The dark red colors show the distribution of the background only. The filled histograms show the distributions from pixels used in the analysis of bunch parameters, and they represent the superposition of signal and background. Orange lines show positions of the cutoff values.

Background distributions from the four different cameras are shown in Fig. 5. The histograms corresponding to cameras with the OTR screens have a similar structure. Namely, they all have a maximum at 0, long tails that extend to the amplitudes of > 2000, and a small bump of saturated pixels at the righthand side of the histograms. To avoid a possible negative impact of the saturation on the analysis, we discard those pixels that exceed the threshold values of 2700, 3400, 2400,1750, for each camera, respectively (see also dashed lines in Fig. 5). The histograms of signal and background show a smooth behavior up to these threshold values without signs of saturation.

The images produced by the last beam observing system have ~ 10 times more pixels compared to the images from the three other cameras. To improve the run-time of the analysis, we average every 3×3 pixels from the last camera. Averaging of the pixels reduces the long tail of the distribution as can be seen in Fig. 5 (bottom subplot). In the following, we will assume that the background on each pixel of the last camera is well-modeled with a truncated (form 0 to 4095) Gaussian distribution. The distribution variance is determined from the histogram, and the mean is fitted with a free parameter.

196 4 Statistical Model

¹⁹⁷ We perform the statistical analysis using a Bayesian approach. Prior probabilities about parameters ¹⁹⁸ λ , ν of the model *M* are updated to posterior probabilities using Bayes' theorem

$$P(\lambda, \nu | M, D) = \frac{P(D|\lambda, \nu) \cdot P(\lambda, \nu | M)}{\int P(D|\lambda, \nu) \cdot P(\lambda, \nu | M) d\lambda d\nu},$$
(4.1)

where $P(D|\lambda, \nu)$ is a likelihood that represents a probability of data given the model, $P(\lambda, \nu|M)$ is a prior probability distribution, and $P(\lambda, \nu|M, D)$ is a posterior probability distribution. The data from one event is denoted as $D \equiv \left\{ d_{x,y}^{j} \right\}$, where *d* is a signal from one pixel, *x*, *y* are the row, column of the pixel and *j* represents the camera index. The dataset consists of multiple events $\{D\}_{i}$ where *i* denotes the event index. In Eq. 4.1, λ represents parameters of interest, and ν represents nuisance parameters. Some of the nuisance parameters are kept constant, and others are free parameters of the fit that will be marginalized at the final stage of the analysis.

We analyze events consecutively and the likelihood of one event is defined as a product of likelihoods of individual pixels

$$P(D|\lambda, \nu) = \prod_{j \in N_{cam}} \prod_{y \in N_{rows}} \prod_{x \in N_{columns}} p(d_{xy}^{j}|\lambda, \nu),$$
(4.2)

where $p(d_{xy}^{j}|\lambda, v)$ is the probability of the detected signal for one pixel given the model parameters. The d_{xy}^{j} are composed of a background noise, with a probability distribution denoted as $P_b(d_{xy}^{j})$, and a signal $P_p(d_{xy}^{j}|\lambda, v)$ produced by the proton bunch. In the following, we will avoid indices x, y, j in d_{xy}^{j} for notational convenience if one pixel is considered. We assume that, for the given camera, the background is the same for all pixels and we approximate it by a binned histogram (see previous section). The resulting superposition of these two contributions is given by the convolution

$$p(d|\boldsymbol{\lambda}, \boldsymbol{\nu}) = \int P_p(\tau|\boldsymbol{\lambda}, \boldsymbol{\nu}) \cdot P_b(d-\tau) d\tau.$$
(4.3)

The convolution is computed numerically for the first three cameras due to the non-analytic form of the background, and it is computed analytically for the last camera, where the background is Gaussian. An example for such a convolution is shown in Fig. 6, where it is assumed that the signal from the proton bunch has a Gaussian distribution. The evaluation of the numerical convolutions is computationally expensive, but it is needed to include correctly the non-analytic features of the background.

221 4.1 Bunch Propagation Equation

We consider a model in which each particle of the bunch follows a linear equation of motion defined as

$$\boldsymbol{r}_{i} = \boldsymbol{r}_{0,i} + \boldsymbol{r}_{i}' \left(z - z_{w} \right), \tag{4.4}$$

where $\mathbf{r} = (x, y)$, *i* denotes the particle's index, z_w denotes the waist position, i.e., the coordinate along the beamline in which the radial bunch size is minimal, $\mathbf{r}_0 = (x_0, y_0)$ is the particle position at the waist, and $\mathbf{r'} = (dx/dz, dy/dz) \approx (\theta_{xz}, \theta_{yz})$ is the particle angle with respect to the beamline in the x - z and y - z planes. The distance along the beamline is denoted by z and is defined as the trajectory of the bunch centroid.

We measure distances in the transverse directions relative to the center of the proton bunch. To determine the center of the bunch, we use two parameters per camera, one for the *x* and one for the *y* directions, labeled as $\mu_{j,x}$, $\mu_{j,y}$ with *j* denoting the camera index (see Table 3). The envelope equation that describes the transverse size of the *x*-component of such a bunch along the beamline can be defined as

$$\sigma_x^2(z) = \langle x(z)^2 \rangle$$

= $\langle x_0^2 \rangle + 2 \langle x_0 x' \rangle (z - z_w) + \langle x'^2 \rangle (z - z_w)^2,$ (4.5)

where $\langle \cdot \rangle$ denotes the average over the ensemble of particles. A similar equation describes the *y* coordinate. It is assumed that there is no correlation between the *x* and *y* projections of the bunch. Furthermore, we assume that $\langle x_0 x' \rangle$ and $\langle y_0 y' \rangle$ are not correlated at the waist position, and the waist position is common for both projections. For notational convenience, the bunch transverse size at the waist will be denoted as $\boldsymbol{\sigma} = (\sigma_x(z_w), \sigma_y(z_w)) = (\sqrt{\langle x_0^2 \rangle}, \sqrt{\langle y_0^2 \rangle})$, and the angular spread of the bunch as $\boldsymbol{\sigma}' = (\sigma'_x, \sigma'_y) = (\sqrt{\langle x'^2 \rangle}, \sqrt{\langle y'^2 \rangle})$. We consider two models that describe the distribution of protons in the beamline.

We consider two models that describe the distribution of protons in the beamline. In the first model, we assume that the proton bunch is represented by a bivariate Gaussian distribution in the transverse plane and a univariate Gaussian distribution in the longitudinal direction.

²⁴³ The transverse distribution of the protons at each light-emitting screen can be described as

$$I_p(x, y|\lambda, \nu, M_1) = \mathcal{N}(x, y|\sigma(\lambda, \nu), \mu(\lambda, \nu)), \qquad (4.6)$$

where $\mu(\lambda, \nu)$, $\sigma(\lambda, \nu)$ denote that the mean vector and the covariance matrix of the bivariate Gaussian distribution are determind by the parameters λ , ν using Eq. 4.5. Model M_1 will be further denoted as 'Single Gaussian'.

In the second model, denoted as 'Double Gaussian', we assume that the transverse plane of the proton bunch is represented by a mixture of two bivariate Gaussian distributions. These components have the same alignment but different sizes, waist positions, and angular divergence. In this model, the transverse distribution of the protons at the light-emitting screen is defined as

$$I_{p}(x, y|\lambda, \nu, M_{2}) = \alpha \mathcal{N}(x, y|\sigma_{1}(\lambda, \nu), \mu_{1}(\lambda, \nu)) + + (1 - \alpha)\mathcal{N}(x, y|\sigma_{2}(\lambda, \nu), \mu_{1}(\lambda, \nu))$$

$$(4.7)$$

where α controls the significance of each contribution. The component with larger angular divergence will be called 'halo' and the smaller 'core', and their parameters will be denoted by subscripts 'c' and 'h', respectively. The single and double Gaussian models are nested, and they predict the same result if $\alpha = 1$.

255 4.2 Camera Modeling

Light with intensity proportional to the number of particles in the bunch is emitted when the proton bunch crosses the light-emitting screen. This light experiences optical smearing that can be represented by a convolution of $I_p(x, y|\lambda, \nu)$ with a Gaussian kernel $\mathcal{N}(x, y|\tilde{\sigma})$ with zero mean and resolution parameters $\tilde{\sigma}$, i.e.

$$I_p(x, y|\boldsymbol{\lambda}, \boldsymbol{\nu}) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} I_p(x - \tau_1, y - \tau_2 | \boldsymbol{\lambda}, \boldsymbol{\nu}) \times \\ \times \mathcal{N}(\tau_1, \tau_2 | \tilde{\sigma}) d\tau_1 d\tau_2.$$
(4.8)

Figure 6. Convolutions of the probability distribution of the signal created by the proton bunch and the background distribution are shown for different assumed mean signal amplitudes and variances for Cam. 3. The signal from the proton bunch, $P_p(d|\lambda, \nu)$, is assumed to be normally distributed (shown in dashed lines). The filled histograms show the background noise. The red lines show a numerical convolution represented by $p(d|\lambda, \nu)$.

The amount of light captured by one pixel is given by the integral over the pixel surface. We assume that the signal at each pixel is described by a Gaussian probability distribution with the

mean given by $i_j I$, and the standard deviation of $f_j \sqrt{I}$, where *j* denotes the camera index and i_j , f_j are coefficients of proportionality represented by free parameters (see Table 3):

$$P_p(d|\lambda, \nu) = \mathcal{N}(d|\mu = i_j I, \sigma = f_j \sqrt{I}). \tag{4.9}$$

This expression is used in Eq. 4.3 to compute the likelihood for one pixel. The likelihoods from all pixels are multiplied together to get the final event likelihood described by Eq. 4.2.

We sample the posterior distribution given by Eq. 4.1 using a Markov chain Monte Carlo (MCMC) algorithm. The likelihood is implemented in the Julia programming language, and the BAT.jl [26] package is used for the statistical inference.

269 4.3 Model Validation

To validate that the analysis leads to the correct reconstruction of the parameters, we performed the following procedure:

- 1. True parameters of the models were defined.
- 273
 2. Simulated events were generated that correspond to these parameters. The simulated events
 274 include background noise, lights fluctuations, optical smearing of cameras.

Figure 7. A comparison of the simulated data and the best-fit result is shown for the double Gaussian model. The blue step-lines show an integrated signal over rows/columns of the camera. The grey-filled regions show the 95% central probability intervals of the model including background and signal. The signal from the proton bunch is shown as points. The grey band for Cam. 4 overlaps with the data and is not visible.

The analysis algorithms were applied and the resulting parameters were compared to the true values.

The validation procedure was performed for both single and double Gaussian models. Excellent agreement was found between the extracted and true parameters for both models. An example of the simulated data and the fitted model for the double Gaussian bunch density is presented in Fig. 7. A violin plot with the parameter distributions is shown in Fig. 8. It can be seen that true parameters are well within the 95% central interval of the posterior distribution.

Fig. 8 shows that some of the parameters, such as the alignment of the bunch, can be recon-282 structed with great accuracy, with uncertainties smaller than 3% of pixel sizes. Another group of 283 parameters, such as the transverse size and angular divergence, is characterized by uncertainties of 284 a few percent. The nuisance parameters that describe the resolution function of the scintillating 285 screen have the largest uncertainty. The camera with the scintillating screen is located at the largest 286 distance from the waist position, and the bunch size is determined primarily by the angular diver-287 gence of the beam. The resolution is not a critical parameter, and it is not correlated significantly 288 with the proton bunch parameters. 289

We have tested the sensitivity of the analysis to the truncation of the data. Pixels that exceed the threshold values determined from the experimental data were discarded from the analysis, and the change in the resulting posterior means is well within the uncertainties of the parameter values.

Figure 8. The figure illustrates the posterior distribution obtained from the simulated event analysis. Each parameter is divided by truth to standardize the scale of the error bars. Blue horizontal ticks show 95% central probability intervals and means.

293 5 Analysis

294 5.1 Parameters and Priors

²⁹⁵ The parameters that describe the proton bunch distribution are

$$\lambda_{SG} = \{\sigma, \sigma', z_w\},$$

$$\lambda_{DG} = \{\sigma_c, \sigma_h, \sigma'_c, \sigma'_h, z_{w,c}, z_{w,h}, \alpha\},$$
(5.1)

where the two vectors correspond to the single and double Gaussian models, respectively. In addition, the nuisance parameters are

$$\boldsymbol{\nu} = \left\{ \boldsymbol{\mu}_{i}, \Delta x_{i}, \Delta y_{i}, \tilde{\boldsymbol{\sigma}}_{i}, \boldsymbol{i}_{i}, \boldsymbol{f}_{i}, \boldsymbol{p}_{4} \right\},$$
(5.2)

where j = 1 ... 4 denotes the camera index, and the bold font is used for the parameters that have the *x* and *y* components. A summary of all the parameters is given in Table 3.

The prior probability distributions for the proton bunch parameters are selected based on 300 the AWAKE design report. The priors of the transverse size of the core and halo components 301 of the bunch at the waist position (denoted as $\sigma_{c,x}, \sigma_{c,y}, \sigma_{h,x}, \sigma_{h,y}$) are described by Gaussian 302 probability distributions with means of 0.2 mm and standard deviations of 0.04 mm. The priors of 303 the angular divergences of the bunch (denoted as $\sigma'_{c,x}, \sigma'_{c,y}, \sigma'_{h,x}, \sigma'_{h,y}$) are described by Gaussian 304 probability distributions with means of 4×10^{-5} rad and standard deviations of 2×10^{-5} rad. Initially, 305 very broad prior ranges were considered for the proton bunch parameters. After learning about 306 the typical locations of the posteriors, the prior ranges were restricted to reduce computational 307 time. We truncate the angular divergence of the core component, denoted as $\sigma'_{c,x}, \sigma'_{c,y}$, to the 308

range $[1 \times 10^{-5}, 8 \times 10^{-5}]$ rad; and the halo component, denoted as $\sigma'_{h,x}, \sigma'_{h,y}$, to the range $[1 \times 10^{-5}, 4 \times 10^{-5}]$ rad to clearly identify the halo and core components. The prior probability distributions for the waist positions of the core and halo components, denoted as $z_{w,c}, z_{w,h}$, are described by a Gaussian distribution with means of 2.774 m and standard deviations of 0.03 m. The coefficient that defines the intensity ratio for the halo and core component is denoted as α and is described by a uniform prior.

Parameters that represent the bunch centroid at the camera i along the x and y directions are 315 denoted as $\mu_{x,j}, \mu_{y,j}$, and they are given by uniform prior probability distributions in the ranges 316 specified in Table 3. The pixel sizes along the x and y directions are denoted as Δx_i and Δy_i , and 317 they are represented by the Dirac delta prior distributions (further denoted as 'constant prior'). The 318 resolution parameters along the x and y directions, denoted as $\tilde{\sigma}_{j,x}, \tilde{\sigma}_{j,y}$, are assumed to be constant 319 for the cameras that have OTR screens. The prior for the camera with the scintillating screen was 320 modeled with a mean of 3 pixels and a standard deviation of 1.5 pixels. The conversion of the 321 proton bunch distribution into the pixel signal is performed by defining proportionality coefficients 322 i_i , that are described by uniform priors. The standard deviations of the Gaussian fluctuations of the 323 light are defined by f_i (see section 4). This parameter has a constant prior for those cameras where 324 the numerical convolutions of the background and signal are computed. For the last camera, the 325 signal fluctuation (f_4) and the mean of the background (p_4) are kept as free variables with uniform 326 priors. 327

328 5.2 Results

We analyzed each event summarized in Table 2 independently, using single and double Gaussian 329 bunch models. A comparison of the data from one event (with a small bunch population and the 330 bunch rotation OFF) to the best-fit predictions from the two models is shown in Fig. 9. It can be 331 seen that the double Gaussian model fits the data more closely than the single Gaussian model. The 332 prediction from the single Gaussian model shows a visible discrepancy with the data in the first, 333 third, and fourth cameras. It is especially evident for the events with a small bunch population. A 334 much better data-model agreement is reached for the double Gaussian model, showing that the data 335 fluctuations are covered reliably by the 95% central interval of the posterior probability distribution. 336 A small disagreement of the distribution for Cam. 4 (see the bottom subplot in Fig. 9) resulted from 337 the fact that some of the pixels were discarded from the analysis due to their saturated signals. In the 338 following, we discuss only the results obtained by using the double Gaussian proton bunch model. 339 The transverse sizes of the halo and core components of the bunch at the waist position are 340 shown in Fig. 10. The size of the core is larger than the size of the halo for all events, and both 341 components are significantly smaller than the mode of the prior distribution. There is a correlation 342 of the bunch size with increasing bunch population. The transverse bunch profile is elliptical. 343

The angular divergences for different events are shown in Fig. 11. Events with a larger bunch population have a smaller angular divergence of the halo component.

The waist positions of the halo and core components are shown in Fig. 12. The figure shows that the core component of the bunch is focused much closer to the expected waist position compared to the halo component, which is focused further downstream.

Figure 9. A comparison of the experimental data and the best-fit result for the single (top) and double (bottom) Gaussian models. The blue step-lines show data from one event integrated over rows/columns. The model prediction is plotted for the mean value of the posterior. The grey-filled regions show the 95% central probability intervals of the model including background and signal. The grey band for Cam. 4 overlaps with the data and is not visible.

The normalized rms emittance can be computed using the bunch size at the waist and angular divergence as

$$\epsilon = \beta \gamma \sigma \sigma', \tag{5.3}$$

Figure 10. The transverse size of the proton bunch at the waist position is shown for events with different bunch populations using a double Gaussian model. Each event is represented by two symbols that show the halo and core components. Darker colors correspond to a larger bunch population. The color scale is non-linear. Dashed lines represent central intervals of the prior probability distributions.

Figure 11. The x and y components of the angular spread of the proton bunch are shown for different bunch populations using a double Gaussian model. Each event is represented by two symbols that show the halo and core components. Darker colors correspond to a larger bunch population. The color scale is non-linear. Dashed lines represent central intervals of the prior probability distributions.

Figure 12. The figure shows the means and standard deviations of the waist positions of the halo and core components of the proton bunch. Darker colors correspond to a larger bunch population. The color scale is non-linear. Dashed lines represent central intervals of the prior probability distributions.

Figure 13. The x and y components of the bunch emittance are shown for different bunch populations using a double Gaussian model. Each event is represented by two symbols that indicate the halo and core components. Darker colors correspond to a larger bunch population. The color scale is non-linear. Dashed lines represent central intervals of the prior probability distributions.

where γ denotes the Lorentz factor and β denotes ratio of the bunch velocity *v* to the speed of light *c*. For the proton bunches used in AWAKE $\beta \gamma \approx 426$. The posterior distributions of the halo and

Figure 14. Parameter α that defines the significance of the halo component is shown versus the bunch population. A more significant halo component is observed in the bunches with a larger bunch population.

Figure 15. Positions of the bunch centroids at the waist. The left plot shows the drift of the bunch centroid with the time of the measurement. The right plot shows the same data with subtracted time drift.

³⁵³ core emittances are summarized in Fig. 13. It can be seen that the bunch emittance increases with
 the increasing bunch population for both components. The x component of the emittance for the
 halo component is more strongly correlated with the bunch population than the y component.

The coefficient that shows the intensity of halo and core components is shown in Fig. 14. There is a correlation of α with the proton bunch population that shows that the halo component is more significant for the events with a larger bunch population.

In the analysis, we use nuisance parameters to determine the coordinates of the bunch at 359 each screen. These coordinates can be combined to determine the relative alignments of the 360 screens together with polar and azimuthal angles of the individual bunch centroids. By propagating 361 individual bunch centroids to the waist position, the drift and jitter of the bunch can be computed. 362 Fig. 15 shows that the bunch center drifts as a function of event number, which is proportional to 363 the time at which measurement occurred. The standard deviation at the waist is $\sigma(\mu_x) \approx 43 \,\mu\text{m}$, 364 $\sigma(\mu_y) \approx 20 \,\mu\text{m}$. Once the time-drift of the bunch is subtracted, the resulting jitters are $\sigma(\mu_x) \approx$ 365 41 µm and $\sigma(\mu_v) \approx 8$ µm. 366

A summary of the average posterior parameters for events with small and large bunch populations is given in Table 3 for the double Gaussian model. A summary of the average proton bunch parameters for the single Gaussian model is given in Table 4.

370 6 Conclusions

We have developed and applied an approach to analyzing the parameters of the proton bunch in the AWAKE experiment. In this approach, the data from multiple beam imaging systems that capture integrated radial bunch profiles were used to determine optimal parameters of the model that describe proton bunch propagation along the beamline. The fitting procedure was performed using a Bayesian approach, and the MCMC sampling was used to extract the posterior distributions. This approach will be used in future AWAKE runs to analyze the stability of the proton bunch parameters over long runs.

Two models that describe the radial bunch density were considered. In the first model, the transverse bunch profile was represented as a Gaussian function, in the second model — as a mixture of two Gaussians denoted as halo and core. By definition, the halo component has a larger emittance compared to the core. These models have been tested using simulated events, and the results show that reconstruction of true parameters is possible with typical uncertainties of a few percent.

We have acquired a dataset with 671 proton bunch extractions, each characterized by varying proton bunch parameters, and applied the developed analysis scheme to this experimental data. It has been demonstrated that the double Gaussian model gives much better agreement with the experimental data compared to the single Gaussian model. The resulting posterior parameters for the double Gaussian model indicate the following:

- The transverse size of the proton bunch at the waist position is smaller than the baseline parameters for all bunch populations.

- Sizes of the halo and core components increase with the increasing bunch population.

- The transverse bunch profile is elliptical (the horizontal size is smaller than the vertical by $\approx 8\%$ and $\approx 40\%$ for the core and halo components, respectively).
- The contribution of the halo component increases with the bunch population.
- ³⁹⁴ The bunch emittance is smaller than the nominal parameters.

³⁹⁵ A systematic drift of the bunch centroid was observed of approximately 50 µm during 6 hours of ³⁹⁶ measurements. The jitter of the bunch at the waist position after drift correction is $\sigma(\mu_x) \approx 41$ µm ³⁹⁷ and $\sigma(\mu_y) \approx 8$ µm.

Table 3. The table summarizes the parameters used in the analysis of the proton bunch with the double Gaussian model. Parameters are separated into the proton bunch (λ) , nuisance (ν) , and calculated categories. The fourth column describes prior probability distributions. If the distribution is uniform on a certain region or truncated, the corresponding region is specified in rectangular parentheses; a single number denotes the argument of the Dirac delta distribution, $\mathcal{N}(\mu, \sigma)$ stands for a Gaussian distribution with a mean μ and a standard deviation σ . The fifth and sixth columns show the mean and standard deviation of the parameters averaged over the datasets with small (1) and large (2) bunch populations.
