Acknowledgements

First of all, I would like to thank Prof. François Maréchal, my thesis director, for having given me the opportunity to complete this thesis. His scientific passion, his multi-disciplinary expertise, his inspiration, his endless ambitions and his advice have been invaluable driving forces for the accomplishment of this thesis. The confidence he has placed in me, as well as the autonomy and the freedom he has accorded me have always motivated me and pushed me forward.

At this place I would also like to thank the members of the jury for having evaluated this thesis and for the interesting and enriching discussion. It has been a great pleasure and honour to have Prof. Rakesh Agrawal, Prof. Marco Mazzotti and Dr. Markus Wolf on my thesis jury headed by Prof. Dominique Bonvin.

I further gratefully acknowledge the financial support of the Competence Center Energy and Mobility (CCEM) and the Competence Center Environment and Sustainability (CCES) in the frame of the CARMA project, as well as the funding of swisselectric and Alstom that have enabled this research work.

I have highly appreciated the collaboration in the interdisciplinary research projects 'Carbon dioxide management in power generation (CARMA)' and 'Technologies for Gas Turbine Power Generation with CO₂ Mitigation'. I would like to thank the head of the CARMA project Marco Mazzotti, as well as Timothy Griffin and Dieter Winkler from Fachhochschule Nordwest Schweiz (FHNW) and the groups of Peter Jansohn, Ioannis Mantzaras and Stefan Hirschberg from PSI for the fruitful collaboration and the competent advice having allowed to validate some of the developed models.

The software support of the BELSIM SA team has been very valuable for the implementation of the flowsheeting models.

Acknowledgements

One of the key factors for the successful accomplishment of this work has been the professional and lively atmosphere at the Industrial Energy System Laboratory headed by Prof. Daniel Favrat, to whom I would like to express my gratitude, as well as to the secretaries for the friendly and valuable administrative support. A great thank also to all my colleagues at LENI for the scientific and motivational support and for the great time we have spent together at work, as well as after work. It has been a pleasure to work together with them and they have all contributed in various ways to my research. Especially I want to thank Nicolas Borboën for having solved many IT troubles; Martin Gassner for having passed to me his passion and knowledge for modelling processes, notably in the field of biomass conversion; Léandro Salgueiro for all his support in many different fields and his constant encouragements; Matthias Dubuis for the collaboration in the research projects and the teaching activities, but especially for his cheerfulness; Léda Gerber for the advices with regard to LCA and Emanuela Peduzzi for contributing to the study of several aspects related to this research. Zacharie, Thierry and Matthias, it has been a pleasure to share the office with you. Thanks a lot for the enjoyable but at the same time quiet atmosphere (before the beginning of the construction works...), for your support and for your patience during the eternal discussions with all my students.

Special thanks to my dear friends from Lausanne and Luxembourg for the unforgettable and joyful time we have spent together. These have been precious moments to distract myself from the never-ending programming bugs. A great thank to Ralph for all the encouragements during the Master studies and the spontaneous help at the final stage of this thesis.

Finally, many thanks go to my family, particularly my parents and my sisters Pascale and Françoise for their constant support during all these years, for sharing my happiness and sadness, and for always believing in me.

Last but not least I would like to thank Scharel for his humour, his optimism and the time we have spent together.

Lausanne, 10 February 2013

L. T.

Abstract

To meet the CO₂ reduction targets and to ensure a reliable energy supply, the development and wide scale deployment of cost-competitive innovative low-carbon energy technologies is essential. Switching to renewable resources and CO₂ capture and storage in power plants, are regarded as promising alternatives. To design and evaluate the competitiveness of such complex integrated energy conversion systems, a systematic comparison including thermo-dynamic, economic and environmental considerations is required. This thesis presents the development of a systematic thermo-environomic optimisation strategy for the consistent modelling, comparison and optimisation of fuel decarbonisation process options. The environmental benefit and the energetic and economic costs of carbon capture are assessed for several process options and energy systems, including H₂ and/or electricity production from natural gas or biomass resources and considering different CO₂ capture technologies. The process performance is systematically compared and the trade-offs are assessed to support decision-making and identify optimal process configurations with regard to the polygeneration of H₂, electricity, heat and captured CO₂.

The results from the systematic process design and comparison studies reveal the importance of process integration, maximising the rational energy recovery by cogeneration, in the synthesis of efficient decarbonisation processes. In addition, the influence of the economic scenario on the process competitiveness and hence on the optimal process design is pointed out. It appears that the various process options are in competition, even with conventional plants without CO₂ capture when a carbon tax is introduced. The choice of the optimal configuration is defined by the production scope and the priorities given to the different thermo-environomic criteria.

Keywords: CO₂ capture and storage, hydrogen, biomass, power plant, process design, process modelling, energy integration, multi-objective optimisation.

Résumé

Afin d'atteindre les objectifs de réduction des émissions de gaz à effet de serre et d'assurer un approvisionnement durable en énergie, le développement et la dissémination à grande échelle de technologies énergétiques innovantes à faible intensité en carbone sont essentiels. La transition vers l'utilisation de ressources renouvelables, ainsi que le captage et stockage de CO₂ émanant de centrales électriques, sont considérés comme alternatives prometteuses. Afin de concevoir de tels systèmes intégrés de conversion d'énergie et d'évaluer leur compétitivité, une comparaison systématique considérant des aspects thermodynamiques, économiques et environnementaux est requise. Cette thèse présente le développement d'une stratégie d'optimisation thermo-environnementale systématique pour la modélisation, la comparaison et l'optimisation cohérente de procédés de décarbonisation. Le bénéfice environnemental et les coûts énergétiques et économiques du captage de CO₂ sont évalués pour diverses options du procédé et différents systèmes énergétiques, incluant la production d'H₂ et/ou d'électricité à partir de gaz naturel ou de biomasse et prenant en compte différentes technologies pour le captage du CO₂. La performance des procédés est comparée systématiquement et les compromis sont relevés en vue d'assister dans la prise de décisions et d'identifier des configurations de procédés optimaux en termes de polygénération d'H₂, d'électricité et de CO₂ capturé.

Les résultats des études systématiques de conception et de comparaison de procédés ont démontrés l'importance de l'intégration énergétique, maximisant la récupération d'énergie par cogénération, dans la synthèse de procédés de décarbonisation efficaces. En plus, il est mis en évidence comment les scénarios économiques influencent la compétitivité des procédés et donc la conception optimale du procédé. Il s'avère que les diverses options de procédés sont en compétition, même avec des centrales électriques conventionnelles sans captage de CO₂ lorsqu'une taxe de carbone est introduite. Le choix de la configuration optimale est défini par le but de production et les priorités données aux différents critères thermo-environnementaux.

Mots-clés : Captage et stockage du CO₂, hydrogène, biomasse, centrale électrique, conception de procédés, modélisation de procédés, intégration énergétique, optimisation multi-objective.

Introduction

Context

Actually the world is facing a dual challenge with regard to sustainable energy supply and greenhouse gas emissions reduction. The complexity consists in supplying more abundant and clean energy, consuming fewer fossil resources and finding appropriate solutions to reduce the emissions while also satisfying the energy requirement. Between 1971 and 2009, global CO₂ emissions doubled and until 2035 an additional increase of 22.4% is predicted due to the growing population and energy consumption. This increase of the greenhouse gas emissions produced by human activities contributes to the global warming which causes climate change. In 2010, fuel combustion emitted worldwide 30 Gt of CO₂, which were mainly attributed to coal 43%, oil 37% and gas resources 20% (IEA (2011a, 2012)). Figure 1 shows that the largest part of the global CO₂ emissions from fuel combustion is related to electricity generation and transport; two sectors consuming primarily fossil fuel resources. In pair with the CO₂ emissions increase, the total primary energy supply increased by nearly 50% between 1973 and 2010 to 12717 Mtoe (147PWh) (IEA (2012)). It is pointed out in Figure 2 that over 80% of the world primary energy is supplied by fossil resources, which will be depleted in the long term, and only a small part by renewable resources. These trends illustrate the need for a more sustainable energy future.

Figure 1: World CO₂ emissions from fuel combustion by sector in 2010 (IEA (2011a)).

Figure 2: World total primary energy supply by fuel in 2010 (IEA (2012)). Others: 2.3% Hydro.

To meet these challenges of climate change mitigation and sustainable energy supply, several proposals have been investigated, particularly since the Kyoto Protocol in 1997, such as reducing the energy consumption, improving the energy efficiency, changing to less carbon intensive fuels and finally switching to renewable fuels. In the short to medium term, CO₂ emissions reduction by carbon capture and storage (CCS), is considered as a promising option for power plants applications, since fossil fuels will still be dominant. A general overview of the main features of CCS is given in the IPCC report (Metz et al. (2005)). In predictions for post 2020 scenarios (ZEP (2012), Finkenrath (2011), European Commission (2011)), CCS is regarded as cost-competitive compared to other low-carbon alternatives including wind and solar power.

The analysis, comparison and optimisation of fuel decarbonisation processes, capturing CO₂ in electricity and/or H₂ generating processes, is the major topic of this thesis. The next sections briefly introduce the principles of CCS and give an overview of fuel decarbonisation research. Based on the outcomes of the state-of-the-art review, the objectives of this thesis are formulated and finally the thesis content is outlined.

CO₂ capture and storage (CCS) principles

CCS could provide up to 20% of the targeted CO₂ emissions reductions until 2050 to keep global warming below 2°C (ZEP (2012)). Therefore a rapid and widespread deployment of CCS is required from small-scale to commercial scale. The major steps of CCS, summarised in Figure 3, are:

- Capture: Gas separation techniques are applied to capture up to 90% of the CO₂ emissions from power plants and heavy industries.
- Transport: The captured CO₂ is first compressed into a liquid state and dehydrated for transport and storage, and then transported to the storage site by pipeline or ship.
- Storage: Potential storage methods are injection into underground geological formations, injection into the deep ocean, or industrial fixation in inorganic carbonates. Natural trapping mechanisms are applied for the safe and permanent CO₂ storage in geological formations, such as deep saline aquifers or depleted gas and oil fields (enhanced oil recovery EOR). These mechanisms include residual, dissolution and mineral trapping. A suitable CO₂ reservoir needs a layer of porous rock to absorb the CO₂ at the right depth (700-5000m) and an impermeable layer of cap rock to seal the porous layer (Metz et al. (2005), ZEP (2012)).

Figure 3: CO₂ capture and storage principle.

CO₂ capture

Three different concepts are distinguished for CO₂ capture in power plants, namely post-, oxy-fuel and pre-combustion, illustrated in Figure 4.

Figure 4: CO₂ capture concepts: (a) Post-combustion CO₂ capture. (b) Oxy-fuel combustion. (c) Pre-combustion CO₂ capture.

Introduction

Post-combustion is an end of pipe capture scheme, illustrated in Figure 4 (a), where after the primary fuel combustion with air, the flue gas consisting of CO₂, N₂ and H₂O is treated in order to capture the CO₂. The design challenge of post-combustion CO₂ capture is related to the low partial pressure of the CO₂ in the flue gas (typically 4-14%vol). Potential separation technologies are chemical absorption, gas separation membranes and cryogenic distillation. The low CO₂ concentration leads to large volumes to be treated and requires a high-capacity chemical solvent.

Oxy-fuel combustion. The CO₂ is captured during the combustion burning primary fuel in pure oxygen instead of air as described in Figure 4 (b). The oxygen is produced in an air separation unit removing the nitrogen either by cryogenic air distillation or by membrane processes. The flue gas consists mainly of H₂O and CO₂ (>80%vol) which is then compressed and dehydrated for transport and storage. One drawback of burning fuel in pure oxygen is that a high flame temperature is required. This impact can however be moderated by recycling CO₂ and/or H₂O-rich flue gas to the combustor. In addition, large amounts of oxygen are required and have to be produced by air separation, which is an energy and cost intensive process. Compared to post-combustion CO₂ capture, the main advantage is that the CO₂ needs only to be purified and that nearly no NO_x are formed.

A new emerging concept with internal CO₂ capture is chemical looping combustion (CLC) using an oxygen carrier to bring the oxygen from the air to the fuel. Potential oxygen carriers are metal oxides such as Fe₂O₃, NiO, CuO or Mn₂O₃ (Metz et al. (2005)).

Pre-combustion. The CO₂ is captured before the fuel is burned. As detailed in Figure 4 (c), syngas, a mixture of H₂ and CO, is generated by reforming or gasifying fuel with oxygen or air. Then steam is added to the syngas in a water-gas-shift (WGS) reactor to convert the carbon monoxide CO to CO₂ and additional H₂. Candidate gas separation technologies are chemical and physical absorption and adsorption processes. The H₂-rich fuel can be used as fuel in boilers, furnaces, gas turbines, engines and fuel cells for power and/or heat generation. The captured CO₂ is compressed and dehydrated for transport and storage. The pre-combustion route is often referred to as 'Hydrogen route' since the generation of a H₂-rich fuel has many parallels with H₂ production by thermo-chemical conversion of hydrocarbons and purification by CO₂ separation. This has the advantage that the reforming and separation technology is commercially available. Especially physical solvents units (Rectisol, Selexol), which are well suited for high partial pressure CO₂ separation, are currently in operation. However, some developments are still required to adapt the gas turbine technology for H₂-rich fuel operation. An additional challenge is, as for the other concepts, the reduction of the efficiency penalty of CO₂ capture, for example by improved solvents, advanced shift with reduced steam consumption or simultaneous integration of the reaction and separation in a sorption-enhanced reactor.

Hydrogen has various applications as chemical for the production of ammonia and methanol and for hydrogenation, but also as energy carrier for transport, power generation and distributed heat production. This has led to the 'Hydrogen Economy' vision (Ball and Wietschel (2009), Ramage (2004)). Produced from a variety of widely available primary energy sources (i.e. renewable and fossil), this secondary energy carrier can supply clean, reliable and affordable energy and displace some demands for fossil fuels in the actual energy system. H₂ can be directly combusted in an internal combustion engine or electrochemically converted to electricity in a fuel cell system with a high efficiency reaching 50 to 60% (Stolten (2010)). When produced from renewable resources, the question of venting or capturing CO₂ is of concern. In this perspective, the pre-combustion or hydrogen routes have to be investigated with regard to the different competing outputs, H₂, heat and power and captured CO₂, and their interactions in polygeneration.

Not all the CO₂ capture concepts are compatible with each type of power plant to capture about 85-95% of the plant's CO₂ emissions. The choice of a specific capture technology is determined largely by the technology availability, the process operating conditions, the amount of CO₂ to be captured, the composition of the gas mixture and the energy requirement. The capture costs depend upon technical, economic and financial factors related to the design and operation of the production process or the power system of interest, and the applied CO₂ capture technology. Table 1 summarises and compares the characteristics of the different CCS schemes. Regarding the widespread commercialisation of large scale installations for CO₂ capture, several challenges have to be addressed and some developments have to be done to improve the technology availability.

Fuel decarbonisation in power plants applications can contribute to the reduction of the environmental impacts, however the power generation efficiency is decreased by up to 10%-points and the production costs are increased by over 30% due to the additional energy requirement and equipment costs for the CO₂ capture and compression. The challenge for R&D in future energy systems design consists therefore in minimising the penalties of CCS by rendering these processes energetically, economically and environmentally competitive by the means of process integration and improvements relative to the resources, technologies, operating conditions and targeted production goal.

Introduction

Table 1: Comparison of CO₂ capture processes (Figueroa et al. (2008), Kanniche et al. (2010), Radgen et al. (2005), Olajire (2010)).

Concept	Post-combustion	Pre-combustion	Oxy-fuel combustion
Gas separation	CO ₂ / N ₂	CO ₂ / H ₂	O ₂ / N ₂
Technology (preferred)	Chemical absorption	Physical/chemical ad-/absorption	Distillation
Technology (alternative)	Membrane /PSA	Membrane	Air separation membrane
Application	PC, NGCC	IGCC, NGCC	PC, NGCC
Advantage	Retrofit technology	High CO ₂ partial pressure Compression costs/loads reduction	Flue gas concentrated in CO ₂ Retrofit, repowering technology
Disadvantage	Low CO ₂ partial pressure Solvent degradation Solvent regeneration	Fuel processing Availability	O ₂ production requirement Cooled CO ₂ recycle to maintain temperature
Developments	Absorbents	H ₂ GT, membranes, gasifier	Burner, membranes
Cost influence	Absorber/compressor	Reformer	Air separation unit

Thermo-environomic evaluation of fuel decarbonisation processes

In the perspective of a sustainable energy future driven by greenhouse gas constraints, alternative energy systems and renewable resources, various ways of fuel decarbonisation by CO₂ capture and storage from large-point source emitters, especially power generation plants, have been studied over the last decades. Several research studies have been performed within the scope of identifying promising CCS processes for fossil fuel conversion into electricity and hydrogen. Some are based on fundamental considerations, while others report on results from basic engineering design. A review of the different process analysis studies is made here, before assessing in more detail the various methodologies that have been applied for the systems analysis and comparison.

Comprehensive assessment

Hydrogen economy. The challenges and opportunities for a future hydrogen economy are widely discussed in literature. The book edited by Ball and Wietschel (2009) was the first to cover H₂ in a holistic manner from a technical, environmental and socio-economic perspective by discussing issues like hydrogen infrastructure strategies and supply scenarios, interactions between H₂ and electricity, and the potential of H₂ as alternative fuel in the transportation sector. Winter (2009) addressed the features of H₂ in view of a change of the energy system with respect to the environmental and climatic relevance, the effect on fossil fuel decarbonisation and the exergy efficiency. The challenges of H₂ production, storage and infrastructures, and of fuel cell applications are addressed in Stolten (2010). The economic aspects of the hydrogen economy are investigated in Ramage (2004). A general overview of H₂ properties, applications and production routes is given in Häussinger et al. (2000).

Power plants with CCS. Technologies for CO₂ capture were explored since the 1970s with the objective of enhanced oil recovery rather than reducing greenhouse gas emissions. Economic, environmental and social issues for the comprehensive understanding of CCS technology are discussed in the IPCC report (Metz et al. (2005)), while the status of CCS in Switzerland

is addressed in Wallquist and Werner (2008). The progress of CCS research and engineering is reviewed in Yang et al. (2008) and Figueroa et al. (2008). In the light of power plants performance improvements, a number of research projects were conducted in the field of fuel decarbonisation. CCS costs in the European Union are studied by the ZEP project (ZEP (2011)). For the oxy-fuel combustion concepts, many cycle configurations have been proposed; the AZEP scheme (Griffin et al. (2005)), the Graz cycle (Jericha et al. (2004)), the Matiant cycle (Mathieu and Nihart (1999)), the semi-closed CO₂-based power cycle (Bolland and Mathieu (1998)) and alternatively the chemical looping combustion (Chiesa et al. (2008)). Post-combustion CO₂ capture concepts were evaluated for natural gas fuelled power plants in Li et al. (2006) and Bernier et al. (2010) based on a multi-objective optimisation strategy and for coal based-power plants in Rao and Rubin (2002) based on stochastic modelling. Performance analyses of pre-combustion CO₂ capture concepts were investigated among others in Andersen et al. (2000), Lozza and Chiesa (2002a,b), Corradetti and Desideri (2005), Hetland (2009) and Romano et al. (2010). Different CCS concepts for natural gas fired power plants were evaluated and compared in Chiesa and Consonni (2000), Bolland and Undrum (2003), Kvamsdal et al. (2007) and Meerman et al. (2012), and for coal and gas power plants in Göttlicher (1999), Rubin et al. (2007) and Kanniche et al. (2010). A comparison of power plants using different resources is made in Parsons et al. (2002). In these studies the performance, efficiency and CO₂ emissions, are assessed essentially by mass- and heat balance simulations and cost estimations. In Zhang and Lior (2008) the process integration dimension was included through a graphical exergy analysis using exergy utilisation diagrams. Thermodynamic losses of fuel decarbonisation processes were quantified and localised extensively in Ertesvåg et al. (2005) and Petrakopoulou and Tsatsaronis (2012) through rigorous exergy analyses.

Co-production of electricity and H₂. Instead of focusing exclusively on power generation with reduced CO₂ emissions, several process simulation studies have looked at possibilities for electricity and H₂ co-generation with CCS and have identified the benefits and interactions between H₂ production and electricity generation. Based on performance and cost data of natural gas fired plants Davison et al. (2009, 2010) have revealed how synergies within the plant can be provided by co-production and face the variability in demand for the two products. The influence of the process configuration on the efficiency, costs and emissions of the co-production of H₂ and electricity from coal is addressed in Chiesa et al. (2005a) and Kreutz et al. (2005). Whereas the thermodynamic features of H₂ and electricity co-production from natural gas were investigated essentially through energy and exergy efficiencies assessments, irrespective of economic considerations in Consonni and Viganò (2005). Instead of extensive flowsheet calculations a data normalisation and standardisation method was applied in Damen et al. (2006, 2007) to make a consistent techno-economic comparison of several decarbonisation concepts and CO₂ removal technologies for state-of-the art and advanced coal and natural gas based power and H₂ plants. In Cormos (2010) process integration is applied to maximise the overall plant energy efficiency. These studies address the questions whether the co-production can be beneficial in terms of primary energy consumption and/or

Introduction

CO₂ emissions and whether such practice is subject to technological and/or thermodynamic constraints.

H₂ production. In the field of hydrogen production, the influence of various operating parameters and technologies on the process performance was studied. H₂ process parameters were already optimised in 1983 for different objectives in van Weenen and Tielrooy (1983). H₂ supply evaluation based on the development of cost estimations was the scope of Simbeck and Chang (2002). Techno-economic analyses were conducted in Tarun et al. (2007) for the production of H₂ from natural gas and in Mueller-Langer et al. (2007) for the production of H₂ from fossil and renewable resources. Fossil fuel routes are compared explicitly in Longanbach et al. (2002), while technical and economic prospects of future production of H₂ from biomass were evaluated in Hamelinck and Faaij (2002), Cohce et al. (2010) and Toonssen et al. (2008). The economics of producing H₂ from fossil and renewable resources are compared in detail in Bartels et al. (2010). Environmental impacts were assessed rigorously by a life cycle assessment (LCA) approach in Spath and Mann (2001), Koroneos et al. (2004, 2008) and Dufour et al. (2012) for different H₂ production routes. Particular interest on the thermal efficiency (i.e. reaction characteristics) was paid in Seo et al. (2002), Lutz et al. (2003, 2004) and Chen et al. (2010b) by examining extensively the thermodynamics of reforming and partial oxidation of natural gas to identify favourable operating conditions yielding the lowest energy cost. The thermodynamics of biomass based processes for H₂ production are studied in Cohce et al. (2010). The importance of energy and exergy analyses for the thermodynamic performance and process improvements was revealed in Rosen (1996), Rosen and Scott (1998), where energy analysis indicates that wastes are valuable, while exergy analysis shows that internal consumption must be reduced to increase the efficiency considerably. In Chen et al. (2010a) it is shown how heat recovery for reactants preheating can increase the H₂ yield by 10%. These researches reveal the importance of the analysis of multiple criteria to identify process improvements and optimal process designs.

Systems assessment methodologies

Several comparison, optimisation and selection methods were developed and applied to H₂ and fuel decarbonisation processes for different resources, technologies and operating conditions based on at least one of the following performance indicators; energy efficiency or penalty, economic profit and environmental impact. Most of them applied extensive flow-sheet simulation methods (Tarun et al. (2007), Kvamsdal et al. (2007)) and for multi-objective optimisation non-dominated sorting genetic algorithms (NSGA) (Rajesh et al. (2001), Oh et al. (2001), Oh et al. (2002)) to understand the trade-off, for example between H₂ production and steam exportation. Pilavachi et al. (2009) applied the 'analytic hierarchy process' a structured tool that supports complex decisions by building a hierarchy based on the goal, criteria and decision alternatives. A steady-state off-design calculation method for studying the part load operation flexibility of CO₂ capture cycles was developed in Nord et al. (2009). Rubin et al.

(2007) applied the Integrated Environmental Control Model (IECM) for calculating under several conditions the performance, emissions and costs of fossil fuelled power plants. Only few methods included second law efficiency evaluations. Exergy efficiency was considered in the multi-criteria assessment in Ridolfi et al. (2009). Moreover, only restricted energy integration was performed in these strategies. In Romeo et al. (2008) several possibilities to integrate power plant and amine scrubbing were proposed to reduce the energy requirement, however no systematic energy integration technique was applied. Although, Yuan et al. (2008) developed an integrated system engineering strategy for modelling, integration and optimisation of hydrogen polygeneration plants considering thermal pinch analysis to identify the minimum energy requirement and applying the waste reduction algorithm for environmental performance estimation. These few studies including process integration aspects revealed the potential improvement of H₂ processes by energy recovery.

Conclusions

Multiple research studies have been carried out in the field of fuel decarbonisation by CCS in power and H₂ plants. Nevertheless, some gaps in technology knowledge have to be overcome and some technology developments have to be done (i.e. high-capacity and energy-efficient solvents, H₂ fuelled gas turbine,...) in the future for large scale commercialisation reliably establishing cost and thermo-environmental performance. Technologies for CO₂ capture are relatively well understood today. However, R&D of emerging concepts and enabling CCS technologies has to be pursued with emphasis on costs, fuel availability, primary energy demand and sustainability. To understand entirely the role the different CCS schemes could play in reducing greenhouse gas emissions, a number of issues need to be addressed simultaneously; like the assessment of all resulting emissions, the energy requirement and the costs of implementation. Considering the characteristics of H₂ as an alternative energy carrier, previous studies have shown the importance to address different process configurations with regard to the targeted production scope; either H₂ or electricity or co-production of both. Some performance results reported for different process configurations without and with CO₂ capture are summarised in Tables 2 and 3.

In each of these studies, the level of detail and the data quality alters considerably due to the variety of technologies and operating conditions considered, the assumptions made, the methodologies applied, the thermodynamic properties models and the software tools used. This yields a large range of performance results making a consistent comparison difficult. Thermodynamic, economic and environmental criteria are generally addressed in a non-integrated fashion to define the synthesis, design and operational mode of process systems due to the lack of a unified approach handling different criteria simultaneously. Most economic studies comparing H₂ and/or electricity generation processes using various resources and technologies are mainly based on a literature survey with regard to the production costs and do not include extensive process modelling and optimisation. Whereas, studies focusing on thermodynamic analysis, rarely include economic analysis, energy integration and

Introduction

environmental aspects.

However, to identify process improvements and optimal process designs it is important to make a consistent comparison using the same methodology and uniform assumptions, and to take into consideration multiple criteria simultaneously. In doing so, different process options can be evaluated against each other and ranked for decision-making. When process designs are only evaluated with regard to one criterion, for example maximum energy efficiency, there is a risk to promote expensive and environmentally harmful processes. Consequently, the process competitiveness needs to be rated by multiple criteria. Several methods have recently been developed to support planning and decision-making essentially in the field of H₂ infrastructures design and to estimate the energy and economic consequences taking into account multiple parameters. So far, only reduced multi-criteria assessments and multi-objective optimisations were applied to power plants with CCS in general. Moreover, in the multi-objective optimisations performed in this field, economic, thermodynamic and/or environmental objectives are chosen generally without considering the use of energy integration techniques and without including rigorous life cycle assessment (LCA). Only few evaluations consider

thermodynamic and exergy analyses extensively. In the view of increasing the energy conversion efficiency, process integration maximising the heat recovery and minimising the energy losses is however inevitable. Therefore, the development of a comprehensive comparison framework for fuel decarbonisation processes comparison and optimisation is needed.

Objectives

To overcome the difficulties of comparing processes with regard to multiple criteria and different assumptions, the goal of this thesis is to propose a comprehensive comparison framework for the quantitative and consistent comparison and optimisation of process options. The objective is to use a uniform methodology for the systematic comparison and optimisation of different fuel decarbonisation process configurations. By combining thermo-economic models, energy integration techniques, and economic and environmental performance evaluations simultaneously, the developed platform based on computer-aided tools will support the decision-making process for H₂ and fuel decarbonisation process development, design and operation with regard to several criteria. Special interest is given to the effect of polygeneration of H₂ fuel, captured CO₂, heat and power, in order to identify its advantages and constraints, and to better understand the trade-offs between efficiency, investment and emissions.

The approach has to be systematic and has to provide a fast, comprehensive and optimal reassessment of design options when conditions change. A methodology able to generate optimal process configurations by taking into account the thermodynamic efficiencies based on process integration techniques, the economic performance and the environmental impacts from LCA results will be beneficial from a sustainability and process engineering point of view to identify possibilities to enhance the competitiveness of power plants and H₂ systems with CCS. The usefulness of an optimisation framework including process integration and considering multiple criteria has already been proven in the field of biomass conversion into biofuels (Gassner and Maréchal (2009a), Gerber et al. (2011), Tock et al. (2010)) and in a previous study of the optimisation of a post-combustion process in Bernier et al. (2010).

Based on the development and application of a consistent evaluation and optimisation methodology, this thesis intends to study and understand the competing energetic, economic and environmental costs of carbon capture for greenhouse gas mitigation and sustainable energy supply in actual and future energy systems. It is focused on two types of feedstocks for the generation of H₂ and electricity: namely fossil natural gas and renewable woody biomass. CO₂ transport and sequestration issues are beyond the scope of this thesis and hence not investigated in detail, however it is accounted for CO₂ compression to 110 bar for subsequent transportation. The potential of CO₂ sequestration in Switzerland is investigated in Chevalier et al. (2010) and a cost estimation of CO₂ storage in the EU is made in ZEP (2011). In Norway, Canada and Algeria industrial-scale storage projects are successfully in operation (Metz et al. (2005)).

Introduction

This research aims at answering the following questions: What defines the economic and environmental cost of fuel decarbonisation? What is the influence of the technology choice and the economic scenario? What is the benefit from process integration implementation? What is the effect of the installation size? What causes the trade-off between the objectives and what are the consequences on the decision-making? What are the technological challenges to be addressed in the future? What are the bottlenecks of this technology to penetrate the market?

In order to address these questions the main challenges and objectives of this research are:

- (i) The development of a **systematic framework** for the thermo-economic modelling, analysis and optimisation. By separating the technology models from the analysis models, models developed with different software can be assembled in large superstructures from which process designs can be extracted and optimised systematically with regard to competitive objectives including energetic, economic and environmental considerations.
- (ii) The development of **flowsheets** to simulate accurately the chemical and physical transformations in fuel decarbonisation processes using different resources and technologies. The challenge of the process operation unit model development is to generate a coherent representation of the existing technologies with the appropriate assumptions and at the same time to include sufficient details to be accurate and flexible but avoid complexity. In addition, these models have to reflect the influence of the design parameters on the chemical conversion and on the energy demands.
- (iii) To identify possibilities for process improvements by **energy integration**. By applying pinch analysis, it will be shown how the quality of the process integration influences the competitiveness of the process configurations; i.e. opportunities for maximising the internal heat exchange and optimising the valorisation of excess heat for combined heat and power generation are revealed.
- (iv) To make a **consistent economic evaluation** (i.e. uniform approach and assumptions) taking into account the variability of the market conditions, the resource prices, the operation time and the interest rate. The main challenge of comparing literature data is primarily related to the various assumptions made, especially in the costs assessment, therefore this systematic evaluation step is crucial in the rational process design methodology. With regard to the CO₂ capture competitiveness, the question of the introduction of a carbon tax has to be assessed.
- (v) To perform **life cycle assessment** to assess the advantage of CO₂ capture with regard to the environmental impacts. This will allow to answer the question of how processes using biomass perform compared to processes using natural gas or coal and compared to alternative renewable processes such as solar or hydroelectricity.
- (vi) To carry out **multi-objective optimisation** to identify optimal process configurations and **support decision-making**. Multi-objective optimisation has the advantage to assess

the trade-off between competing objectives with regard to different decision variables including the process configuration and the design parameters (i.e. operating conditions).

- (vii) Evaluate the impact of CO₂ capture on the thermodynamic, economic and environmental performance of H₂ and power generation plants by comparing and optimising different CO₂ capture concepts and technologies. For different feedstocks (i.e. natural gas and biomass) and technologies the optimal process design and performance is determined for different economic scenarios. This allows to answer the question of the potential and **competitiveness of CO₂ capture** in processes producing hydrogen and/or electricity based on fossil or renewable resources. The break even economic conditions (i.e. carbon tax and resource price) making these options competitive in a more sustainable energy future can be identified.

Outline

The methodology developed for the design, optimisation and comparison of fuel decarbonisation processes is described in detail in Chapter 1. Different technologies for CO₂ capture are introduced in Chapter 2 and the respective thermo-economic models are set up. In Chapters 3-6, the presented methodology is applied to study pre- and post-combustion CO₂ capture processes. In Chapter 3, the performance of different pre-combustion CO₂ capture process configurations producing H₂ and/or electricity from biomass or natural gas is assessed and optimised. The detailed comparison of different CO₂ separation technologies applied to pre-combustion CO₂ capture processes in Chapter 4 reveals the importance of process integration. The impact of post-combustion CO₂ capture with chemical absorption with amines and of flue gas recirculation in natural gas combined cycle plants (NGCC) is assessed in Chapter 5. In Chapter 6, the energy and cost penalty of chemical absorption with amines and of chilled ammonia applied to NGCC plants are compared. It is pointed out how process improvements can be identified from the energy integration results. A methodology for developing surrogate models of CO₂ capture technologies predicting accurately the costs and energy demands with a reduced computation time is established in Chapter 7. The optimal process configurations for electricity generation by the different pre- and post-combustion CO₂ capture processes are compared in detail in Chapter 8 with regard to the life cycle environmental impacts and with regard to different economic scenarios. In addition, an approach to support decision-making based on the Pareto results is presented in Chapter 8. Finally, conclusions on the potential of these options in an sustainable energy future and on the R&D challenges of CCS are drawn.

1 Thermo-environomic optimisation methodology

This chapter describes the thermo-environomic (i.e. energetic, economic and environmental) evaluation and optimisation strategy that has been applied throughout the thesis. The basis of the strategy has been published in Tock and Maréchal (2012e).

1.1 Introduction

To design complex integrated energy conversion systems, such as power plants with CCS, taking into account energetic, economic and environmental considerations, a systematic approach is developed. The methodology relies on previous developments presented in Bolliger et al. (2009), Bolliger (2010), Gassner and Maréchal (2009a) and Gerber et al. (2011). Bolliger et al. first presented a generic approach to analyse energy conversion systems by separating the process unit models from the data needed to model the energy and mass integration in the system. Following this approach, models can be assembled in large superstructures from which system configurations can be extracted and optimised systematically with regard to competitive objectives. Dissociating system models from the system design methods is the main advantage compared to other platforms such as DOME (Pahng et al. (1998)) and CAPE-OPEN (Dickinson (2008)) dealing essentially with the flowsheeting and requiring an explicit definition of the interconnections.

The development of this platform is motivated by the need of a flexible tool for the conceptual process design combining thermodynamic analysis, energy integration, performance evaluation and multi-objective optimisation strategies. Such a systematic methodology has previously been applied successfully to study biofuel production systems (Gassner and Maréchal (2009a,b), Tock et al. (2010)) and fuel cell systems (Facchinetti et al. (2011), Maréchal et al. (2005), Autissier et al. (2007)). For H₂ and power generation plants with CCS, such an consistent approach has not been applied yet. This chapter introduces the developed thermo-environomic (i.e. thermodynamic, economic and environmental) evaluation and optimisation strategy for studying CO₂ capture options in H₂ and power generation plants.

1.2 Strategy

The process design methodology combines process modelling, using established flowsheeting tools, and process integration models in a multi-objective optimisation framework following the approach presented in Gassner and Maréchal (2009a). The main features of the methodology are summarised in Figure 1.1. Technology models representing the physical behaviour are separated from the thermo-economic analysis models and the multi-objective optimisation including energy integration, economic evaluation and environmental impact assessment. Through a MATLAB-language based platform (MathWorks Inc.), structured data is transferred between the different models. The advantage of dissociating the technology models from the analysis models is that process unit models developed with different software can be assembled in a superstructure for subsequent large processes design and optimisation.

First a block flow diagram of the studied conversion process is set up and suitable technologies are summarised in a superstructure. For each building block of the process superstructure, chemical and physical models of process units are developed and the heat transfer requirement is defined. The energy-integration model optimises the heat recovery in the system and the combined heat and power production by applying the pinch analysis concept. Knowing the flows and operating conditions in the selected units of the energy system, the size and equipment costs are estimated in order to calculate the economic and environmental performance. The trade-off between competing performance indicators is assessed by sensitivity analysis and multi-objective optimisation defining the optimal values of the decision variables and of the system design. The platform consists hence of different layers: the model, the computation type (i.e. optimisation, sensitivity analysis, one run) and the results extraction.

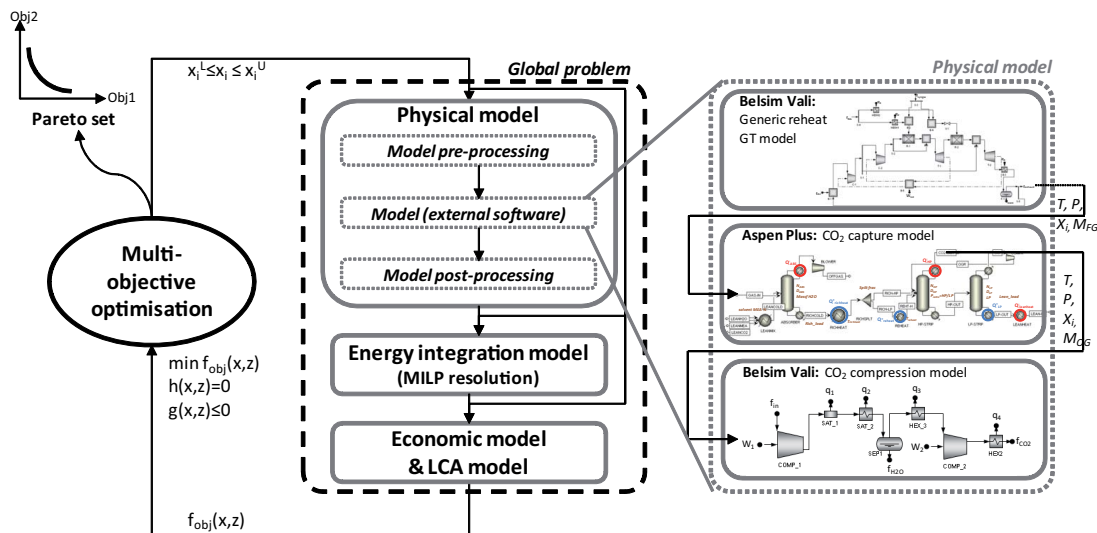

Figure 1.1: Illustration of the developed platform for studying energy conversion systems.

1.3 Thermo-environomic modelling

1.3.1 Process superstructure

For the process design, a block flow diagram of the conversion process to be studied is first set up. Therefore, the available feedstocks and energy resources, the products and by-products specifications, the main process steps and the thermodynamically and technically feasible operating conditions are identified based on a literature survey. For the different process unit operations, such as feed preparation, thermo-chemical conversion/synthesis, gas treatment, and purification, candidate process technologies are assembled in a process superstructure. The superstructure is completed with technology options for the heat recovery and the optimal energy conversion system, such as gas turbines, heat pumps and Rankine cycles. Such a superstructure is illustrated for pre-combustion CO₂ capture processes in Chapter 3 Figure 3.1.

1.3.2 Energy-flow model

Process models are developed within specially tailored modelling languages using numerical solvers to solve the set of equations describing the thermo-physical and chemical conversion operations of the technology for a given set of decision variables and unit model parameters. The variables to be specified are defined by a degree of freedom analysis. Each model follows this calling sequence: pre-processing, simulation, post-processing. The pre-processing phase selects the process model, collects necessary parameters and transfers the decision variables to the model. The simulation phase calculates the process unit using an external flowsheeting software; for example *Belsim Vali* (Belsim S.A.) which is suitable for design as well as for data reconciliation purposes and uses a simultaneous resolution approach, or *Aspen Plus* (AspenTech, Aspen Technology Inc.) using a sequential resolution approach for process simulation. The post-processing phase extracts from the simulation results, the data needed to define the unit interface with the rest of the process. Since each model is organised as an input (decision variables) - output entity, the internal mathematical formulation appears as a black box for the process synthesis model. The asset of defining the models in this way is that process unit models developed with different software can be combined. The communication between different models, the calculation sequence and the process synthesis model set-up is organised in a MATLAB-language code (MathWorks Inc.).

In the physical model, the thermodynamic state of the process unit operations are calculated based on mass and energy balances. Each process unit carries decision variables whose value will be fixed by optimisation. The challenge of the process modelling is to generate a coherent representation of the existing technologies that reflects the influence of the operating conditions accurately. For the developed models, the modelling assumptions and operating ranges are essentially based on literature data, due to lack of experimental data. However, if experimental results are available a systematic parameter validation of the developed models

can be performed, which then could also be used for the design of experiments. The platform extracts the data required for the analysis models, such as the material conversion and the heat and power requirement. The characteristics of the hot and cold streams are required for the energy integration. The flowrates, material, pressure and temperature are needed for the cost estimation and the life cycle inventory.

1.3.3 Energy integration model

Once the chemical and physical transformations and the heat transfer requirements are determined, energy integration can be performed. The energy consumption of the process is minimised by calculating thermodynamically feasible energy targets and achieving them by optimising the heat recovery and the combined heat generation. The systematic combination of the different options for fuel conversion for combined heat and power integration is developed using the superstructure concept and the optimal system configuration is then defined by selecting the most profitable energy conversion system. The problem is solved as a Mixed Integer Linear Programming Problem (MILP) minimising the operating costs, while computing the mass balances and the heat cascade as explained in Maréchal and Kalitventzeff (1998) and Gassner and Maréchal (2009a).

The energy integration model is based on the definition and the identification of the hot and cold streams temperature-enthalpy profiles and their minimum approach temperature ΔT_{min} . By definition a hot stream needs to be cooled down so it is a heat producer; while a cold stream has to be heated up and consequently is a heat consumer. The temperature of each stream is corrected by the minimum approach temperature ΔT_{min} to assure a feasible heat exchange and to account for different values of the heat transfer coefficients. For hot streams the temperature value is reduced by $\Delta T_{min}/2$ and for cold streams increased by $\Delta T_{min}/2$. $\Delta T_{min}/2$ values of 8, 4 and 2 K are assumed for gaseous, liquid and condensing/evaporating streams, respectively. By solving the combined mass and energy integration, the optimal heat recovery is determined and the combined production of fuel, heat and power is computed.

The composite curves are calculated by assembling the hot and cold streams. The hot composite curve characterised by an enthalpy-temperature diagram (i.e. H-T diagram), represents the heat available in the process and the cold composite curve the heat demands of the process. The composite curves are usually reported in corrected temperature axis (i.e. accounting for the ΔT_{min}). The pinch point is the point where the temperature difference between the hot and cold curve is minimal. The maximum heat recovery is determined by considering that heat exchange can only take place, if the temperature difference between the composite curves is superior to ΔT_{min} . Globally, the process requires energy above the pinch point (i.e. heat sink) and releases energy (i.e. heat source) below the pinch point. The graphical analysis of the composite curves and the identification of the pinch point is applied to propose process improvement options, such as polygeneration including steam cycles, combined heat and power, refrigeration and heat pumping.

The heat required by the cold streams is usually supplied by the conversion of primary energy sources, waste streams, or intermediate process streams and by recovering heat from the hot streams in the heat exchangers. The cooling demand is satisfied by conventional cooling by river water, or by refrigeration cycles if the required temperature is below ambient temperature. After heat recovery, the energy balance can show an excess of heat. This excess heat that is released from the process can be valorised by producing high and low level steam that can be used either as heat source for industrial purposes or in steam turbines to generate additional electricity. To satisfy the energy requirements, the following rules have to be respected:

- 1) No cold utility used above the pinch point.
- 2) No hot utility used below the pinch point.
- 3) No exchanger can transfer heat across the pinch point.

The key points here are to define the superstructure including all potential hot and cold utilities, to determine the best utility operating conditions, to choose adequate minimum approach temperatures with regard to the energy-capital trade-off and to minimise the losses by appropriate process integration with respect to the process operation characteristics. In the following chapters, it is shown how the quality of the process integration determines the process performance.

1.3.4 Performance evaluation model

To assess the process performance several indicators are defined in the performance evaluation model. The competitiveness of the process configurations is primarily evaluated by some thermodynamic, economic and environmental indicators. These indicators are differently weighted combinations of the material, energy and monetary process inputs and outputs determined based on the process flowsheet.

- Energy: chemical efficiency, energy efficiency,...
- Economic: investment cost, operating cost, production cost, CO₂ avoidance cost,...
- Environmental: local CO₂ emissions, life cycle impacts,...

To evaluate these performance indicators, the equipment is sized to estimate the respective costs and the environmental impacts are assessed based on a life cycle inventory (LCI).

Equipment sizing and cost estimation

The economic performance is defined on the one hand by the capital investment and on the other hand by the operation and maintenance costs. The major concern is to make a reliable economic evaluation. Ideally, real market prices for commercial equipment or manufacturer's data for emerging technologies have to be used for an accurate analysis. However manufacturers publish only little information and generally precise information is hardly available.

Therefore, the investment costs are evaluated here by using costs correlations. These estimations are based on the size and the type of construction material of each equipment that depend on the process productivity determined by the decision variables and the operating conditions. For the preliminary rating, equipment design heuristics from literature are used to estimate the size at the given production scale. Following the approach outlined in Turton (2009), the equipment costs are then estimated by applying the correlations given in Turton (2009) and Ulrich and Vasudevan (2003) for a multitude of equipment. In literature various approaches are found to estimate costs (Turton (2009), Ulrich and Vasudevan (2003), Chauvel et al. (2001), Mussatti (2002), Klemeš et al. (2007)). The comparison of these estimations, applied for evaluating the costs of CO₂ capture by chemical absorption in Appendix A, reveals the difficulty of precisely estimating the costs with regard to the technology, size and operating conditions. According to Turton (2009) the accuracy of the estimations is about $\pm 30\%$. Since this approach, using the uniform assumptions, is systematically applied for evaluating the different process configurations it allows nevertheless to make a consistent comparison of the options and to rank them. The comparison of the results with other published data (Section 8.4) shows all in all a good agreement. With real market data are available, the comparative study made here could be validated.

Investment cost. The equipment purchase costs are estimated by general correlations, assuming atmospheric pressure and carbon steel construction, given by Eq.1.1 (Turton (2009)).

$$\log C_{pc} = K_1 + K_2 \log A + K_3 (\log A)^2 \quad (1.1)$$

where K_i are constants and A is the characteristic size parameter (i.e. power for compressors, length/diameter for reactors and heat transfer area for heat exchangers).

Based on these correlations the bare module costs C_{BM} , representing the purchase costs adjusted by material (F_M) and pressure (F_P) factors, that take into account the specific process pressures and materials, are defined by Eq.1.2.

$$C_{BM} = (B_1 + B_2 F_M F_P) I \cdot C_{pc} \quad (1.2)$$

where B_i are constants and I is the actualisation factor expressed by the ratio of the Marshall and Swift Equipment Cost Index at actual time to the cost data's reference year.

The total gross roots costs C_{GR} defining the total investment costs (i.e. initial investment cost C_I) for a new production site are calculated from the bare module cost by using further multiplication factors to take into account indirect expenses like labour, transportation, fees, contingencies and auxiliary facilities (Eq.1.3).

$$C_{GR} = C_I = (1 + \alpha_1) \sum_{i=1}^n C_{BM,i} + \alpha_2 \sum_{i=1}^n C_{BM,n,i} \quad (1.3)$$

where $C_{BM,n,i}$ represents the bare module costs of the i^{th} equipment for the base case conditions (i.e. atmospheric pressure and carbon steel material) and $C_{BM,i}$ the costs at the operating conditions. The two factors represent additional costs related to the construction of the plant being dependent (α_1) or independent (α_2) of the process conditions. According to Turton (2009) conventional values for these factors are: $\alpha_1=0.18$ (contingencies 0.15 and fees 0.03) and $\alpha_2=0.35$ (auxiliary facilities, site development and buildings).

Equipment sizing: Reactor. The equipment's size is defined based on the physical quantities computed from the flowsheet models. For example, the size of a reactor is estimated based on an empiric relation (Eq.1.4) between the diameter d , the volumetric flowrate \dot{V} and the mean gas velocity u_{mean} , and an exponential relation (Eq.1.5) between the height h and the volumetric flowrate \dot{V} .

$$d = 2\sqrt{\frac{\dot{V}}{\Pi \cdot u_{mean}}} \quad (1.4)$$

$$h = h_o \dot{V}^b \quad (1.5)$$

For shell and tube reactors with catalysts the sizing and cost estimation method reported in Maréchal et al. (2005) is applied. The costs are mainly defined by the carbon conversion and the flowrate in the reactor. The cost evaluation comprises the catalyst volume and cost estimation, and the reactor volume and cost assessment.

The volume of the catalyst in the reactor k , $V_{catalyst}^k$, corresponds to the volume required to achieve the target conversion of reactant X and is computed from the reaction kinetics $-r_r^k$.

$$V_{catalyst}^k = \frac{n_{r,in}^k}{\rho_B^k} \int_0^X \frac{dX}{-r_r^k} \quad (1.6)$$

where $n_{r,in}^k$ is the molar flow rate of reactant coming out of reactor k [mol/s] and ρ_B^k the bulk density of catalyst used in reactor k [kg/m³].

The catalyst costs are then evaluated from the volume by knowing the volume cost $\pi_{catalyst}^k$:

$$C_{catalyst}^k = V_{catalyst}^k \cdot \pi_{catalyst}^k \quad (1.7)$$

Chapter 1. Thermo-environmental optimisation methodology

The volume of the reactor V_{Rct}^k is estimated from the catalyst volume by introducing a proportionality constant F_V^k .

$$V_{Rct}^k = F_V^k \cdot V_{catalyst}^k \quad (1.8)$$

Finally, the costs of the reactor volume C_{volume}^k is computed by scaling from a reference case with known costs C_{ref}^k and volume V_{ref}^k .

$$C_{volume}^k = C_{ref}^k \cdot F_V^k \cdot \left(\frac{V_{Rct}^k}{V_{ref}^k} \right)^\gamma \quad (1.9)$$

where γ is the scale exponent and F_V^k the proportionality constant taking into account the scaling due to pressure and material factors.

The values for the sizing and costing of the steam methane reformer (SMR) and the water-gas shift (WGS) reactor are summarised in Table 1.1. The appropriate catalyst is chosen in accordance with the process temperature. For the SMR reforming the selected catalyst is Ni/Al₂O₃ and for the water-gas shift reaction at high temperature (HTS) 1%Pd/Al₂O₃ and at low temperature (LTS) 5%Ni/Al₂O₃.

Table 1.1: Assumptions for the sizing of the SMR and WGS reactors (Maréchal et al. (2005)).

Process	SMR	WGS (HTS)	WGS (LTS)
Catalyst	Ni/Al ₂ O ₃	1%Pd/Al ₂ O ₃	5%Ni/Al ₂ O ₃
α	-	0.14	-0.14
β	-	0.38	0.62
k [kmol/kgs]	227.8	1.93	39

Equipment sizing: Columns. According to Turton (2009) and Ulrich and Vasudevan (2003) the costs of distillation columns with tower packings are evaluated as the sum of the cost of the vertical vessels and the packings. Alternative approaches are presented in Appendix A. For packed towers the active tower height (H_a) is defined by Eq.1.10 and the diameter d is calculated (Eq.1.11) based on the gas mass flowrate [kg/s] (\dot{m}_{gas}), gas density [kg/m³] (ρ_{gas}) and the vapour flow velocity [m/s] (u_g) (Ulrich and Vasudevan (2003)). The vapour flow velocity is estimated based on the Souders-Brown relation K_{SB} and the gas and liquid densities

($\rho_l = 1013 \text{ kg/m}^3$ for monoethanolamine (Radgen et al. (2005))) (Eq.1.12).

$$H_a = N_{stages} \cdot HETP \quad (1.10)$$

$$d = 2 \sqrt{\frac{\dot{m}_{gas}}{\rho_{gas} \cdot \Pi \cdot u_g}} \quad (1.11)$$

$$u_g = K_{SB} \sqrt{\frac{\rho_l - \rho_g}{\rho_g}} \quad (1.12)$$

For the columns a maximal diameter of 5m is considered as construction constraint. If the calculated value by Eq.1.11 is higher, several units operating in parallel are considered. To calculate the height equivalent to a theoretical plate HETP the following relations are considered with ϵ being the tray efficiency (considered 90%) (Ulrich and Vasudevan (2003)).

$$HETP = 0.5d^{0.3}/\epsilon \quad d > 1m \quad (1.13)$$

$$HETP = 0.4d/\epsilon \quad d < 1m \quad (1.14)$$

The costs of the vessel and of the packings are defined by correlations taking into account the height, the diameter and the material (here cast steel) and the pressure by the corresponding factors.

Equipment sizing: Heat Exchanger. The capital cost estimation of the heat exchanger network is based on the average surface area and the number of units necessary to satisfy the minimum energy requirements computed by the energy integration. Since this approach does not include the actual heat exchanger network design, the cost estimation is not based on the proper sizing of each equipment and therefore the costs are overestimated because the minimum energy requirement generally results in a greater number of units having smaller surface areas. The disadvantage of this method is, that it does not account for the specific process conditions. However, for heat exchangers operating in the range of 1-50 bar, this influence is negligible. The costs of the heat exchangers are given by the correlation for a fixed tube sheet heat exchanger. The overall costs are assessed by the average value of the costs of a heat exchanger operating at high pressure (construction material nickel alloy) and one at low pressure (construction material carbon steel) multiplied by the minimal number of heat exchangers.

Production costs. The production costs C_P , expressed in $\$/GJ_e$ or $\$/GJ_{H2}$, are evaluated by Eq.1.15 dividing the total annual costs of the system consisting of annual investment ($C_{I,d}$) and operating and maintenance costs (COM) by the annual production of electricity or fuel (P_a). All the costs have been updated to year 2011 by using the Marshall and Swift Index (Table 1.2).

Chapter 1. Thermo-environomic optimisation methodology

The operating and maintenance costs (COM) consist of the costs of raw materials (C_{RM}), utilities (i.e. electricity demand) (C_{UT}), labour (C_{OL}) and maintenance (C_M) calculated based on Eqs.1.16-1.21. By using this method, it is possible to study the balance between the costs arising from the initial investment and the performance of the equipment with regard to the consumption of resources.

$$C_P = C_{I,d} + COM \quad (1.15)$$

$$COM = C_M + C_{OL} + C_{UT} + C_{RM} \quad (1.16)$$

$$C_{I,d} = \frac{i_r \cdot (1 + i_r)^n}{(1 + i_r)^n - 1} \cdot \frac{C_I}{P_a} \quad (1.17)$$

$$C_M = 0.05 \cdot \frac{C_I}{P_a} \quad (1.18)$$

$$C_{OL} = \frac{C_{salaries}}{P_a} \quad (1.19)$$

$$C_{RM} = GJ_{RM,consumed} \cdot c_{RM} \quad (1.20)$$

$$C_{UT} = GJ_{e,consumed} \cdot c_{el} \quad (1.21)$$

The discounted investment costs (i.e. annual investment costs) $C_{I,d}$ take into account the technical and economic lifetime n of the installation and the interest rate i_r . The annual maintenance costs C_M are supposed to amount to 5% of the initial investment. Unitary prices for raw material and electricity are termed c_{RM} and c_{el} respectively. The different assumptions for the economic analyses are reported in Table 1.2.

Table 1.2: Assumptions for the economic analysis.

Parameter	Value
Marshall and Swift index	1473.3
Dollar exchange rate	1.2 \$/€
Expected lifetime	25 years
Interest rate	6%
Yearly operation	7500h/y
Operators ^a	4 ^h p./shift
Operator's salary	91'070 \$ /y
Wood price ($\theta_{wood}=50\%wt$)	13.9 \$ /GJ _{BM}
Electricity price (green)	75 \$ /GJ _e
MEA price	0.970 \$/kg _{MEA}
Natural gas price	9.7 \$/GJ _{NG}

^a Full time operation requires three shifts per day. With a working time of five days per week and 48 weeks per year, one operator per shift corresponds to 4.56 employees.

^b For a plant size of 20 MW_{th,wood}. For other production scales, an exponent of 0.7 with respect to plant capacity is used.

For the processes generating electricity as the main product, the production costs C_P correspond to the electricity production costs known as COE (cost of electricity) and C_{UT} is

considered to be zero (i.e. no electricity purchase). In Chapter 8 it is shown how these economic assumptions influence the competitiveness of the process configurations.

Environmental impacts evaluation

With regard to CO₂ emissions mitigation, an assessment of the overall life cycle environmental impacts from the resource extraction along the production chain to the final product, including off-site emissions and construction emissions, is essential. Life cycle assessment (LCA) has been proven to be suitable for this scope. LCA is a well-established method, standardised in ISO 14040 & 14044 (ISO (2006a,b)), that allows to assess the environmental performance of a product, a system or a service accounting for its full life cycle and related to its function. LCA consists of four main stages; the goal and scope definition, the life cycle inventory (LCI), the impact assessment (LCIA) and the interpretation.

In the goal and scope definition step, the function of the studied system is defined and quantified by the functional unit (FU) and the systems boundaries are defined. Common choices for the functional units are the unitary consumption of the feedstock (e.g 1 MW of natural gas) or the unitary production of the main product (e.g. 1 kg of H₂ or 1 GJ of electricity).

In the life cycle inventory phase (LCI), the extractions, resources and emissions involved in the process are identified and quantified.

In the life cycle impact assessment (LCIA), the cumulated emissions and extraction inventory is then aggregated in more global indicators, having an environmental significance. Typical indicators are the global warming potential, the resources depletion, the acidification and eutrophication potential.

The interpretation phase has as a goal to identify, quantify, check, and evaluate information from the results of the life cycle inventory and/or the life cycle impact assessment in order to support decision-making.

As shown by Gerber (Gerber (2012), Gerber et al. (2011)), life cycle assessment can be included in the thermo-economic models. For this purpose, the LCI is written as a function of the characteristics (i.e. design variables, mass and energy balances, equipment size) of the thermo-economic model. The influence of the process scale is included by scale-up laws similar to the costing. The results from the energy flow and energy integration models are used to perform the LCI of emissions and extraction flows from the process operation and equipment in the considered system boundary illustrated in Figure 1.2. Based on the LCI, a LCIA is performed and the impact categories defining the environmental performance can be included as an objective in the multi-objective environomic optimisation. The choice of the system boundary, the functional unit and the impact method are very important for a consistent comparison and ranking of process options with regard to both environmental and economic performance. More details of this methodology are found in Gerber (2012) with an application to biofuel processes and geothermal systems.

Figure 1.2: Typical system's boundary for the life cycle inventory.

1.4 Multi-objective optimisation

1.4.1 Performance indicators

The performance of different process options is evaluated by thermodynamic, economic and environmental performance indicators defined from the thermo-environomic process model. The energetic performance depends on the one hand on the efficiency of the chemical conversion into fuel defined by the technology choice, the operating conditions, the stoichiometry and the product type, and on the other hand on the quality of the process integration that depends on the energy conversion technologies, the heat recovery and the combined heat and power production. The energetic performance is defined generically based on the schematic process description reported in Figure 1.3 (a).

Figure 1.3: (a) Schematic process description. (b) Avoided CO₂ definition illustration.

The first law energy efficiency ϵ_{tot} calculated by Eq.1.22, takes into account the energy of the products and the resources, and considers thermal and mechanical energy as being equivalent. In order to take into account the difference of the quality of the energy, the natural gas equivalent efficiency ϵ_{eq} is defined by Eq.1.23. In this definition, the consumed electricity is presented by the net electricity output ($\Delta\dot{E}^- = \dot{E}^- - \dot{E}^+$). The net electricity output is substituted by an equivalent amount of natural gas required for generating the same amount of electricity in a combined cycle with an energy efficiency η of 57.3%. The ϵ_{tot} expression is reduced to Eq.1.24 for power plants applications. The reported efficiencies are expressed on

the basis of the lower heating value (Δh^0 , LHV).

$$\epsilon_{tot} = \frac{\Delta h_{H2,out}^0 \cdot \dot{m}_{H2,out} + \dot{E}^-}{\Delta h_{feed,in}^0 \cdot \dot{m}_{feed,in} + \dot{E}^+} \quad (1.22)$$

$$\epsilon_{eq} = \frac{\Delta h_{H2,out}^0 \cdot \dot{m}_{H2,out} + \frac{1}{\eta} \Delta \dot{E}^-}{\Delta h_{feed,in}^0 \cdot \dot{m}_{feed,in}} \quad (1.23)$$

$$\epsilon_{tot} = \frac{\Delta \dot{E}^-}{\Delta h_{feed,in}^0 \cdot \dot{m}_{feed,in}} \quad (1.24)$$

To assess the CO₂ mitigation potential, the CO₂ capture rate is defined in Eq.1.25 by the molar ratio between the CO₂ captured and the carbon entering the system (Figure 1.3 (a)). For electricity import in H₂ production processes, green electricity is considered since the aim is to evaluate the potential CO₂ emissions reduction. Consequently no local carbon emissions have been accounted for electricity importation. The CO₂ capture cost is evaluated by the CO₂ avoidance costs, which are expressed in Eq.1.26 by the difference of the emissions and the difference of the total production cost with regard to a reference plant without CO₂ capture. Figure 1.3 (b) illustrates the definition of the avoided CO₂ emissions. For the reference plant the performance data reported in Table 1.3 are considered in the following chapters. In addition, the life cycle impacts of the whole process chain are considered to evaluate the environmental performance indicators (e.g. global warming potential, resources extraction) as explained in Sections 1.3.4 and 8.2.2.

$$\eta_{CO2} = \frac{\dot{n}_{CO2,captured}}{\dot{n}_{C,in}} \cdot 100 \quad (1.25)$$

$$$/t_{CO2,avoided} = \frac{C_{PCC} - C_{Pref}}{\dot{m}_{CO2,emitted_{ref}} - \dot{m}_{CO2,emitted_{CC}}} \frac{[$/GJ]}{[t_{CO2}/GJ]} \quad (1.26)$$

The economic performance is evaluated by the capital investment and the production costs following the approach described in Section 1.3.4.

Table 1.3: Reference plants performance considered for the CO₂ avoidance costs assessment.

Process	H ₂	NGCC	NGCC
Reference	Metz et al. (2005)	Finkenrath (2011)	this work chap. 5& 6

$C_{P,ref}$	7.8 \$/GJ _{H2}	21 \$/GJ _e	18.3\$/GJ _e

1.4.2 Optimisation problem definition

In order to define optimal conceptual process designs based on the competing performance indicators (objectives), multi-objective optimisation techniques are applied. The major steps to set up the optimisation problem are the decision variables definition, the problem formulation (i.e. objective functions), the problem resolution and the comprehensive analysis. By combining the decision variables of the process operating conditions (i.e. design) with the integer decision variables related to the technology choice (unit existence) and the inter-connections (i.e. process configuration), the problem becomes a mixed integer non-linear programming and differentiable problem that is solved with an evolutionary multi-objective optimisation algorithm described in Molyneaux et al. (2010). The use of an evolutionary algorithm makes the approach less sensitive to non-convergence problems and the proper definition of the decision variables allows to stabilise the robustness of the model. Compared to other algorithms requiring the calculation of derivatives, this kind of evolutionary algorithms based on biological mechanisms, such as crossover and mutation techniques, are more suitable for non-linear, non-continuous optimisation problems. Evolutionary algorithms working with populations instead of a single data point, generate multiple promising solutions in the form of a Pareto optimal frontier. The Pareto optimal configurations correspond to the configurations for which it is not possible to improve one objective without simultaneously downgrading one of the other objectives. During the Pareto frontier generation infeasible solutions are avoided through heuristics embedded in the sizing and cost estimation models. Figure 1.4 illustrates the thermo-environomic optimisation strategy including the data exchange between the thermodynamic and analysis models.

In the multi-objective optimisation procedure the goal is to find the set of optimal solutions $\{\vec{z}_0\}$ in the space of the decision variables that minimises/maximises the objective function $F(\vec{z}, \vec{y})$. The multi-objective optimisation problem is written as follows:

$$\begin{aligned} \min_{\vec{z}} F(\vec{z}, \vec{y}) \text{ subject to:} \\ \vec{h}(\vec{z}, \vec{y}) = 0 \\ \vec{g}(\vec{z}, \vec{y}) \leq 0 \\ \vec{L}(\vec{z}, \vec{y}) = \text{True} \end{aligned}$$

In multi-objective problems $F(\vec{z}, \vec{y})$ has more than one dimension and the optimisation yields a set of solutions $\{\vec{z}_0\}$ reflecting the compromise between the objectives. F is optimised under the constraints of the model equations including the equalities ($\vec{h}(\vec{z}, \vec{y})=0$), the inequalities ($\vec{g}(\vec{z}, \vec{y})\leq 0$) and logical equations ($\vec{L}(\vec{z}, \vec{y})=\text{True}$). For a given value of the decision variables \vec{z} , the dependent variables \vec{y} are computed by solving the model equations.

The objective functions definition is a key point in the competitiveness evaluation. In fact, the choice of the adequate objective function depends on the aspired target, for example; maximal electricity or H₂ production, maximal energy efficiency, maximal CO₂ capture rate/ minimal

CO₂ emissions, lowest investment or production costs. The optimal process configuration will consequently change with regard to the objective. The question of either optimising the global problem or the CO₂ capture subproblem can arise (Chapter 7). The comprehensive analysis of the multi-objective optimisation results helps to identify and understand the trade-off between thermodynamic, economic and environmental considerations. These results can support decision-making by selecting the optimal process configuration from the Pareto-optimal results. Since each solution included in the Pareto frontier is optimal with regard to the chosen objectives, it is not obvious which specific solution has to be selected. The analysis made in Chapter 8 and the proposed approach show how to support decision-making under different economic conditions.

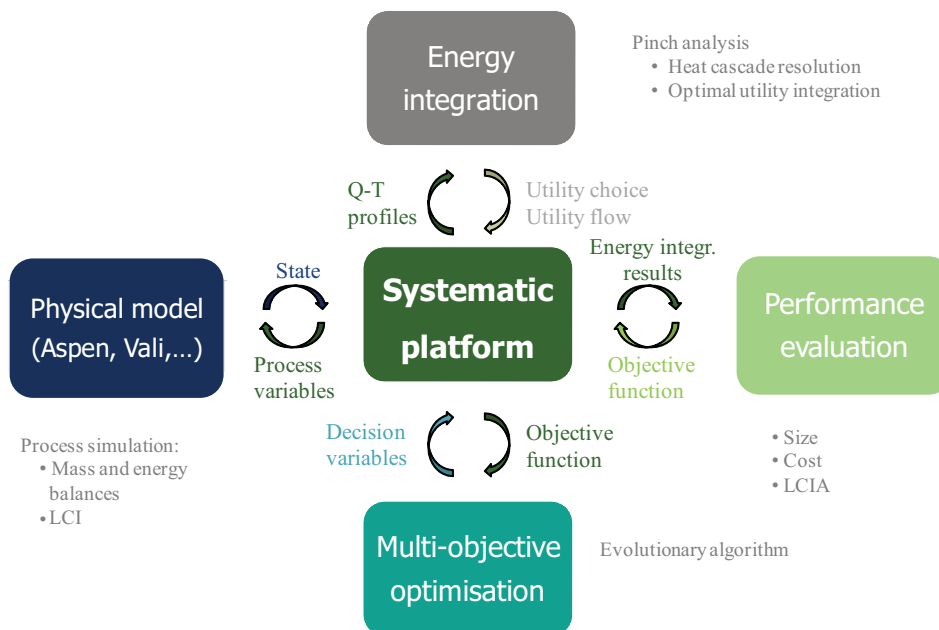

Figure 1.4: Schematic illustration of the thermo-environomic optimisation strategy.

1.5 Conclusions

A MATLAB-language based platform (MathWorks Inc.) for studying, designing and optimising complex integrated energy systems is developed. The main goal is to have a flexible tool for the conceptual process design combining flowsheeting models using commercial packages, energy integration, performance evaluation (i.e. economic and environmental) and multi-objective optimisation strategies. In the proposed approach physical models are separated from the design and integration methods. A key feature is the possibility to connect process unit models developed with different software and to make a consistent comparison on a common basis. The advantage of including the process integration model in the design process is that the influence of the design and operation is reflected on the thermo-environomic performance of an energy balanced system. It turns out that the availability of reliable cost

Chapter 1. Thermo-environomic optimisation methodology

data is a major concern for the economic performance evaluation. The choice of the objective functions for the multi-objective optimisation is of importance in order to assess the trade-off between competing objectives and to support decision-making. The developed platform is applied to study the thermo-economic and environmental impacts of the integration of a CO₂ capture in H₂ and power generation plants in the following chapters.

2 Process models development for CO₂ capture technologies

For CCS the main step is the separation of CO₂ from the flue gas. Different technologies are suitable for this purpose. Here the principles of the different technologies are described and the advantages and disadvantages of each technology are pointed out for H₂ and electricity production applications. Thermodynamic models are developed for the most important candidate technologies. These models have been developed for the studies made in Tock and Maréchal (2012c) and Tock and Maréchal (2012d).

2.1 Introduction

Introducing CCS in power plants leads to an efficiency decrease and cost increase. The performance penalty depends on several factors, primarily related to the applied CO₂ separation technology. The relevant technologies summarised in Figure 2.1 are based on the reviews made in Figueroa et al. (2008), Metz et al. (2005), Radgen et al. (2005), Yang et al. (2008), Olajire (2010) and MacDowell et al. (2010). In the following sections the different technologies are described and the developed thermodynamic models are presented.

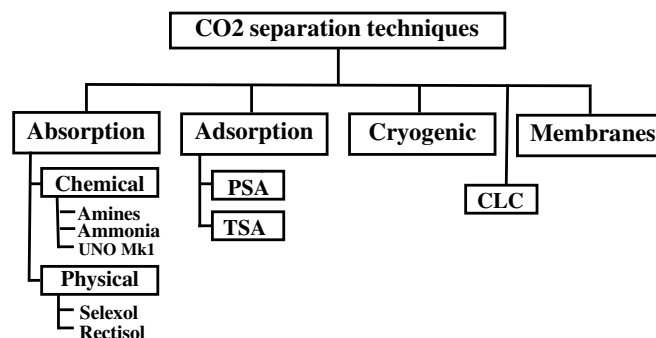

Figure 2.1: CO₂ separation technologies.

2.2 CO₂ separation technologies

2.2.1 Principles

CO₂ can be separated from the flue gas by gas separation techniques that are based on the differences in volatilities, dissolution, diffusion and permeation. General information about gas separation principles are given in Bart and von Gemmingen (2005), Hiller et al. (2006) and Schlauer (2008).

2.2.2 Technologies description

Chemical absorption

Chemical absorption is a gas-liquid contacting and separating equipment using aqueous solutions for scrubbing acidic gases like CO₂ from the flue gas. This process schematically presented in Figure 2.2 typically comprises two operations; absorption and desorption (i.e. solvent regeneration). The flue gas raises in the absorber column, while the chemical solvent trickles down in counter-current and acts as a weak base, neutralising the acidic compounds to turn the molecules into ions (i.e. CO₂ into HCO₃⁻) and dissolving them in the gas-scrubbing solution. The solvent entering the column at the top is referred as 'lean', since it contains none or little of the component to be absorbed. The column includes horizontal trays or packing material to ensure sufficient mixing and contacting. After the extraction of the CO₂ from the gas stream, the saturated 'rich' solution leaving the bottom of the column is heated and passes a regeneration column with a condenser at the top and a reboiler at the bottom. The reboiler heats the liquid stream to up to 150°C (Radgen et al. (2005)) in order to break the chemical bounds and release the pure acid gas from the solvent. The lean aqueous solution is recovered and reused in the absorber. The heat requirement consists of the sensible heat, the heat of vaporisation and the heat of reaction. The key energy penalty of the chemical absorption process arises from the solvent regeneration (approximately 3-5GJ/t_{CO2} at 150°C), the compression of the flue gas and the pumping of the solvent through the removal plant (0.5-1.5GJ/t_{CO2}) (Radgen et al. (2005)).

The process is suited for gas streams with low partial pressure of CO₂. However, high solvent flowrates are required to achieve high CO₂ capture rates. The main advantage is the high capture efficiency and selectivity, while the main disadvantage is the high energy requirement. The solvent determines the thermodynamic and kinetic limits of the process. The choice of the solvent depends on many different factors such as the flue gas composition, the required CO₂ recovery and purity, the solvent regeneration, the sensitivity to impurities, and the capital and operation costs. Amine solvents are preferably used. Recent researches focus on the development of new advanced CO₂ absorption solutions like blends and sterically hindered amines. Alternatively, the use of ionic liquids (i.e. liquids composed entirely of ions with a melting point below 100°C) is studied in Wappel et al. (2010) and Heldebrant et al. (2009) and possible energy savings between 12 and 16% are predicted for 60 %wt ionic liquid solutions.

The ideal chemical solvent should have the following characteristics; high reactivity with respect to CO₂, low heat of reaction with CO₂, high absorption capacity, high stability (i.e. low thermal and chemical degradation), low environmental impact and low costs.

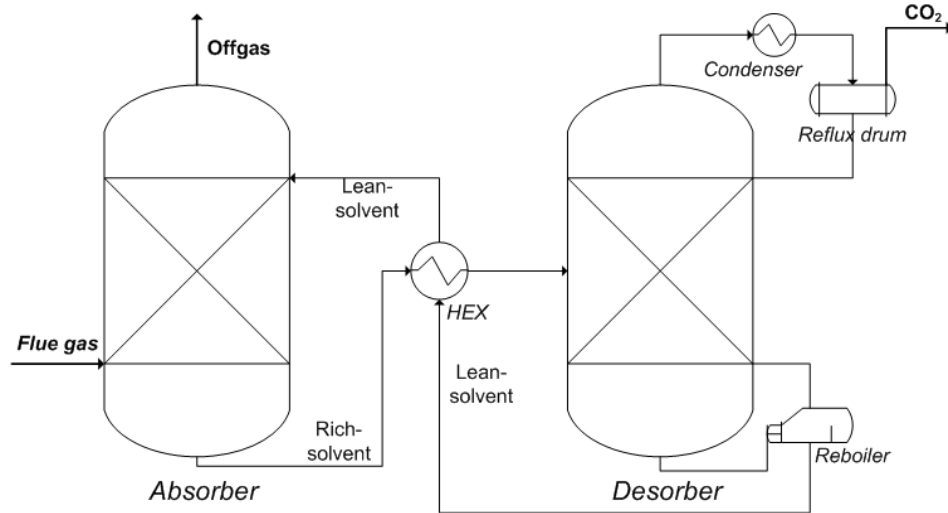

Figure 2.2: Schematic flowsheet of the chemical absorption process (omitting pressure change devices).

Chemical absorption with amines is a mature commercialised technology used over many decades in natural gas industry. Aqueous solutions of ethanolamines like mono- (MEA), di- (DEA) and triethanolamines (TEA) are commonly used to remove CO₂ from flue gases. The acid-base neutralisation reaction is given by Eq.2.1 where R is any alkanol group. The absorber typically operates between 40 and 60°C (Metz et al. (2005)). The temperature for the amine regeneration is around 100-140°C (1.5-2 bar) and the heat requirement depending on the purity constraints, is in the range of 1.5-3.4GJ/t_{CO₂} (Metz et al. (2005)). Typical values for the electricity requirement are 0.06-0.11 GJ_e/t_{CO₂} for post-combustion CO₂ capture in coal-fired power plants and 0.21-0.33 GJ_e/t_{CO₂} for post-combustion CO₂ capture in natural gas fired combined cycles (Metz et al. (2005)).

The major drawbacks of the MEA process in power plants applications are the low CO₂ loading capacity, the equipment corrosion, the thermal and oxidative degradation of amines by SO₂, NO₂ and oxygen (Gouedard et al. (2012)), and the large energy requirement for the solvent regeneration. Reported amine solvent makeup due to degradation losses is around 0.5-3.1kg_{MEA}/t_{CO₂} (Rao and Rubin (2002)). Given the relative low degradation temperatures of amines the solvent regeneration operates at low pressure compared to the one required for CO₂ transport and storage. Consequently, considerable energy and costs penalties are

induced by CO₂ compression to 110 bar. The electricity consumption for the CO₂ compression from 1 to 100 bar is in the order of 0.4GJ_e/t_{CO2} (Metz et al. (2005)). This leads to an electrical production efficiency decrease of about 2%-points in an NGCC plant.

Chemical absorption with chilled ammonia. As a possible alternative to amine solvents, ammonia is identified, since it satisfies some of the ideal solvent characteristics such as energy efficient CO₂ capture, i.e. high CO₂ absorption capacity and low regeneration energy, stable (no degradation) and globally available low-cost reagent. The chilled ammonia process (CAP) patented by Gal (2006) is developed by *Alstom Power* for CO₂ capture in power plants and tested at the AEP Mountaineer plant. In this process the absorption operates at low temperature 0-20°C. The operation at low temperature has the advantage of decreasing the NH₃ slip in the absorber and the flue gas volume. The cooled flue gas is contacted in the absorber with the lean solvent composed of 28%wt NH₃ and having a CO₂ loading (CO₂/NH₃ molar ratio) of 0.25-0.67 and preferably in the range of 0.33-0.67. A high loading increases the vapour pressure of CO₂ and decreases the capture efficiency, while a low loading increases the vapour pressure of NH₃ leading to NH₃ losses by evaporation. In these operating ranges the solubility limits may be reached and solid particles such as ammonium bicarbonate (NH₄HCO₃) precipitate. Hence the CO₂ rich stream is a slurry that has a CO₂ loading of 0.5-1 (preferably 0.67-1). The CO₂ rich stream is pressurised and heated up before entering the desorber. In the stripper operating at 50-200°C (preferably 100-150°C) and 2-137 bar, the CO₂ is evaporated from the solution. The high purity CO₂ is released and the lean solution is recycled back to the absorber. The desorption operation at high pressure has the advantage that the released CO₂ has to be compressed less for CO₂ transport and storage. In addition, the vapourisation of water and ammonia is limited at these conditions and hence the energy consumption is reduced. According to Jilvero et al. (2012) the heat requirement for the regeneration of aqueous ammonia is around 2.5GJ/t_{CO2}. Compared to MEA processes the heat of reaction is similar, however the lower water evaporation during the pressurised regeneration with ammonia results in a lower energy requirement and makes absorption of CO₂ by ammonia beneficial.

Physical absorption

In physical absorption, the acidic gas is physically bound to the organic solvent (rather than reacting chemically) by absorption at high pressure and low temperature and the solvent is regenerated by heating or release of pressure. The regeneration is often performed in multiple flash drums. The physical absorption of CO₂ is driven by the solubility of CO₂ within the solvent and hence depends on the partial pressure and temperature. Consequently, it is applicable to gas streams which have high CO₂ partial pressure (>15%vol) since the solubility of CO₂ in physical solvents increases linearly with its partial pressure. The interaction between the CO₂ and the absorbent is weak compared to chemical absorption, which leads to a lower energy requirement for the solvent regeneration. The main energy requirement is related to

the flue gas pressurisation. Commercial applications of this process are the removal of CO₂ and H₂S in natural gas processing and the removal of CO₂ from syngas in hydrogen, ammonia and methanol production. Common commercially available solvents are Rectisol (based on methanol developed by Lurgi and Linde), Selexol (DEPG: polyethylene glycol dimethyl ether manufactured by Union Carbide and Dow) and Purisol (NMP: N-methyl-2-Pyrrolidone licensed by Lurgi AG). Different solvents and the corresponding gas solubility are compared in Burr and Lyddon (2008).

In the Selexol process the absorption operates at low temperature 0-40°C (20-30 bar). Selexol has a high viscosity (0.0058 Pa·s (Burr and Lyddon (2008))) which reduces mass transfer rates and tray efficiency and increases packing or tray requirement. The Selexol solvent has the advantage of having chemical and thermal stability and being non-corrosive and inherently non-foaming.

In the Rectisol process, chilled methanol is used as a solvent and the absorption normally operates at -60 to -30°C (>20 bar) because of the high vapour pressure of methanol (boiling point 65°C). The rich solvent is regenerated by flashing at low pressure, consequently there is no reboiling heat requirement. The methanol solvent has the advantage of having a high thermal and chemical stability and being non-corrosive. The main disadvantage is that the solvent needs to be cooled down which results in high capital and operating costs for the refrigeration. However, this can be balanced by a lower solvent flowrate for CO₂ separation compared to other solvents. The Rectisol process layout is flexible and many different flow schemes can be applied. Water washing of effluent flows is often introduced to recover methanol.

Physical adsorption

Adsorption is a physical process based on the attachment of a gas or liquid to a solid surface. The attachment can be either physical (physisorption) or chemical (chemisorption). Fundamentals about adsorption processes are reported in Bart and von Gemmingen (2005). The basic steps of this cyclic process are an adsorption step in which the more adsorbable species is selectively removed from the feed gas and a regeneration (desorption) step where these species are removed from the adsorbent which is then reused for the next cycle. The process is enhanced by high pressure and low temperature, accordingly adsorption and regeneration are achieved through pressure (pressure swing adsorption PSA) or temperature (temperature swing adsorption TSA) cycles. The solvent choice depends on the adsorption capacity, as well as on the relative diffusion velocities of the species. Potential adsorbents for CO₂ capture are activated carbon, zeolites, alumina and metallic oxides.

Pressure swing adsorption (PSA) is described in detail in Barg et al. (2000), Malek and Farooq (1998), Ritter and Ebner (2007) and Sircar and Golden (2000). PSA is based on the use of anhydrous organic solvents such as activated carbon and zeolites which dissolve the acids and can be stripped by reducing the acid-gas partial pressure without the application of heat. The

separation principle is that adsorbent beds adsorb more impurities at high gas-phase partial pressure than at low partial pressure (Longanbach et al. (2002)). For H₂ purification, the gas stream passes through adsorption beds at 15-28 bar, and the impurities are purged from the beds at around 0.2 bar to obtain a high recovery of H₂. The minimum pressure ratio between the feed and purge gas of the PSA unit is about 4:1. The PSA process operates on a cyclic basis. The adsorption temperature influences also the efficiency. In fact, fewer impurities are adsorbed at higher temperatures because the equilibrium capacity of the molecular sieves decreases with increasing temperature. With PSA H₂ purities of over 99%mol can be reached. Regarding PSA applications for pre-combustion CO₂ capture extensive experimental and modelling research is done by Schell et al. (2012) and Casas et al. (2012). The main challenge of current adsorption systems for large-scale power plants applications is the low absorption capacity and low selectivity of the available adsorbents at low to moderate CO₂ concentration.

Membrane technology

A relative novel capture concept is the use of selective membranes to separate one component from a gas stream. This could be applied in post-combustion systems to remove CO₂ from the flue gas, in pre-combustion systems to remove CO₂ from hydrogen and in oxy-fuel combustion systems to remove O₂ from N₂. These technologies are described in detail in Brunetti et al. (2010), Bredesen et al. (2004), Ockwig and Nenoff (2007), Adhikari and Fernando (2006) and Stolten (2010).

For membrane separation there are different mechanisms that can operate; Knudsen diffusion, molecular sieving, solution-diffusion separation, surface diffusion and ionic transport. Different types of materials find applications in gas purification. The membranes are either organic (i.e. polymeric) or inorganic (i.e. carbon, zeolite, ceramic or metallic) and can be porous or non-porous. The membrane performance is defined by the permeability and the selectivity. The membrane acts as a filter separating one or more gases from a gas mixture based on selective permeation. The partial pressure difference between the feed and the permeate is the driving force for membrane separation, therefore high-pressure streams are preferred. Consequently, the selectivity for CO₂ capture is low and thus only a small fraction is captured and the purity is low (Yang et al. (2008)). To increase the CO₂ capture, multi-stage membrane separation has to be included which adds additional energy demand and cost. Moreover, membranes are sensitive to sulphur compounds.

Cryogenic distillation

The separation by cryogenic distillation is a low temperature separation process based on the boiling temperature difference of the compounds of the gas mixture. Cryogenic separation is not applicable for atmospheric pressure exhaust gases containing a low amount of CO₂ because it requires too much energy for refrigeration and is too expensive. However, for high pressure, high CO₂ content gas mixtures it is possible to liquefy it by cooling without requiring

2.3. CO₂ capture process modelling

too much energy. Cryogenic distillation is a commercial process used for air separation and for liquefying and purifying high purity CO₂ (>90%mol). Consequently, this process is well suited for oxy-fuel processes. This process has the advantage that the pure CO₂ is recovered in liquid form and can be transported easily. Applied to hydrogen separation, it yields hydrogen with moderate purity <95%mol.

Performance comparison

Key features and operating conditions of CO₂ capture technologies are summarised in Table 2.1.

Table 2.1: Comparison of the physical and chemical ab- and adsorption processes for CO₂ separation (Göttlicher (1999)).

Process	Conditions	Gas removed	Thermal energy [kWh/kg _{CO2}]	Mechanical work [kWh/kg _{CO2}]	CO ₂ purity [%mol]
Rectisol	$T_{abs} \approx -10/ -70^{\circ}C$ $p_{CO2} > 10$ bar	CO ₂ , NH ₃ H ₂ S, COS, HCN	0.025	0.038	<90%
Selexol	$p_{CO2} \approx 7-30$ bar	CO ₂ , NH ₃ H ₂ S, COS, HCN	0.016-0.024	0.03-0.06	
MEA	$T_{abs} \approx 40^{\circ}C$, 1-5 bar $T_{desorb} = 95 - 120^{\circ}C$	CO ₂ , CS ₂ H ₂ S, SO ₂ , COS	2.3 ($\approx 0.48kWh_e/kg_{CO2}$)	0.05-0.3	< 99%
PSA-Flue gas 28-34% CO ₂	$P_{ads}=1$ bar $P_{desorb}=0.05-0.9$ bar	CO ₂	0.16-0.18		
PSA - syngas	$P_{ads}=13-21$ bar $P_{desorb}<1$ bar	CO ₂	-	-	>90%

2.3 CO₂ capture process modelling

For the different CO₂ capture technologies discussed previously, thermodynamic models are developed here to be used in the subsequent pre- and post-combustion CO₂ capture processes optimisation.

2.3.1 Chemical absorption

Amines: MEA

The flowsheet of the CO₂ capture process by chemical absorption with MEA illustrated in Figure 2.3 is based on the one developed by Bernier et al. (2010).

The model developed in Aspen Plus (AspenTech) is adapted from the default rate-based model available from *AspenTech*. In the thermodynamic model, the electrolyte NRTL method is used for the liquid phase and the Redlich-Kwong method for the vapour phase. The electrolyte solution chemistry is defined by the equations Eqs.2.2-2.9.

Figure 2.3: Process model of the CO₂ capture by chemical absorption with amines. Decision variables reported in Table 2.2 and heat exchanges (i.e. hot stream: red, cold stream: blue) are depicted.

The absorber and desorber are modelled by a rate based RadFrac column including reaction kinetics. The considered reactions include the reaction between MEA and CO₂ given by Eq.2.9. The CO₂ capture rate is defined by the columns design (i.e. number of stages, diameter, etc.) and the operating conditions. CO₂ compression to 110 bar for subsequent CO₂ transport and storage is modelled separately in *Belsim Vali* (Belsim S.A.) by a two stage compressor with intercooling. Table 2.2 summarises the decision variables and the corresponding variation range for optimisation.

2.3. CO₂ capture process modelling

Table 2.2: Decision variables and feasible range for optimisation for the chemical absorption process using an aqueous MEA solution.

Operating parameter	Value	Range
Lean solvent CO ₂ loading [kmol/kmol]	0.2	[0.18-0.25]
Rich solvent CO ₂ loading [kmol/kmol]	0.48	[0.4-0.5]
Split fraction [-]	0.5	[0-0.7]
Rich solvent pre-heat T [^o C]	105	[95-105]
Rich solvent re-heat T [^o C]	125	[115-125]
LP stripper pressure [bar]	1.98	[1.7-2.1]
HP / LP pressure ratio [-]	1.5	[1-1.5]
Nb stages absorber	15	[10-17]
Nb stages HP stripper	11	[8-15]
Nb stages LP stripper	8	[6-10]
Absorber diameter [m]	8	[6-12]
HP stripper diameter [m]	6	[3-6]
LP stripper diameter [m]	3	[2-5]
MEA concentration in solvent [- wt]	0.35	[0.3-0.35]
Absorber steam out [kg _{H2O} /t _{FG}]	307	[306-309.5]

Amines: TEA

The model for the chemical absorption with TEA is similar to the one presented for MEA and is illustrated by Appendix Figure B.1. While MEA is suited for capturing CO₂ from flue gas, TEA is more appropriate to separate CO₂ from a H₂-rich fuel. The model is adapted from the default rate-based model available from *AspenTech*. The absorber is modelled by an equilibrium RadFrac column and the desorber by a single stage flash unit. The lean solvent recycling is not modelled explicitly, but by imposing design specifications it is ensured that the streams are identical after solvent make-up. The main decision variables are summarised in Table 2.3. The CO₂ capture rate is defined by the flowrate of the lean solvent and the columns design.

Table 2.3: Decision variables and feasible range for optimisation for the chemical absorption process using an aqueous TEA solution.

Operating parameter	Value	Range
TEA concentration [%wt]	35	[25-40]
H ₂ /TEA ratio [kg/kg]	0.049	[0.035-0.055]
Absorber T [^o C]	40	[20-45]
Absorber P [bar]	28.8	[15-30]
Nb stages absorber	25	-
Absorber packing	Pall ring & Ralu-ring (rasching)

Regeneration T [^o C]	67	[25-120]
CO ₂ compression [bar]	110	-

Chilled ammonia

Process models of chilled ammonia systems have recently been developed in a few research studies (Mathias et al. (2010), Darde et al. (2010, 2012), Valenti et al. (2009), Jilvero et al. (2011), Dave et al. (2009)). The vapour-liquid equilibrium of the CO₂-NH₃-H₂O system was extensively studied in Göppert and Maurer (1988) and Kurz et al. (1995) based on experimental data and a thermodynamic model was proposed by Thomsen and Rasmussen (1999).

The thermodynamics of the CO₂-NH₃-H₂O system is complex since it is a vapour-liquid-solid system with electrolytes present in the liquid state. The electrolyte NRTL model available in *Aspen Plus* (AspenTech) is used to model this system based on the data published by Pinsent et al. (1956), Göppert and Maurer (1988) and Kurz et al. (1995). This model represents adequately the vapour-liquid equilibrium and the precipitation of solids (i.e. ammonium bicarbonate NH₄HCO₃) based on the chemistry model given by Eqs.2.10-2.15, including auto-pyrolysis of water, dissociation of ammonia and carbon dioxide, and formation of carbonate.

The developed flowsheet for the chilled ammonia process, illustrated in Appendix Figure B.2, includes the following steps: CO₂ absorption, NH₃ stripping from vent gas, CO₂ desorption and solvent regeneration, and CO₂ compression. The absorber and the desorber are modelled by a single flash stage assuming physical and chemical equilibrium. The main design specifications and decision variables are given in Table 2.4. In the absorber the CO₂ capture rate is defined by the lean solvent flowrate. The NH₃ concentration in the aqueous solution (without CO₂) and the CO₂ loading of the lean solution (i.e. CO₂/NH₃ molar ratio) highly influence the separation performance. Since the NH₃ slip from the absorber is in the range of 500-3000ppm_v, which is much too high for gases vented to the atmosphere, a water wash column is introduced in order to reduce the level to 10ppm_v. The vent gas is heated up to around 45°C in order to satisfy flume conditions before being released to the atmosphere. The rich solvent passes a pump and an heat exchanger before entering the regeneration column. The temperature of the heat exchanger is defined such that all the ammonium bicarbonate is dissolved before entering the flash column in order to have no fouling issues. The reboiler temperature is defined such that the required CO₂ regeneration is achieved. The recycling of the solvent is defined by a design specification assuring that the input lean solvent equals the output lean solvent after the addition of the stripped NH₃ after the water wash of the vent gas and of fresh NH₃. The cooling down below atmosphere to the absorber temperature is modelled in the

energy integration by a refrigeration cycle.

Table 2.4: Decision variables and feasible range for optimisation for the chilled ammonia process.

Operating parameter	Value	Range
NH ₃ concentration [%wt]	28	-
CO ₂ capture rate [%]	90	[85-95]
Lean CO ₂ loading [kmol/kmol]	0.4	[0.33-0.67]
Absorber T [^o C]	5	[0-10]
Absorber P [bar]	1	-
Regeneration P [bar]	30	[2-136]
CO ₂ compression [bar]	110	-

2.3.2 Physical absorption

Compared to chemical absorption the thermodynamic modelling of the physical absorption is less complex since no ions are involved and no chemical reactions take place in the absorber/desorber. The model is adapted from the default models for physical solvents available from *AspenTech*. To model the thermo-physical properties the PC-SAFT equation of state model for vapour pressure, liquid density, heat capacity and phase equilibrium is used. The absorber is modelled as a RadFrac column and the desorber as a single stage flash unit. Again the solvent recirculation is defined by a design specification and is not modelled explicitly. The CO₂ capture rate is defined by the flowrate of the lean solvent and the columns design. The flowsheet of the Rectisol and Selexol processes are illustrated in Appendix Figures B.4 & B.3. The main design specifications and decision variables of the physical absorption process are given in Table 2.5 for the Rectisol solvent and in Table 2.6 for the Selexol solvent.

Table 2.5: Decision variables and feasible range for optimisation for the physical absorption process using the Rectisol solvent.

Operating parameter	Value	Range
MeOH/CO ₂ ratio [kmol/kmol]	13.6	[10-15]
Absorber T [^o C]	-37	[-70-0]
Absorber P [bar]	27.5	[15-60]
Absorber packing	Ceramix intalox saddles

Absorber packing	Pall ring	
Regeneration P [bar]	1.2	[1-10]
Regeneration T [^o C]	31	[25-100]
CO ₂ compression [bar]	110	-

2.3.3 Pressure swing adsorption

For the pressure swing adsorption model, the approach outlined in Gassner and Maréchal (2009b) is adapted for the H₂/CO₂ separation based on data from Jee et al. (2001). The purity and the amount of H₂, and the CO₂ recovered in the respective outlet streams is defined by the PSA cycle design, namely the durations of the adsorption, recycling and purging periods. Depending if the objective is to generate highly pure H₂ or highly pure CO₂, the PSA setup has to be modified. To define the relative durations of these periods the parameters t_{r1} and t_{r2} are introduced. The time-averaged flow of species i that leaves the adsorber system ($\dot{m}_{i,out}$) or is recycled to its inlet ($\dot{m}_{i,rec}$) is determined by the equations Eqs.2.16-2.18 based on a regression $f(i, tr)$ on data from Jee et al. (2001):

$$\dot{m}_{i,out} = f(i, t_{r1}) \dot{m}_{i,in} \quad (2.16)$$

$$\dot{m}_{i,rec} = f(i, t'_{r2}) \dot{m}_{i,in} - \dot{m}_{i,out} \quad (2.17)$$

$$t'_{r2} = (1 - t_{r1}) t_{r2} + t_{r1} \quad (2.18)$$

2.3.4 Membrane processes

The membrane process has been modelled in a preliminary study as two subsequent membranes following the approach of Gassner et al. (2009) with the data of Franz and Scherer (2010) for a CO₂ selective Pebax membrane. The decision variables are the pressure and the stage cuts. The results yield low H₂ process efficiencies due to the low H₂ purity that has been achieved with this membrane design. This process has to be further optimised following the design approaches reported in Gassner et al. (2009) and Pathare and Agrawal (2010). Due to time constraints this future technology for CO₂ capture was not addressed further in this thesis. However, regarding the advances in membrane research and the relative low energy penalty of this technology it might become a competitive options which has to be investigated in more detail.

2.4 Conclusions

Based on a technology review, the most important candidate technologies for CO₂ separation from other gases are identified and thermo-economic models are developed for the different options. With regard to H₂ and power production applications the choice of one specific technology depends on the gas composition, the required CO₂ recovery and purity, the energy requirement and the capital and operation costs. The energy penalty of the CO₂ capture is a key concern for the competitiveness and deployment of CCS. In addition, the energy requirement for CO₂ compression for transportation and storage is not negligible with 0.4 GJ_e/t_{CO2} for the compression from 1 to 110 bar. In fact, in power plants CO₂ capture and compression leads to a reduction of the electrical production efficiency up to 10%-points, whereof 2%-points are on account of CO₂ compression.

The different CO₂ capture process models are applied in the following chapters to evaluate, compare and optimise pre- and post-combustion CO₂ capture processes. Based on the simulation models, the hot and the cold streams are computed for subsequent process integration and the equipment sizes are calculated for the cost estimation as explained in Section 1.3.4. The advantage of this modelling approach is that the impact of the operating conditions on the process integration and on the investment cost is taken into account. Consequently, the models are well adapted for thermo-economic optimisations.

3 Thermo-economic analysis of pre-combustion CO₂ capture processes

In this chapter the thermo-environmental modelling of processes generating H₂ and/or electricity with CO₂ capture are presented. Different process options using natural gas or biomass as a resource are analysed, compared and optimised as in the published versions (Tock and Maréchal (2012a,b)).

3.1 Introduction

Several research studies have already identified promising fuel decarbonisation processes for H₂ production and/or electricity generation using different resources. Reported efficiencies range from 69 to 80% for fossil fuel H₂ production (Longanbach et al. (2002), Damen et al. (2006), Consonni and Viganò (2005)) and from 51 to 60% for biomass fed H₂ processes (Hamelinck and Faaij (2002), Toonssen et al. (2008)) (Table 3). Whereas for pre-combustion CO₂ capture in natural gas combined power plants, efficiencies of 42-48% are reported and of 33% for integrated biomass gasification combined cycle plants (Table 2). CO₂ capture reduces the efficiency of power plants by around 10%-points and increases the production costs by 30% due to the energy consumption for CO₂ capture and compression. This yields CO₂ avoidance costs in the range of 13-75\$/t_{CO₂,avoided} according to Metz et al. (2005). In each study, different assumptions are made and different technologies are considered. This adds up in a large range of performance results making a consistent comparison difficult. Therefore, the objective is to apply the developed systematic methodology to compare and optimise pre-combustion fuel decarbonisation process configurations for H₂ and electricity generation with regard to energy, economic and environmental considerations. Special interest is given to the effect of polygeneration of H₂-fuel, captured CO₂, heat and power, in order to identify its advantages and constraints, and to better understand trade-offs between efficiency, costs and emissions.

3.2 Pre-combustion CO₂ capture processes description

3.2.1 Pre-combustion CO₂ capture process layout

The general superstructure presented in Figure 3.1 summarises the different technological options that are considered for pre-combustion CO₂ capture process designs. The main process steps are resource extraction and treatment, syngas (i.e. H₂ and CO) generation by natural gas (NG) reforming or biomass (BM) (i.e. wood) gasification, gas cleaning and treatment, H₂ purification and/or H₂ burning for electricity generation. In both natural gas and biomass based H₂ pathways, a CO₂ removal step is included during the H₂ purification which allows for CO₂ capture (CC) and further sequestration for greenhouse gas mitigation. The energy demand of the process can be satisfied by importing electricity or by burning part of the H₂-fuel in a gas turbine (GT) to close the balance. Alternatively, the H₂-fuel could be used for fuel cell applications. Consequently, depending on the production purpose, the process produces either H₂ with and without captured CO₂, imports electricity or is self-sufficient in terms of power, or exports electricity if all the H₂-fuel is burnt. When CO₂ is captured, CO₂ pressurisation to 110 bar is taken into account to satisfy the conditions for transport and sequestration.

Figure 3.1: Process superstructure of the pre-combustion CO₂ capture process options.

3.2.2 Pre-combustion CO₂ capture process technologies

The main feature of pre-combustion CO₂ capture processes is the generation of an intermediate fuel mixture of H₂ and CO (syngas) from which H₂ and CO₂ can be separated after gas treatment and purification. Syngas can be produced from nearly any carbon containing fuel ranging from natural gas, coal and oil products to biomass. If the feed has a high sulphur content, a desulphurisation step is required to prevent catalyst poisoning. The main technologies and chemical reactions are discussed in the following sections.

Natural gas reforming

Presently, natural gas is the dominant feedstock to produce H₂. The most common method to produce syngas from natural gas is steam methane reforming (SMR) expressed by Eq.3.1. SMR is an endothermic process that takes place in the presence of a Ni-catalyst and is favoured at low pressure, high temperature and low steam-to-carbon ratio. Typical operating pressures are 10-40 bar since pressurisation yields an economic advantage due to the smaller equipment size. Common operating temperatures are 830-1000°C and steam to carbon ratios of 2-6 to prevent coking (Spath and Dayton (2003), Stolten (2010)). In the reformer, the water-gas shift reaction Eq.3.4 occurs simultaneously which leads to the overall equation described by Eq.3.2. The reforming reaction yields a H₂/CO ratio close to 3. This ratio can however be varied over a large range, since the reforming reaction is coupled to the shift reaction. The reactor is a tubular reformer composed of catalyst-filled alloy steel tubes that are surrounded by a firebox providing the heat necessary for the endothermic reforming reaction. A large variety of reformer designs exist and can be used in various process configurations described in Häussinger et al. (2000). The main components of the reformer furnace are a combustion chamber, a radiant heat transfer section, and a convection section. The radiant section supplies heat to the catalyst tubes by burning the air/fuel (i.e. recycled syngas from the hydrogen purification) mixture and the convection section recovers heat by cooling down the flue gases (Spath and Dayton (2003)). The syngas leaves the reformer tubes close to thermodynamic equilibrium. If a desulphurisation unit is required before the reformer unit to avoid catalyst degradation by sulphur compounds, it usually consists of a hydrogenator followed by a zinc oxide bed (Spath and Dayton (2003)).

An alternative to steam reforming is partial oxidation (POX) of the fuel with air or pure O₂ according to Eq.3.3. Since the reaction is exothermic, there is no need for a complex heated reactor. There are three ways to carry out POX; non-catalytic partial oxidation, autothermal reforming (ATR) and catalytic partial oxidation (CPO). In the non-catalytic POX, high temperatures are required to yield high conversion of methane and avoid soot formation (Stolten (2010)). The benefit of this process is that it can be operated at high temperatures without the use of catalysts (i.e. 1600-1350°C, 150 bar). However, high combustion temperatures cause problems with NO_x formation. The POX reaction together with WGS produces however less H₂ than the reforming reaction. In an autothermal reformer (ATR) the endothermic steam reforming (Eq.3.1) is combined with the exothermic partial oxidation (POX) (Eq.3.3). The oxygen for the reaction can be supplied either by air or pure O₂. The advantage of adding pure O₂ is that no N₂ is present in the downstream process which reduces the installation size and facilitates CO₂ capture. However, air separation by cryogenic distillation or oxygen transfer membranes consumes energy and adds additional costs. To maximise the H₂ production, the ATR reactor is typically operated at high temperature (900-1100°C) and S/C ratio of 1 to 3.7. The autothermal reformer consists of a specially designed burner and a fixed catalyst bed in a brick-lined reactor (Stolten (2010)). The syngas composition is defined by the thermodynamic equilibrium at the exit temperature and pressure. In the catalytic partial oxidation the fuel and the air/O₂ are premixed and fed to a catalytic reactor (Rh-catalyst) without a burner. The

partial oxidation reaction (Eq.3.3) is typically operated around 950°C. In practice the reaction is accompanied by SMR and WGS reactions and at high conversions the syngas is close to thermodynamic equilibrium (Stolten (2010)).

Biomass gasification

Biomass-based technologies gained considerable attention in the last years, because they use renewable resources and emit no or very few net CO₂ emissions, if carefully managed, since the released CO₂ was previously fixed in the plant as hydrocarbon by photosynthesis. H₂ production from biomass can be divided into two categories; thermo-chemical processes (i.e. biomass gasification and pyrolysis) and biological processes (i.e. biophotolysis and fermentation). An overview of these processes and their economics is given in Bartels et al. (2010). Here it is focussed on the thermochemical lignocellulosic biomass gasification processes using wood as a resource.

After biomass handling, the wood has to be dried because the high moisture content would reduce the gasifier performance. Steam and air drying are reported to be the most common technologies. Their performance depends on the energy integration with the rest of the process and on the potential heat recovery. Optionally the biomass feed can be treated in a thermochemical torrefaction or pyrolysis step to improve the thermal and mechanical properties by drying the biomass further and breaking the feedstock down (Gassner and Maréchal (2009b)). During wood gasification, the solid macromolecules are broken into H₂, CO, CO₂ hydrocarbons, tars and ash in the presence of steam or oxygen as gasifying agent. The heat for this endothermal process can be delivered by different gasifier technologies such as indirectly or directly heated entrained or fluidised bed gasifiers. When the heat is provided by partial oxidation using air/O₂ the process is known as autothermal. An example of directly heated gasification is the Viking reactor and of indirectly heated gasification the fast internally circulating fluidised bed (FICFB) gasifier studied in Gassner and Maréchal (2009). A detailed technology description, as well as the advantages and disadvantages of the different gasifier technologies are reported in Olofsson et al. (2005) and Spath and Dayton (2003). The generated producer gas (PG) consists mainly of CO, CH₄ and other hydrocarbons, consequently these components need to undergo gas cleaning and conversion via steam reforming (Eq.3.1) and shift reactions (Eq.3.4) to generate a H₂/CO/CO₂ mixture. The particulates are removed through cyclone separators in a cold gas cleaning step and the produced char is burnt to generate heat that can be reused in the process.

3.2. Pre-combustion CO₂ capture processes description

Water gas shift reactor

The syngas (H₂-CO mixture) generated by reforming or gasification is cooled down for heat recovery purposes and catalytically reacted with H₂O in a water gas shift (WGS) reactor to increase the H₂ and CO₂ content according to Eq.3.4. The WGS reaction is exothermic and proceeds nearly to completion at low temperature and is independent of pressure. Conventionally, a dual shift reactor realising the shift in a successive high temperature (HTS) (i.e. T=350-420°C) and low temperature (LTS) (i.e. T=200-250°C) reactor is applied to increase the CO conversion and profit from the high temperatures (Longanbach et al. (2002)). The steam to carbon ratio S/C is an important parameter for this reaction. In practice, the ratio is set between 1 and 4. A high S/C ratio favours the conversion, but on the other hand the production of steam is energy consuming. Typically reaction pressures are in the range of 1-30 bar. For HTS iron oxide or chromium oxide catalysts are used, while for LTS a catalyst mix of zinc oxide, copper oxide and aluminium oxide catalysts are preferred.

Purification and CO₂ capture

After the shift section, the H₂/CO₂ mixture is separated. First water is removed by condensation to avoid a decrease of the separation efficiency due to high water contents. To generate high purity H₂ and CO₂ simultaneously, chemical absorption with amines or physical absorption is followed by a pressure swing absorption step. These processes have been described in detail previously in Section 2.2.2.

H₂ applications

After the separation of H₂, the H₂-rich fuel can be used as fuel in boilers, furnaces, gas turbines, engines and fuel cells for power and/or heat generation, or as chemical for other applications. Fuel cell applications are reviewed in Stolten (2010). Thermo-economic analysis of fuel cell systems have previously been made in Facchinetti et al. (2011), Maréchal et al. (2005), Autissier et al. (2007), van Herle et al. (2003) and Morandin et al. (2009). Using H₂ in combustion systems is challenging, because compared to other hydrocarbons H₂ has an higher specific heat, higher diffusivity, larger flammability limits and higher laminar flame speed (McDonell (2006)). In Chiesa et al. (2005b) the issues of burning H₂ in a heavy-duty gas turbine designed for natural gas are discussed and some adaptation techniques are proposed especially also with regard to NO_x control. The most relevant effects of the variation of the flowrate and of the thermo-physical properties are on the matching between turbine and compressor and on the cooling system. Within the objective to produce electricity with CO₂ capture, it is focused here on pre-combustion systems burning H₂-rich fuel in a gas turbine. The options of burning the H₂-rich fuel after CO₂ separation by chemical absorption and/or after H₂ purification by PSA are considered.

3.3 Pre-combustion CO₂ capture process modelling

The developed models for the different technological options of processes producing H₂ and/or electricity with pre-combustion CO₂ capture are based on literature data. Details for each process unit are given hereafter with regard to the different resources being either biomass or natural gas. The natural gas fed process layout illustrated in Figure 3.2 is established using mainly literature data from Longanbach et al. (2002), Damen et al. (2006), Consonni and Viganò (2005), Romano et al. (2010) and Maréchal et al. (2005).

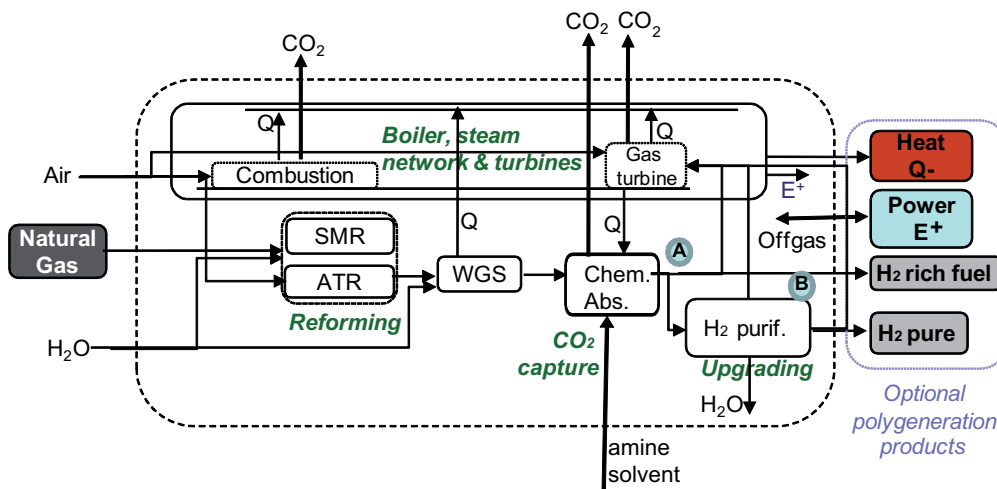

Figure 3.2: Process layout of the natural gas reforming processes with pre-combustion CO₂ capture. The products are defined by the decisions made at the cross points A and B.

The biomass conversion processes outlined in Figure 3.3 rely mainly on previous works (Gassner and Maréchal (2009b), Gassner and Maréchal (2009), Tock et al. (2010)) and on literature data (Hamelinck and Faaij (2002), Spath et al. (2005), Carpentieri et al. (2005)).

The detailed process flowsheets of the each process step are developed within the *Belsim Vali* (Belsim S.A.) software. Tables 3.1 and 3.2 summarise the different modelling assumptions and the nominal operating conditions, respectively. To predict accurately the thermodynamic properties, such as fugacity, enthalpy and molar volume different methods are chosen. For pure compounds the fugacity is calculated by the Raoult law for the liquid phase and by the ideal gas law for the gas phase. For mixtures the fugacity is calculated by the Peng-Robinson equation of state. The Lee-Kesler method is applied for the enthalpy and vapour volume calculation and the Gunn Yamada method for the liquid volume. For the gas separation units, the specific models described in Section 2.3 are considered.

3.3. Pre-combustion CO₂ capture process modelling

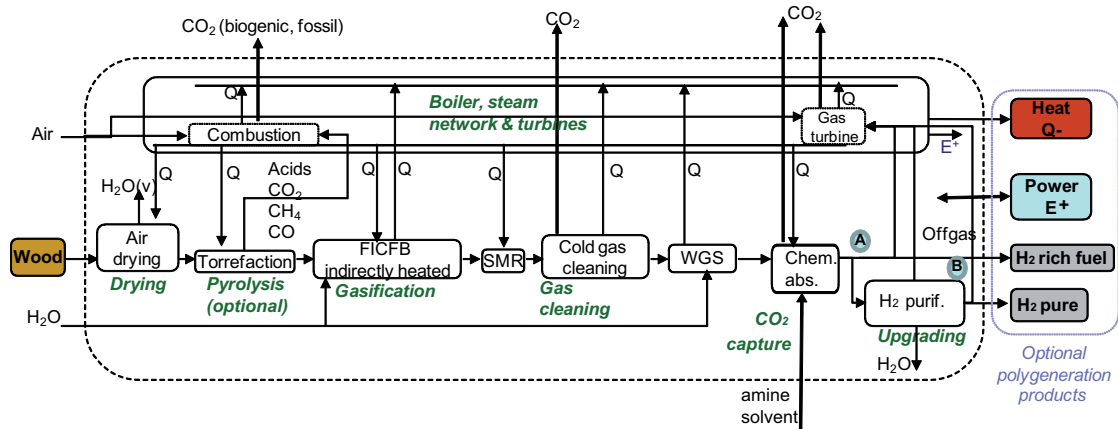

Figure 3.3: Process layout of the biomass conversion processes with pre-combustion CO₂ capture. The products are defined by the decisions made at the cross points A and B.

Table 3.1: Parameters for the energy-flow models of the pre-combustion CO₂ capture processes using natural gas or biomass as a feedstock.

Section	Specification	Value
Biomass feedstock	Composition	C=51.09%, H=5.75%
	[%wt]	O=42.97%, N=0.19%
	$\theta_{wood,in}$	50%wt
Natural gas feedstock	Composition	CH ₄ = 100 %
Chemical absorption (95% efficiency) (Radgen et al. (2005))	\dot{Q} @ 423 K	3.7MJ/kgCO ₂
	Electric Power	1.0MJ _e /kgCO ₂
Physical adsorption	Adsorption P	10 bar
	Purging P	0.1 bar
	H ₂ recovery	90%
CO ₂ compression	Pressure	110 bar
	$\eta_{compressor}$	85%
Gas turbine	$\eta_{compressor}$	85%
	$\eta_{turbine}$	90%

3.3.1 Syngas production

Natural gas reforming

With regard to feedstock pretreatment, it is assumed that the sulphur content is low and consequently desulphurisation is omitted and has not been modelled. The natural gas reforming reactor is modelled as an isothermal reactor indicating that the reaction is performed at constant temperature. For the reactor modelling the approach described in Maréchal et al. (2005) applying the minimum exergy losses representation is followed. This modelling approach allows to decouple the heat transfer from the chemical reaction heat and consequently to maximise the energy recovery for power generation. It is assumed that the reactions (Eqs.3.1&3.4) reach thermodynamic equilibrium defined by the reaction temperature. In reality it is difficult to achieve isothermal conditions for exothermic or endothermic conditions since heat has constantly to be withdrawn or supplied. However in a shell and tube heat exchanger based

reactor, isothermal conditions can be assumed since heat transfer can take place simultaneously as the reaction continues. For the autothermal reforming, the reactor is also modelled as isothermal reactor with equilibrium reactions. The POX reaction (Eq.3.3) using air as an oxidant is modelled as a conversion reaction by imposing complete consumption of the oxygen. The operating pressure, temperature and the steam to carbon ratio are decision variables that are optimised in the multi-objective optimisation.

Table 3.2: Operating conditions and feasible range for optimisation for the pre-combustion CO₂ capture processes using natural gas or biomass as a feedstock.

Section	Specification	Nominal	Range

Biomass gasification

For the biomass drying and gasification, the models developed in previous works (Gassner and Maréchal (2009b), Tock et al. (2010)) for the production of synthetic natural gas (SNG) and liquid fuels (BtL) have been adapted in accordance with literature data considering biomass conversion into H₂ (Hamelinck and Faaij (2002), Spath et al. (2005)). The model for biomass drying by air or steam is based on the one described in Gassner and Maréchal (2009b) taking into account the wood humidity θ and the mass and heat transfer coefficients. For the gasifier, it is focused on an indirectly heated steam-blown fluidised bed gasifier (FICFB). The heat is supplied by circulating a hot medium between the gasifier vessel and the char combustion chamber and the steam is supplied from the steam cycle. The chemical conversion in the gasifier is modelled by equilibrium relationships with an artificial temperature difference as explained in Gassner and Maréchal (2009b). The gasification temperature and pressure are key decision variables. The cleaning and reforming is modelled according to the previous works (Gassner and Maréchal (2009b), Tock et al. (2010)). The high temperature stage reforming is

modelled by considering the reactions at equilibrium. The reforming temperature is a decision variable and the steam to carbon (S/C) ratio is fixed by the amount of steam supplied to the gasifier.

3.3.2 Gas treatment and purification

Water gas shift

For the water gas shift reactor, the option to include one reactor operating at intermediate temperature or to include a dual shift reactor consisting of one reactor operating at high temperature and one at low temperature is considered. The WGS reactor is modelled as an isothermal reactor and it is assumed that the WGS reaction (Eq.3.4) reaches thermodynamic equilibrium at the specified reaction temperature which is a decision variable. Similar to the reforming reactor modelling, the isothermal modelling of the reactor follows the approach outlined in Maréchal et al. (2005). No additional water is added at this stage for the natural gas fed process. The amount of water that is available is defined by the S/C ratio of the reforming section. However, for the biomass fed process additional water can be fed to the WGS reactor. The optimal amount is defined by optimisation.

CO₂ removal and H₂ purification

In the purification section, chemical absorption with amines is followed by a pressure swing absorption step (PSA) to generate high purity H₂ and CO₂ simultaneously. In a first approach, the CO₂ capture unit is modelled as a blackbox using the average data reported in Table 3.1. This simplified model does not represent the influence of decision variables that are inherent to the CO₂ removal process and could allow to increase the CO₂ capture efficiency. However, it gives a first prospect of the penalty of CO₂ capture in Section 3.4. The influence of the CO₂ capture unit design is investigated in more detail in Chapter 4 and in Tock and Maréchal (2012c).

The PSA model is based on the one described in Section 2.3.3 with the assumptions given in Table 3.1. The targeted H₂ purity is above 95%mol.

After the CO₂ capture unit, the H₂-rich gas exits at the process pressure and after the PSA unit at atmospheric conditions or lower. No H₂ compression for storage and transportation has been included in this study. If CO₂ sequestration is considered, CO₂ compression up to 110 bar by a two stage compression with intermediate cooling is included. It has to be noted that the CO₂ purification step possibly required before the CO₂ compression to reach the purity characteristics for transportation and storage (min 95%vol) has not been included.

3.3.3 H₂ applications

Gas turbine

Within the objective to produce electricity with CO₂ capture, the burning of H₂ fuel in a gas turbine is investigated. The options of burning the H₂-rich fuel after CO₂ separation by chemical absorption and/or after H₂ purification by PSA are considered (Figures 3.2 & 3.3). Even if in practice there are still some concerns with regard to flame stability which have to be addressed for pure H₂ combustion, it is assumed in the modelling that by some technology adaptations it will be feasible in the future. In the gas turbine model, the oxidant is air which is first compressed and is then preheated to the combustion temperature. The preheating temperature is optimised in the energy integration. The preheated fuel is completely oxidised in the combustion chamber. It is modelled by an adiabatic reactor taking into account atomic balances and by a heat exchanger cooling the gas down to the turbine inlet temperature. For the compressor and the turbine isotropic efficiencies of 85% and 90% respectively, are considered. The combustion and turbine inlet temperatures are decision variables that will be optimised. The model is applied for natural gas, as well as for impure and pure H₂ burning.

Fuel cells

The usage of H₂ in fuel cells has been studied in previous works (Maréchal et al. (2005), Facchinetti et al. (2011, 2012), Autissier et al. (2007), van Herle et al. (2003), Morandin et al. (2009)) and has not been addressed here in detail. The results are included in the discussion part for comparison purpose.

3.4 Thermo-economic evaluation of pre-combustion CO₂ capture processes

To assess the impact of pre-combustion CO₂ capture, different scenarios for H₂ and/or electricity generation are studied. These scenarios include:

- biomass gasification (BM)
- natural gas reforming by SMR
- natural gas reforming by ATR

For H₂ generation processes, the possibility to import electricity (E_{imp}) or to burn part of the H₂-rich gas to satisfy the process power demands (self-sufficient, *self*) is considered. The H₂ production is compared with the production of electricity burning the H₂-rich fuel in a gas turbine (*GT*) after capturing the CO₂. Each scenario integrates a combined steam cycle. The performance analyses are performed for a plant capacity of 725MW_{th,NG} of natural

3.4. Thermo-economic evaluation of pre-combustion CO₂ capture processes

gas and 380MW_{th, BM} of dry biomass, respectively. The biomass installation size is chosen in accordance with Hamelinck and Faaij (2002). Larger plants would be favourable in terms of annual production and infrastructure's cost, but are penalised by the logistics of wood transport depending on the average collection distance related to the plant size (Gerber et al. (2011)). The competitiveness of H₂ and electricity generation processes is evaluated by the performance indicators defined in Section 1.4.1 for the economic assumptions reported in Table 1.2. A multi-objective optimisation is performed to assess the trade-off of competing factors defining the process performance of the H₂ and electricity generation with CO₂ capture. The maximisation of the overall energy efficiency ϵ_{tot} (Eq.1.22) and the maximisation of the overall carbon capture rate η_{CO_2} (Eq.1.25) are chosen as objectives within the aim of optimising the CO₂ capture integration. The key process operating conditions given in Table 3.2 are chosen as decision variables.

3.4.1 Multi-objective optimisation of pre-combustion CO₂ capture in H₂ processes

The Pareto optimal frontiers generated by the multi-objective optimisation of CO₂ capture in different H₂ production processes reveal in Figure 3.4 the efficiency decrease with increasing CO₂ capture rate. Due to the energy consumption for CO₂ capture and compression, the net electricity output is decreased and consequently the overall energy efficiency also. The increase of the power consumption with regard to the CO₂ capture rate is illustrated in Figure 3.5.

Figure 3.4: Pareto optimal frontiers for CO₂ capture in H₂ production processes maximising the energy efficiency and the CO₂ capture rate. Dashed lines represent the CO₂ capture level of configurations yielding a compromise with regard to both objectives.

For the natural gas fed H₂ processes with CO₂ capture the trade-off between efficiency, CO₂ capture and production costs is presented in Figure 3.6. High efficiencies and low production costs are reached for process configurations with low CO₂ capture rates. These solutions

having a higher H₂ productivity release however more CO₂ emissions. While high CO₂ capture rates, reduce the efficiency and increase the production costs due to the additional investment and the increase of the energy demand for CO₂ capture (Figure 3.5).

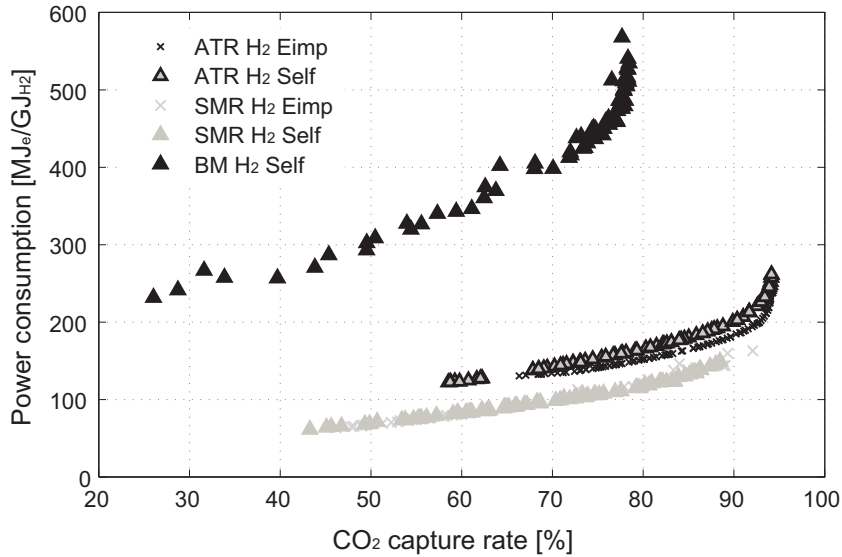

Figure 3.5: Multi-objective optimisation results of CO₂ capture in H₂ production processes: Trade-off between CO₂ capture rate and power consumption.

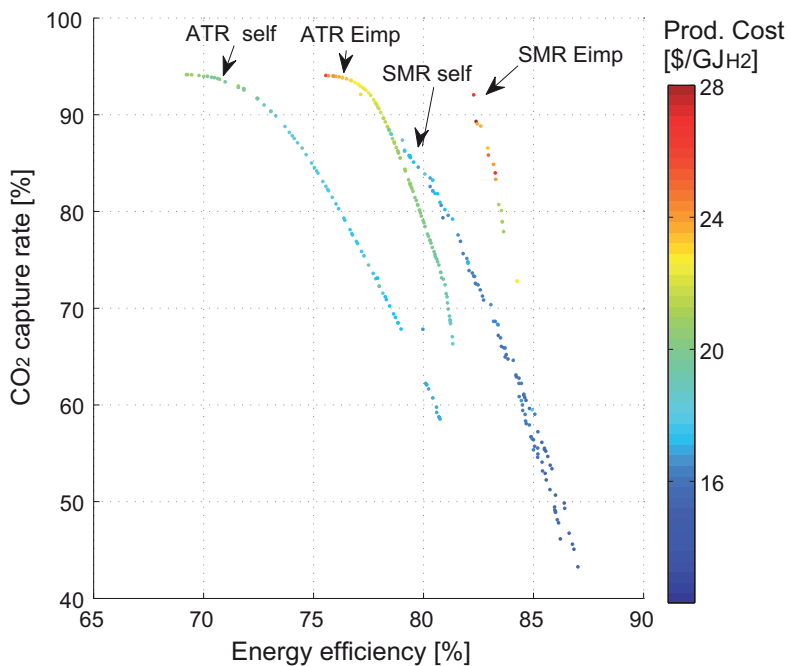

Figure 3.6: Multi-objective optimisation results of CO₂ capture in natural gas fed H₂ production processes: Trade-off between efficiency, CO₂ capture rate and production costs.

3.4. Thermo-economic evaluation of pre-combustion CO₂ capture processes

Self-sufficient H₂ production processes (*self*) with CO₂ capture yield lower efficiencies and lower costs than scenarios importing electricity from the grid (*Eimp*). For self-sufficient H₂ production processes with CO₂ capture part of the H₂-rich fuel has to be burnt in a gas turbine to close the power balance, which reduces the H₂ productivity and hence the overall energy efficiency. The increase in power generation by the gas turbine fed with H₂-rich fuel with the increasing CO₂ capture rate is illustrated in Figure 3.7. In H₂ production processes importing electricity, only a small amount of the H₂-rich fuel has to be burnt at high capture rates in order to deliver the heat required for the CO₂ capture. From an energy integration point of view, configurations satisfying the thermal energy demand by the heat from the steam network and by the combustion of waste and product streams are preferred.

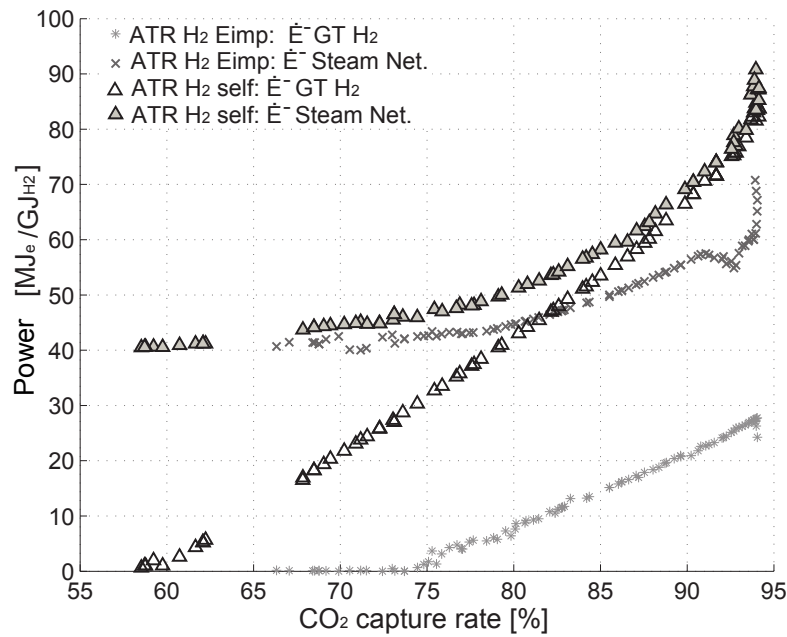

Figure 3.7: Power generation by the steam network and by the H₂-rich fuel gas turbine along the Pareto optimal frontiers of the H₂ production by ATR (self and Eimp) with CO₂ capture.

For each scenario one configuration yielding a compromise between efficiency and CO₂ capture is chosen in order to compare in detail the performance of the different process configurations. For natural gas fed processes the Pareto optimal configuration corresponding to a capture rate of 90% is chosen, while for biomass conversion processes the one with 65% capture rate is selected. For biomass conversion a lower capture rate can be considered in order to reach a higher efficiency ϵ_{tot} , because it corresponds to the capture of biogenic CO₂. CO₂ capture generates in this case a negative balance since the captured carbon comes from the CO₂ assimilated in the biomass by photosynthesis. The specific performance results of the selected configurations expressed per GJ of H₂ produced (based on the lower heating value) are summarised in Table 3.3 and the corresponding operating conditions are reported in Appendix Table D.1.

Chapter 3. Thermo-economic analysis of pre-combustion CO₂ capture processes

Table 3.3: Performance of H₂ process configurations with pre-combustion CO₂ capture. The net electricity output expressed in MJ of electricity per GJ of hydrogen is negative when the integrated process requires electricity importation and positive when it generates electricity. The corresponding operating conditions are reported in Appendix Table D.1.

3.4.2 Pre-combustion CO₂ capture process performance: H₂ production

The comparison of the H₂ production processes with CO₂ capture using different resources and importing electricity (E_{imp}) or being self-sufficient (self) in terms of power shows that the highest efficiency is reached for the natural gas SMR process importing electricity (Figure 3.4). The performances summarised in Table 3.3 are analysed and discussed in detail in the following paragraphs.

Energy integration

For self-sufficient H₂ production processes with CO₂ capture using different resources the variation in terms efficiency is highly linked to the difference in the energy demands illustrated in Figure 3.8 by the composite curves resulting from the energy integration.

The endothermic gasification and SMR processes require heat supply for the syngas generation, while in the ATR process the heat is delivered internally by a POX reaction. As a consequence, the ATR process requires the lowest amount of hot utility. The heat demands above the pinch point are satisfied by the combustion of offgases and, if necessary, of part of the H₂-rich gas. In the purification step, the CO₂ separation by chemical absorption requires a large amount of energy for the amine-solvent regeneration. Below the pinch point, the heat excess is valorised in a steam network for electricity generation. In these configurations, the quality of the energy integration is improved by introducing a mechanical vapour recompression (MVR) between the absorber (condensation at 429 K) and the stripper (evaporation at 378 K) of the chemical

3.4. Thermo-economic evaluation of pre-combustion CO₂ capture processes

absorption unit for CO₂ capture.

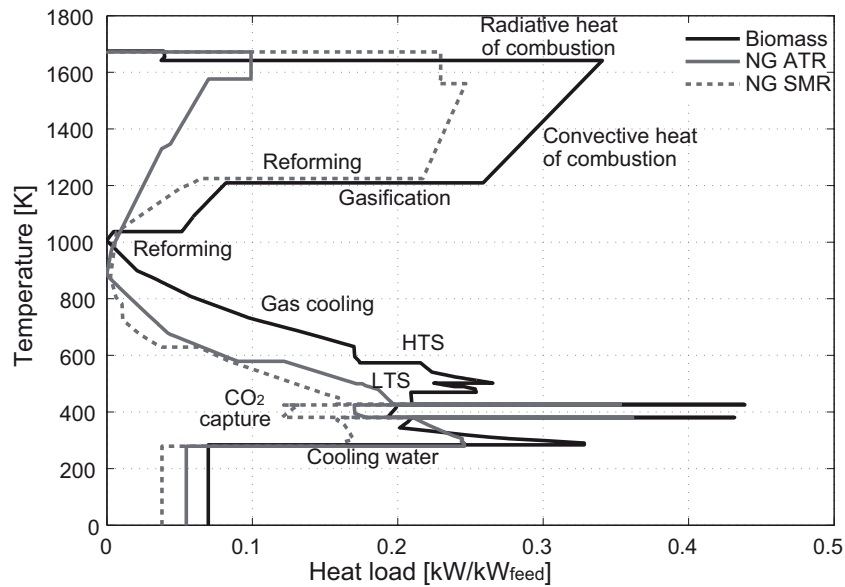

Figure 3.8: Integrated composite curves of self-sufficient H₂ production processes with CO₂ capture using different resources reported in Table 3.3 (ATR self, SMR self, BM self). The steam network integration is omitted on the figure for clarity.

The composite curves illustrated in Figures 3.9& 3.10 clearly reveal the benefit of introducing MVR in self-sufficient natural gas fed H₂ production process (ATR) with CO₂ capture by chemical absorption. The integration of the MVR is reported by the integrated composite curve in Figure 3.10. Although it is realised below the pinch point, the MVR integration appears to be energetically needed because the combined production of heat and power creates a utility pinch point at the level of the desorption. Introducing the MVR, reduces the medium pressure steam usage needed for the CO₂ desorber. This steam can be expanded to very low pressure in the condensing turbine stage which maximises the combined production of power. The increase of the mechanical power production is larger than the amount required to compensate the mechanical power needed by the compression in the MVR. The efficiency is increased by 3%-points through the conversion of waste heat into mechanical power (Table 3.3). Even if the productivity is increased, the production costs remain nearly constant due to the increased capital costs for the compressor purchase around 98.8M\$/kW_{H2}.

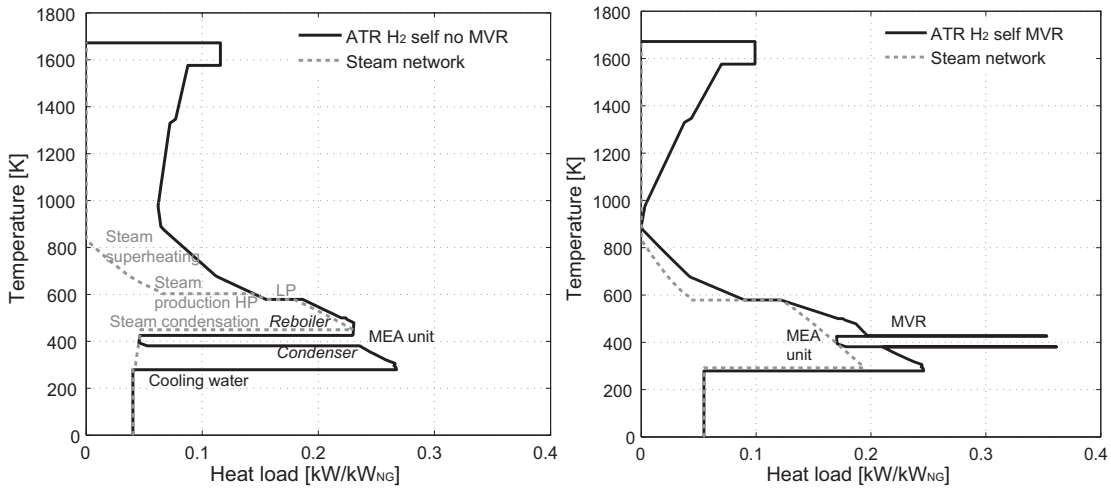

Figure 3.9: Integrated composite curves of the self-sufficient natural gas fed H₂ production process with CO₂ capture without (left) and with MVR integration (right) reported in Table 3.3 (ATR self and ATR self no MVR).

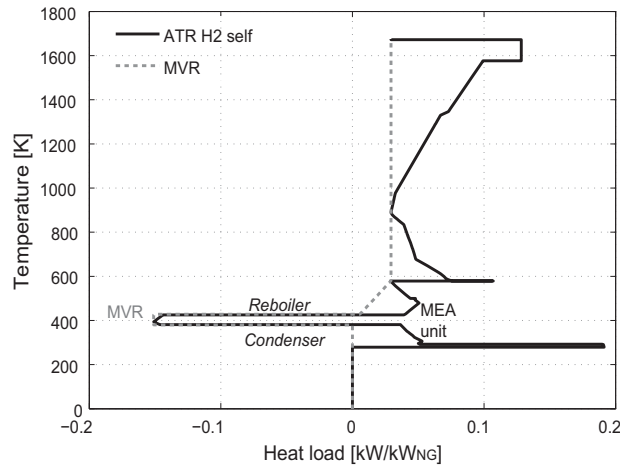

Figure 3.10: MVR integration for the self-sufficient natural gas fed H₂ production process with CO₂ capture (Table 3.3 ATR self).

For biomass fed H₂ production processes with CO₂ capture, the impact of CO₂ capture and MVR on the energy integration is illustrated in Figure 3.11 for the compromise process configuration importing electricity from the grid. The corresponding performance results are summarised in Table 3.3. For the biomass fed H₂ processes purifying H₂ by PSA without or with CO₂ capture, there is a pinch point at low temperature created by the drying, respectively by the chemical absorption for CO₂ capture (Figure 3.11 (left)). Consequently, there is no heat excess available for cogeneration. By introducing mechanical vapour recompression, excess heat from below the pinch can be transferred to a higher temperature for valorisation in a Rankine cycle and consequently the energy integration of the CO₂ capture unit is improved as shown in Figure 3.11 (right). Through H₂ purification by CO₂ capture, the H₂ yield is increased

3.4. Thermo-economic evaluation of pre-combustion CO₂ capture processes

by over 10% and the environmental impact is decreased by 90kg_{CO2}/GJ_{H2}.

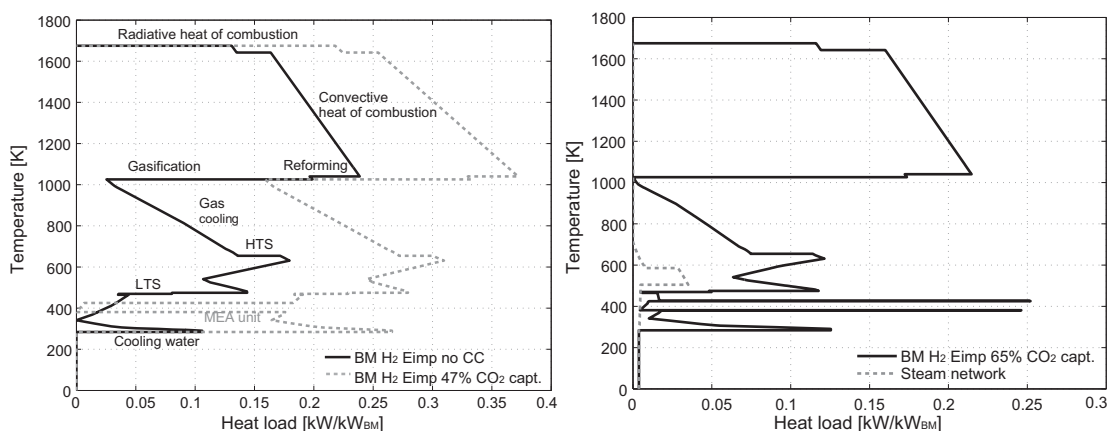

Figure 3.11: Integrated composite curves for the biomass fed H₂ production process (with electricity import) without and with CO₂ capture (left) and with MVR (right) reported in Table 3.3 (BM Eimp, no CC and no MVR).

Power balance

The variation of the H₂ production processes efficiency summarised in Table 3.3, reflects the difference in the power demand and supply. The power balance reported in Figure 3.12 shows that the largest power demand is attributed to gas treatment and purification including CO₂ capture and compression. Moreover, the heat pumping by MVR improving the capture unit integration requires power for the compression. Power is generated by the steam network and by the gas turbine burning offgases. For self-sufficient configurations, the balance is closed by burning part of the H₂ product in a gas turbine, while for the other scenarios electricity is imported from the grid.

For the H₂ production by ATR processes, using air as oxidant, some N₂ remains in the products yielding a H₂ purity around 96%mol compared to over 99.5%mol for SMR and biomass based processes. The purification of the syngas produced by ATR is more power demanding and more expensive due to the larger flows to be treated. In addition, air has to be compressed to the operating pressure explaining the larger power demand for the synthesis. Feeding the ATR with pure O₂ might become an alternative if purities over 99%mol H₂ are mandatory. Adding pure O₂ has the advantage that no N₂ is present in the downstream process which reduces the equipment size and facilitates CO₂ capture. However, it requires pure O₂ to be produced in an air separation unit consuming a large amount of energy. This trade-off remains to be investigated in future studies.

Comparing the self-sufficient H₂ processes including CO₂ capture, the natural gas fed SMR process has the lowest power consumption (Figure 3.12) explaining the higher efficiency ($\epsilon_{tot}=78\%$), even if the thermal energy demand is larger (Figure 3.8). The power demand is reduced by 18% and 34% when compared with the ATR and the biomass fed process respec-

tively. Since less process gas has to be burnt in a gas turbine for power generation more H₂ is produced. The H₂ productivity is decreased by 6% for the ATR and by 45% for the biomass based process. The lower efficiency of the biomass fed process is related to the lower energy content compared to the natural gas resource and to the endothermic gasification. These trends are also reflected by the difference in the production costs reported in Figure 3.13.

Figure 3.12: Power balance of the different H₂ process configurations with CO₂ capture reported in Table 3.3.

When electricity is imported from the grid, the energy efficiency ϵ_{tot} of the ATR process is increased by nearly 5%-points and of the biomass fed process by more than 16%-points, because more H₂ is produced since none has to be burnt for power generation. However, expressed in terms of natural gas equivalent efficiency given by Eq.1.23, the efficiency of the self-sufficient scenario is nearly 3%-points higher for the ATR process and over 6%-points for the biomass based process. This shows that the internal electricity generation is more efficient than the separate production of electricity from natural gas. The marginal production expressed by $\Delta\dot{E}/\Delta H_2$ is around 70% for the ATR and biomass based processes. Even if, 13% more H₂ is produced for the ATR process with electricity import, Figure 3.13 shows that the production costs are around 15% higher due to the electricity purchase at the price of green electricity being 75\$/GJ_e. An electricity purchase price of around 34.7\$/GJ_e would make both solutions equivalent.

Economic performance

The economic performance expressed in terms of production costs in Figure 3.13 is related to the productivity. The natural gas fed H₂ production processes have lower production costs because of the higher H₂ yield. The H₂ production costs are composed mainly of the resource purchase, the annual investment and the electricity purchase for configurations importing electricity. The H₂ production costs of the biomass gasification processes are high because of the lower efficiency and the larger investment required especially for the gasifier purchase that

3.4. Thermo-economic evaluation of pre-combustion CO₂ capture processes

corresponds to about 1/3 of the capital investment costs. The capital investment costs buildup in Figure 3.14 emphasis the large contribution of the gasifier costs to the syngas generation costs. For the natural gas fed H₂ production processes, the investment costs for CO₂ capture and compression are more important since the capture rate is higher. It is to note that the equipment sizing and costing method might overestimate the equipment costs; nevertheless biomass gasification being an emerging technology is as a matter of cause more expensive than the well-established reforming technology.

Figure 3.13: Production costs buildup for the different H₂ process configurations with CO₂ capture reported in Table 3.3 based on the base case economic assumptions given in Table 1.2.

Figure 3.14: Capital investment buildup for the different H₂ process configurations with CO₂ capture reported in Table 3.3.

Taking into account a variation of the resource price between 5.5 and 19.5\$/GJ_{res}, the assessed H₂ production costs in the range of 12.5-61\$/GJ_{H₂} are comparable to the one reported in Bartels et al. (2010) for fossil and renewable resources and competitive with the costs of 7.5-14\$/GJ_{H₂} assessed in the IPCC report (Metz et al. (2005)) for a CO₂ capture in natural gas

fuelled H₂ plants yielding an efficiency in the order of 52-68%. These reference processes published in Metz et al. (2005) feature a lower efficiency than the one in this study (73-78%). This efficiency increase can be explained by the improved quality of the process integration. Biomass gasification technology development could lead to a capital costs reduction and consequently to more competitive biomass based H₂ production processes in the future.

Considering as a reference a H₂ plant without CO₂ capture from Metz et al. (2005) (producing 1530MW_{H2}) from natural gas with a cost of 7.8\$/GJ_{H2} (with 5\$/GJ_{NG}) and emissions of 137kg_{CO₂,emitted}/GJ_{H2}, the computed CO₂ avoidance costs 36-263\$/t_{CO₂,avoided} are comparable to the ones reported in Metz et al. (2005) (2-56\$/t_{CO₂,avoided}) with a resource price around 5\$/GJ_{Res}. With CO₂ capture, CO₂ emissions in H₂ plants using natural gas can be reduced to around 7.5kg_{CO₂,emitted}/GJ_{H2}, while for the biomass fed H₂ production process the CO₂ emissions are biogenic and consequently accounted as being null or even negative if CO₂ is captured. The introduction of a carbon tax will promote these solutions even more as discussed in Chapter 8. In addition, the environmental benefit of capturing CO₂ in H₂ production processes is clearly revealed by the life cycle assessment results reported in Appendix E.

This reveals that fuel decarbonisation for H₂ production is not only competitive with regard to environmental considerations but also with regard to the energetic and economic performance for specific resource prices.

3.4.3 Multi-objective optimisation of pre-combustion CO₂ capture in power plants

Instead of generating pure H₂, the option to generate electricity by burning the H₂-fuel in a gas turbine after CO₂ capture is investigated. The trade-off between CO₂ capture, energy efficiency and costs revealed by multi-objective optimisation is reported in Figure 3.15 (left). CO₂ capture reduces the efficiency due to the additional power consumption for CO₂ capture and compression decreasing the net electricity output (Figure 3.15 (right)). As for the H₂ production processes, MVR is introduced in order to improve the energy integration of the chemical absorption unit for CO₂ capture.

The performance results of the compromise power plant scenarios capturing 90% of the CO₂ emissions for natural gas fed processes and 65% for biomass based ones are compared in Table 3.4 and discussed in detail hereafter. The operating conditions are summarised for each process configuration in Appendix Table D.2.

3.4.4 Pre-combustion CO₂ capture process performance: Electricity generation

For the different power plants configurations with pre-combustion CO₂ capture, the difference in the energy demands is illustrated in Figure 3.16 by the composite curves resulting from the energy integration. As for the H₂ production scenarios, the difference between SMR and ATR is clearly seen by the hot utility requirement. In addition, the difference in the cogeneration

3.4. Thermo-economic evaluation of pre-combustion CO₂ capture processes

potential is revealed by the heat excess at low temperature.

Compared to a conventional natural gas plant (NGCC) without CO₂ capture generating electricity with an efficiency of 55-58%, production costs of 18-24\$/GJ_e and CO₂ emissions of 100-105kg_{CO₂}/GJ_e (Finkenrath (2011)), CO₂ mitigation reduces the efficiency by around 8%-points and increases the costs by over 20% due to the energy demand and the costs of CO₂}

capture by chemical absorption and of CO₂ compression. With pre-combustion CO₂ capture, electricity production costs in the range of 22.7-50\$/GJ_e are assessed for natural gas based processes with an efficiency of around 55%, compared to 28% and 46.6-96\$/GJ_e for biomass fed processes taking into account a resource price variation from 5.5 to 19.5\$/GJ_{res}. With CO₂ avoidance costs of 14-306\$/t_{CO₂,avoided} and 72-212\$/t_{CO₂,avoided} for natural gas and biomass fed electricity production processes respectively, CO₂ capture is promising with regard to the future energy market, especially when high CO₂ taxes are imposed. The use of biomass becomes competitive compared to fossil resources from environmental point of view and even from an economical one if gasifier costs can be reduced. The analysed pre-combustion CO₂ capture processes reveal to be competitive compared to an NGCC power plant with post-combustion CO₂ capture yielding an efficiency of about 50%, production costs in the range of 23-35\$/GJ_e (with 9.7\$/GJ_{NG}) and CO₂ avoidance costs around 62-128\$/t_{CO₂,avoided} (Finkenrath (2011)). Depending on the production purpose and the market scope, the decision between generating electricity or H₂ with electricity import or self-sufficient, with or without CO₂ mitigation can be made with the developed thermo-environomic models.

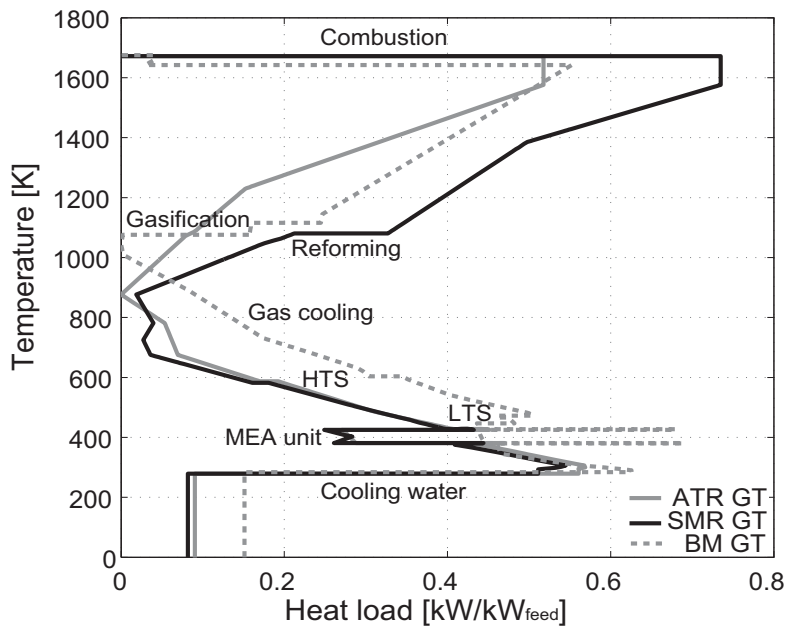

Figure 3.16: Integrated composite curves of power plant's configurations with pre-combustion CO₂ capture using different resources (Table 3.4). The steam network integration is omitted on the figure for clarity.

The competitiveness of different power plant designs with pre-combustion CO₂ capture is investigated more in detail in Chapter 4 and the influence of the economic assumptions (i.e. resource price, carbon tax) is assessed in Chapter 8.

3.5 Conclusions

This chapter presented the development of thermo-economic models for the conceptual design and comparison of fuel decarbonisation processes producing H₂ and/or electricity from either natural gas or biomass resources with CO₂ capture by chemical absorption. The competitiveness of different process configurations is evaluated consistently with respect to energy efficiency, costs and environmental impacts. It is highlighted in particular, how appropriate energy integration and operating conditions optimisation improve the process performance by maximising the combined production of fuel, heat and power. Using natural gas as a resource overall energy efficiencies in the range of 73-82% are reached for H₂ production with CO₂ capture and 43-60% for biomass fed processes. Under selected economic assumptions, CO₂ avoidance costs in the range of 36-263\$/t_{CO₂,avoided} are obtained for H₂ producing plants and 14-306\$/t_{CO₂,avoided} for power plants. It is shown that the competitiveness of the process configurations highly depends on the resource price, the imposed CO₂ taxes and the production scope. With regard to climate change mitigation, fuel decarbonisation for H₂ and/or electricity generation using fossil and even renewable resources can become competitive under given economic scenarios. This aspect is further studied in Chapter 8.

4 Thermo-economic comparison of CO₂ capture technologies in pre-combustion CO₂ capture processes

In the previous chapter, the energy and cost penalty of CO₂ capture by chemical absorption in pre-combustion CO₂ capture processes has been highlighted based on a simplified chemical absorption model. In this chapter different CO₂ capture technologies, i.e. chemical and physical absorption, are compared more in detail based on accurate flowsheeting models in order to evaluate the impact on the performance of pre-combustion CO₂ capture processes producing H₂ or electricity. The results presented for the H₂ production processes have been published in Tock and Maréchal (2012c) and the one for the electricity production processes partly in Tock and Maréchal (2012f).

4.1 Introduction

Since CO₂ capture affects the process performance through the thermal and mechanical energy requirement for CO₂ capture and the related investment, it is of interest to evaluate the impact of different technology options. The efficiency and competitiveness of these processes is highly defined by the quality of the energy integration, however in most of the studies this aspect is not investigated in detail. In Lozza and Chiesa (2002a,b) different natural gas fed pre-combustion CO₂ capture process configurations including chemical and physical absorption are compared with regard to the thermodynamic and economic performance. According to their results, systems based on partial oxidation and on chemical or physical absorption yield similar efficiencies (around 48%) and electricity production costs (13.1-13.8\$/GJ_e) for a capture rate of 90%. When comparing CO₂ capture by chemical and physical absorption, process integration becomes of importance, since there is a competition between the energy demands. Chemical absorption requires a large amount of energy for solvent regeneration, while physical absorption needs energy for the refrigeration as explained in Section 2.2.2. Consequently, the process integration and performance will be affected differently. The objective is therefore to compare different pre-combustion CO₂ capture process options for H₂ or electricity generation, focusing on the potential performance improvement by process

Chapter 4. Thermo-economic comparison of CO₂ capture technologies in pre-combustion CO₂ capture processes

integration. By performing a multi-objective optimisation, the influence of the operating and design conditions of the process units are investigated in order to assess the trade-offs and the competitiveness of the process configurations.

4.2 Process description: Pre-combustion CO₂ capture

The pre-combustion CO₂ capture processes that are considered produce electricity or H₂ from natural gas ($725\text{MW}_{th,NG}$) or biomass resources ($380\text{MW}_{th,NG}$) by using the same technologies as described in Chapter 3. The investigated technologies for CO₂ capture are chemical absorption with triethanolamine (TEA) and physical absorption with Rectisol or Selexol which have been described previously in Section 2.2.2. The corresponding process flowsheets are illustrated in Appendix Figures B.1, B.3 and B.4. For comparison purpose, some performance results presented in Section 3.4 based on process models considering a simple chemical absorption blackbox model (BBA) for CO₂ capture are included. The thermo-economic models have been described in Section 2.3 for the CO₂ capture technologies and in Section 3.3 for the different syngas production processes. Since the syngas production models are developed with the *Belsim Vali* (Belsim S.A.) software and the CO₂ capture models with the *Aspen Plus* (AspenTech) software, the key feature of the thermo-environmental modelling and optimisation framework allowing to set-up a process model by using parts developed with different flowsheeting software is valuable here. Similar to the H₂ production processes studied in Section 3.4, the process energy demand is satisfied either by importing electricity from the grid (Eimp) or by burning part of the H₂-rich fuel in a gas turbine to be self-sufficient (self) in terms of energy. For the scenarios generating only electricity, the H₂-rich gas leaving the CO₂ capture unit is either burnt directly in a gas turbine or either sent to a hydrogen purification unit (PSA) before being burnt. The competition between the energy demand for the H₂ purification and the gain in the combustion energy is revealed. The removed CO₂ is compressed to 110 bar for transport and storage. The process competitiveness is evaluated based on the performance indicators defined in Section 1.4.1 and the economic assumptions reported in Table 1.2. After briefly investigating H₂ production configurations in Section 4.3, it is focused in Section 4.4 more on the study of electricity generating configurations including different technologies for pre-combustion CO₂ capture.

4.3 Performance of H₂ production processes with different CO₂ capture technologies

Multi-objective optimisation is performed to optimise the CO₂ capture integration in H₂ production processes with regard to the decision variables given in Tables 2.3, 2.5, 2.6 & 3.2. The chosen objectives are the maximisation of the energy efficiency ϵ_{tot} and of the overall CO₂ capture rate η_{CO_2} . The trade-off between CO₂ mitigation, efficiency and cost is illustrated for the different H₂ production scenarios in Figure 4.1. CO₂ mitigation reduces the efficiency and increases the costs due to the energy demand for CO₂ capture and compression to 110

4.3. Performance of H₂ production processes with different CO₂ capture technologies

bar and the associated costs.

To compare the different processes, configurations with around 85-90% CO₂ capture are selected for the natural gas scenarios and around 60-65% for the biomass scenarios. The performance results are summarised in Table 4.1 and the corresponding operating conditions are given in Appendix Table D.3. The same trends as the one discussed in Section 3.4 are of course identified by comparing biomass and natural gas fed H₂ production configurations, as well as self-sufficient and electricity importing configurations.

Figure 4.1: Trade-off between CO₂ mitigation, energy efficiency and production cost for H₂ production process configurations including different CO₂ capture technologies.

Table 4.1: Performance of the compromise H₂ production process configurations with CO₂ capture. The specific performances are expressed per GJ of H₂ produced. The corresponding operating conditions are reported in Appendix Table D.3.

Chapter 4. Thermo-economic comparison of CO₂ capture technologies in pre-combustion CO₂ capture processes

With regard to the different CO₂ capture technologies applied to the H₂ production, the difference in the overall efficiencies can be explained by the change in the energy integration. This is illustrated in Figure 4.2 by the comparison of the composite curves for the H₂ production by ATR with 90% of CO₂ capture by chemical absorption with TEA or physical absorption with Selexol. The excess heat available below the pinch point is different, consequently the cogeneration potential changes. For the self-sufficient scenarios, this translates into a variation of the H₂ productivity, since some H₂-rich fuel has to be burnt in order to generate electricity in addition to the steam network to satisfy the process demand as shown in Figure 4.3. Due to the lower energy demand for solvent regeneration, the Selexol physical absorption process yields a slightly higher efficiency for the self-sufficient scenario generating H₂ from natural gas.

Figure 4.2: Comparison of the composite curves for self-sufficient H₂ production processes capturing 90% of the CO₂ by chemical or physical absorption (Table 4.1: ATR self TEA & Selexol). The steam network integration is omitted on the figure for clarity.

The changes in the H₂ productivity explain also the difference in the H₂ production costs. The H₂ production costs build-up illustrated in Figure 4.4 shows that, the resource purchase contributes to more than two thirds of the production costs. Decreasing the resource price to 5.5\$/GJ_{res} will reduce the costs by 30%, while an increase of the resource price to 20\$/GJ_{res} will lead to up to 60% higher H₂ production costs. Consequently, the competitiveness of the process configurations is highly influenced by the resource price and the introduction of a carbon tax. This influence of the economic scenario on the economic performance of CO₂ capture in H₂ production processes is illustrated in Appendix Figure E.3 and discussed in detail in Section 8.3 for the power plants competitiveness. The environmental benefit of capturing CO₂ in H₂ production processes is clearly revealed by the LCIA results reported in Appendix E.

4.3. Performance of H₂ production processes with different CO₂ capture technologies

Regarding the different impact contributions, the same conclusions as the one discussed in Section 8.3 for the electricity producing processes can be drawn.

Figure 4.3: Power balance for the different H₂ production process configurations with CO₂ capture reported in Table 4.1.

Figure 4.4: Production cost buildup for the different H₂ production process configurations with CO₂ capture reported in Table 4.1.

4.4 Performance of electricity generating processes with different pre-combustion CO₂ capture technologies

To study the influence of pre-combustion CO₂ capture technologies on the power plants performance, different process configurations assembled from the superstructure in Figure 3.1 are analysed in a multi-objective optimisation. The objectives are to maximise the energy efficiency ϵ_{tot} and the overall CO₂ capture rate η_{CO_2} with regard to the decision variables given in Tables 2.3, 2.5, 2.6 & 3.2. For generating electricity two different options are considered according to the flowsheet in Figure 3.2. The H₂-rich fuel is either directly burnt in a gas turbine after the CO₂ removal by chemical or physical absorption, or the H₂-rich fuel is further purified by PSA and then supplied to the gas turbine. The trade-off between CO₂ mitigation, efficiency and cost is illustrated for electricity generating configurations including different pre-combustion CO₂ capture technologies in Figure 4.5. The efficiency decrease and the cost increase with the CO₂ capture rate is depicted.

Figure 4.5: Trade-off between CO₂ mitigation, energy efficiency and production cost for power plant configurations including different pre-combustion CO₂ capture technologies.

The different process options are compared in detail in the following sections. The comparison is based on configurations with around 90% CO₂ capture for the natural gas scenarios and around 60% for the biomass scenarios. For biomass feedstock, these kind of electricity generating plants are known as integrated biomass gasification combined cycle (IBGCC) plants. The performance results are summarised in Table 4.2 and Figures 4.6&4.7. For these compromise power plants configurations with pre-combustion CO₂ capture, the optimised operating conditions are reported in Appendix Table D.4.

The comparison of the performance results for the natural gas fed electricity generation process with pre-combustion CO₂ capture assessed in Section 3.4.4 with the simplified chemical absorption model and the one computed here with the detailed chemical absorption model clearly reveals the benefit of optimising the CO₂ capture unit design (Table 4.2: NG ATR BBA vs TEA). The simplified model allows to make a good preliminary estimation of the CO₂ capture penalty. However, by optimising the CO₂ capture design and integration the efficiency can be

4.4. Performance of electricity generating processes with different pre-combustion CO₂ capture technologies

improved by 2.5%-points and the production costs reduced by 25%.

Table 4.2: Performance of the compromise electricity generation configurations with pre-combustion CO₂ capture. The specific performances are expressed per GJ of electricity produced. The corresponding operating conditions are reported in Appendix Table D.4.

4.4.1 Influence of feedstock type

The performance of power plants with pre-combustion CO₂ capture is influenced by the feedstock type, being either fossil natural gas or renewable woody biomass. The biomass fed processes yield lower efficiencies than the natural gas based processes due to the lower biomass conversion (Figure 4.5). In order to satisfy the energy demand of the gasification, part of the process gas has to be burnt which reduces the amount of fuel sent to the gas turbine and consequently the electricity output (Table 4.2: BM Selexol and TEA). Considering a CO₂ capture rate of 60%, an efficiency around 36% can be reached by the IBGCC plant with physical absorption. CO₂ capture by physical absorption in an IBGCC plant yields a 1.4%-points higher efficiency than chemical absorption with TEA and 28% lower electricity production costs. The computed efficiencies are in the range of the IBGCC power plant efficiency reported in Carpentieri et al. (2005), Corti and Lombardi (2004) and Klimantos et al. (2009). In Carpentieri et al. (2005) an efficiency of 33.9% is assessed with CO₂ capture. The higher efficiency computed here can be explained by the improved quality of the process integration. The electricity production costs for biomass fed processes are much higher than for natural gas fed power plants (Figure 4.7), especially because of the higher investment costs related to the gasifier purchase. However, when a CO₂ tax is introduced, CO₂ capture in biomass based electricity generation processes becomes competitive since the captured CO₂ is biogenic which leads to a net gain from the tax as discussed more in detail in Chapter 8.

Chapter 4. Thermo-economic comparison of CO₂ capture technologies in pre-combustion CO₂ capture processes

Figure 4.6: Power balance for the different electricity generating configurations with pre-combustion CO₂ capture, reported in Table 4.2.

Figure 4.7: Production cost buildup for the different electricity generating configurations with pre-combustion CO₂ capture, reported in Table 4.2.

4.4. Performance of electricity generating processes with different pre-combustion CO₂ capture technologies

4.4.2 Influence of reforming technology

For the electricity generation from natural gas two different options can be considered to generate the syngas intermediate in the pre-combustion concepts, either SMR or ATR. The energy demand difference between both process configurations is illustrated in Figure 4.8 for 90% of CO₂ capture by chemical absorption with TEA (ATR TEA GT and SMR TEA GT). The endothermic steam methane reforming requires heat at high temperature which has to be satisfied by combustion. The electricity consumption of the SMR process is nearly half the one of the ATR process requiring air compression (Figure 4.6). These differences in the energy demand lead to a 6% lower net electricity production and a 3%-points lower efficiency for the SMR power plant with pre-combustion CO₂ capture (Table 4.2). Both process options yield comparable electricity production costs, since the resource purchase contributes to nearly 80% of the costs and the specific annual investment is comparable (Figure 4.7).

Figure 4.8: Integrated composite curves comparison for electricity generation from natural gas by SMR and ATR with 90% of CO₂ capture by chemical absorption with TEA (Table 4.2).

4.4.3 Influence of hydrogen purity

The Pareto frontiers in Figure 4.5 clearly show the performance difference between pre-combustion CO₂ capture processes burning pure hydrogen after PSA purification (>96%mol) and processes burning the H₂-rich fuel (65% mol) directly in a gas turbine after CO₂ removal. The detailed comparison between two natural gas based electricity generating process options burning pure H₂ after PSA (ATR TEA PSA GT) or burning the H₂-rich fuel after chemical absorption with TEA capturing 90% of the CO₂ (ATR TEA GT) allows to explain this difference. The energy integration result, reported in Figure 4.9, shows that more excess heat is available when H₂ purification is included which leads to a 15% higher electricity generation in the

Chapter 4. Thermo-economic comparison of CO₂ capture technologies in pre-combustion CO₂ capture processes

steam turbine. H₂ purification by PSA requires however a large amount of electricity for the compression which leads to an increase of the process power consumption around 50% (Figure 4.6). Since the increase in the electricity generation by high quality fuel combustion does not compensate the electricity consumption for purification, the energy efficiency is reduced by 15.5%-points. The lower electricity output leads to an increase of the electricity production costs around 25% (Figure 4.7). For the subsequent analyses it is hence focussed on pre-combustion power plants generating electricity by burning the H₂-rich fuel after CO₂ removal without an additional H₂ purification step.

Figure 4.9: Integrated composite curves comparison for electricity generation from natural gas with 90% of CO₂ capture by chemical absorption with TEA with and without H₂ purification by PSA (Table 4.2).

4.4.4 Influence of CO₂ capture technology

The comparison of the different CO₂ capture technologies that can be applied for pre-combustion power plants concepts yield similar conclusions as for the H₂ production processes. Taken as whole, the different technologies are competitive with regard to energetic, economic or environmental criteria, as reported in Table 4.2. Physical absorption allows to cogenerate more electricity, however the larger power consumption balances this effect and leads to comparable electrical production efficiencies. Physical absorption with Selexol and Rectisol are both competitive in terms of energy efficiency. The economic performance is highly dependent on the resource purchase price. The specific capital investment of the different options is in the same order of magnitude. Since the investment costs estimation takes into account the operating conditions, differences may occur for similar installations such as Selexol and Rectisol. All in all the differences are not significant with regard to the investment costs estimation error in the order of 30% according to Turton (2009). The competitiveness of these pre-combustion CO₂ capture concepts with regard to post-combustion CO₂ capture in

power plants depends mainly on the economic scenario as reported in detail in Chapter 8.

4.5 Conclusions

By applying the developed multi-objective optimisation strategy, the competitiveness of different H₂ production process and power plant configurations with pre-combustion CO₂ capture are compared with regard to thermodynamic, economic and environmental criteria. It is highlighted how the production purpose (i.e. H₂ or electricity) and the technology choices affect the performance. Due to the lower energy demand for solvent regeneration, physical absorption processes yield slightly lower efficiency losses for CO₂ capture, however the overall performance is comparable. With 90% of CO₂ capture, efficiencies around 52% are assessed for pre-combustion CO₂ capture processes using natural gas as a feedstock to generate electricity and around 80% for processes generating pure H₂, with production costs in the order of 25\$/GJ_e and 15\$/GJ_{H2} respectively. For biomass fed processes with around 60% of CO₂ capture the efficiency and the costs assessed for power and H₂ production plants are 36% and 47\$/GJ_e, respectively 60% and 29\$/GJ_{H2}. The environmental benefit of capturing biogenic CO₂ is assessed in detail by performing a life cycle impact assessment in Chapter 8. Moreover, the competitiveness of these pre-combustion CO₂ capture processes will be compared to post-combustion CO₂ capture processes for electricity generation in Chapter 8 and the influence of the resource price and the CO₂ tax will be evaluated.

5 Thermo-economic analysis of post-combustion CO₂ capture processes

After having studied pre-combustion CO₂ capture processes, post-combustion CO₂ capture options are evaluated here with the aim of making a consistent performance comparison in Chapter 8. Post-combustion CO₂ capture in natural gas combined cycle (NGCC) power plants has been investigated in the frame of the project "Technologies for gas turbine power generation with CO₂ mitigation" funded by Swisselectric research. The outcomes of this project have been published in Tock and Maréchal (2012e) and Griffin and Mantzaras (2012).

5.1 Introduction

With regard to climate change mitigation, post-combustion CO₂ capture is frequently mentioned because it can be applied to retrofit or new plant applications. However, one of the main issues of implementing post-combustion CO₂ capture in natural gas combined power plants is the efficiency decrease and the costs increase by the capture of low partial pressure CO₂. To overcome this, one proposed solution is to introduce flue gas recirculation (FGR) that increases the CO₂ concentration in the flue gas and reduces the volume of the flue gas to be treated in the CO₂ capture plant. Consequently, the efficiency and economics of CO₂ mitigation in gas turbine combined cycle power plants could be improved. This process including the gas turbine itself, the hydrogen production, the steam network and the CO₂ capture unit is studied and optimised here by applying the developed systematic thermo-economic modelling and optimisation approach without including fluid simulation of the turbomachinery. Different process configurations are investigated in order to study the impact of FGR on the compressors, turbines, combustion, CO₂ capture and the steam network. Single stage and reheat combustion processes without and with CO₂ capture are evaluated to define with regard to the thermodynamic efficiency and the economic performance the best options for an integrated electricity generating process with efficient CO₂ capture and low CO₂ avoidance costs. The impact of H₂ injection to stabilise the combustion has been studied by considering the integration of syngas production. The results of the combustion studies from Fachhochschule Nordwestschweiz (FHNW) are integrated to define the amount of H₂ required in the burner for flame stability purposes.

5.2 Post-combustion CO₂ capture process description

Post-combustion CO₂ capture in power plants is studied by focusing on a natural gas combined cycle with flue gas recirculation and CO₂ capture (i.e. chemical absorption), illustrated in Figure 5.1 for a reheat combustion process and in Appendix Figure B.6 for the single stage combustion gas turbine.

Figure 5.1: Process model of post-combustion CO₂ capture in an NGCC power plant with FGR.

5.3 Post-combustion CO₂ capture process modelling

The process models of the different process steps, being the gas turbine, the CO₂ capture and compression, and the steam network, are developed with different flowsheeting software. The connection between the different models is done by the material streams characteristics, namely composition, massflow, temperature and pressure as detailed in Figure 1.1. This application highlights again the usefulness of the special feature of the thermo-environmental modelling and optimisation framework which allows to set-up a process model by using parts developed with different flowsheeting software.

5.3.1 Power plant model

To study the combustion issues a modern, highly efficient, and low NO_x emitting machine (similar to the Alstom GT26 (Alstom)) has been considered to develop a generic reheat gas turbine model with sequential combustion. For comparison purpose a generic single stage combustion gas turbine model has also been developed. The gas turbine models are developed with the *Belsim Vali* (Belsim S.A.) software and illustrated in Appendix Figures B.5&B.6. The details of the gas turbine modelling and the operating parameters are reported in Appendix B (Tables B.1-B.4). The main modelling assumption defining the plant capacity is that the volumetric flowrate at the compressor inlet is constant ($\dot{V}=400\text{m}^3/\text{s}$) to maintain the velocity triangle in the compressor. The turbine inlet temperature is limited by the capacity of the blade cooling system and controlled by the air excess in the combustor. The temperature is set to 1100°C for the first turbine (LP) and to 1300°C for the second one (HP). To model the recirculation, the recirculation itself, a heat recovery steam generator and the H₂ injection have been included. The flue gas recirculation (FGR) ratio is defined as the molar ratio of

5.3. Post-combustion CO₂ capture process modelling

dry gas recycled to the total molar dry flow (after H₂O condensation). To address the flame stability concerns at high FGR, syngas can be injected. The syngas production is modelled by a high temperature oxygen separation membrane autothermal reforming reactor based on the same principles as in Section 3.3.1 (Appendix Figure B.7). The amount of H₂ to be added to the fuel is calculated based on measurements from FHNW that determined the amount of H₂ that is required as a function of the excess O₂ left after the combustion reported in Figure 5.2.

Figure 5.2: Fit of the FHNW data: amount of H₂ to be added for flame stability (Griffin and Mantzaras (2012)).

The results for pure H₂ and syngas injection have been fitted by Eqs.5.1 & 5.2, respectively.

$$x_{H_2}(x_{O_2}) = 0.6009 \cdot e^{(-0.4177 \cdot x_{O_2})} \quad (5.1)$$

$$x_{H_2}(x_{O_2}) = 0.4356 \cdot e^{(-0.3839 \cdot x_{O_2})} \quad (5.2)$$

where x_{O_2} is the volume fraction of O₂ in the flue gas and x_{H_2} the amount of H₂ required [kmol/kmol]. For the syngas case, this is the amount of H₂ after mixing of the syngas and the natural gas. The flowsheets of the gas turbine and the syngas production model are presented in Appendix Figures B.5-B.7. The main decision variables are given in Table 5.1.

Table 5.1: Decision variables and feasible range for optimisation for the NGCC plant.

Operating parameter	Range
FGR [-]	[0-0.56]
ATR temperature [K]	[1050-1300]
S/C [-]	[1.5-4]

5.3.2 CO₂ capture model

For separating the CO₂ generated in the combustion from the N₂ and excess O₂ contained in the exhaust gas, chemical absorption with monoethanolamine (MEA) is considered. The process model developed in *Aspen Plus* (AspenTech) is described in detail in Section 2.3.1. The captured CO₂ is compressed to 110 bar by a two stage compressor with intercooling modelled in *Belsim Vali* (Belsim S.A.).

5.3.3 Steam network model

The optimal steam network integration is defined in the energy integration model as explained in Girardin et al. (2009). Different headers are defined by the pressure, temperature, steam quality and the type being either production header (i.e. steam injection), usage header (i.e. steam distribution) or condensation header (i.e. steam is condensed and sent back to the HRSG). The steam network characteristics are detailed in Table 5.2 for both gas turbine configurations.

Table 5.2: Steam network characteristics for the NGCC plant (Li (2006)).

Steam cycle	GT simple		GT sequential	
	P [bar]	T [C]	P [bar]	T [C]
HP level	40	500.6	132	581.5
IP level			28.4	581.5
LP level	8	464.8	3	229.5
Condensation	0.06		0.05	

5.4 Performance evaluation of post-combustion CO₂ capture processes

The energy and economic costs of capturing CO₂ and the impact of CO₂ recirculation on the compressors, turbines, combustion, CO₂ capture and the steam network is assessed. The performance is expressed by the energy efficiency ϵ_{tot} (Eq.1.22), the electricity production costs COE, the CO₂ capture rate η_{CO_2} and the CO₂ avoidance costs (Eq.1.26). The modelled gas turbine configuration with reheat combustion without FGR and without CO₂ capture is considered as a reference plant in the CO₂ avoidance costs assessment in order to compare performances calculated on a common basis. For the economic estimations a yearly operation of 8000h/y is considered together with the assumptions in Table 1.2. The plant capacity is defined by the volumetric flowrate at the compressor inlet. Assuming a flowrate of 400 m³/s (Appendix Table B.2), this corresponds to a natural gas feed in the order of 560-580MW_{th,NG}. With regard to the gas turbine configuration, it is focused on the one with reheat combustion because it yields an around 7%-points higher efficiency and 10% lower electricity production costs than the single stage combustion gas turbine, as reported by the performance results in Table 5.3. The impact of post-combustion CO₂ capture and FGR is studied in detail hereafter for the gas turbine configuration with reheat combustion (Table 5.4).

5.4. Performance evaluation of post-combustion CO₂ capture processes

COE [\$/GJ _e]	21.1	19.02

5.4.1 CO₂ capture impact

The energy and cost penalty of the post-combustion CO₂ capture on the natural gas fuelled power plant performance is reported in Table 5.4. The comparison of the composite curves of the natural gas fuelled power plant without and with 85% CO₂ capture (no FGR) in Figure 5.3 clearly reveals the difference in the energy integration. The thermal energy demand for the solvent regeneration in the chemical absorption process leads to a reduction of the power cogeneration in the steam network of about 19MJ_e/GJ_{e,net}. The electricity consumption is increased due to the mechanical power requirement of the CO₂ capture unit (i.e. solvent pumping, blower) and of the CO₂ compressor. Consequently, the net electricity output with CO₂ capture is reduced by over 15%. This leads to a decrease of the overall energy efficiency from 58.8 to 49.9% without FGR. CO₂ compression to 110 bar accounts for 1.3%-points to the overall energy penalty of about 9%-points.

Figure 5.3: Integrated composite curve with steam network integration for the NGCC plant (no FGR) without (left) and with post-combustion CO₂ capture by chemical absorption (right).

Chapter 5. Thermo-economic analysis of post-combustion CO₂ capture processes

The reduced productivity leads together with the additional investment costs for the CO₂ capture and compression equipment to around 25% higher electricity production costs as detailed in Figures 5.4&5.5. The reduction of the CO₂ emissions to 17.7kg_{CO2}/GJ_e (without FGR) leads to CO₂ avoidance costs around 55.8\$/t_{CO2,avoided}. The dependence of the process competitiveness on the natural gas purchase price, which contributes to up to 80% of the COE (Figure 5.5), is investigated in detail in Chapter 8.

Table 5.4: Performance of the NGCC configurations without and with FGR and post-combustion CO₂ capture (natural gas price 9.7\$/GJ_{NG}, operation 8000h/y).

5.4.2 Flue gas recirculation impact

Sensitivity analyses have revealed that FGR does not considerably impact the process efficiency but improves the economics of CO₂ capture by increasing the CO₂ concentration in the flue gas illustrated in Figure 5.6 (left) and reducing therefore the CO₂ capture costs as reported in Table 5.4 and Figure 5.4.

The overall electricity production costs are however not significantly reduced with FGR since the natural gas purchase contributes to nearly 80% of the costs and the annual investment only to 10% as shown in Figure 5.5. The process efficiency is not affected considerably, since the higher natural gas consumption required for H₂ production to ensure combustion stability balances the slightly higher power output. Due to the emissions from the natural gas combustion satisfying the energy demands, the CO₂ capture rate decreases at very high FGR and the specific CO₂ emissions increase as reported in Figure 5.6 (left). This leads with regard to the CO₂ avoidance costs to an optimum FGR around 45%, illustrated in Figure 5.6 (right).

5.4. Performance evaluation of post-combustion CO₂ capture processes

Figure 5.4: Specific investment costs buildup for the different NGCC configurations without and with FGR and post-combustion CO₂ capture reported in Table 5.4.

Figure 5.5: Production cost buildup for the different NGCC configurations without and with FGR and post-combustion CO₂ capture reported in Table 5.4.

Figure 5.6: Influence of the FGR on the flue gas CO₂ concentration and the specific CO₂ emissions (left) and on the CO₂ avoidance costs (right) for the NGCC plant with 85% post-combustion CO₂ capture.

5.4.3 Multi-objective optimisation of post-combustion CO₂ capture processes

A multi-objective optimisation is performed in order to study the influence of the FGR together with the design of the CO₂ capture unit. Therefore, the electricity production costs COE are minimised and the CO₂ capture rate η_{CO_2} is maximised with regard to the decision variables in Tables 5.1 and 2.2. The results represented by the optimal Pareto curve in Figure 5.7 reveal the trade-off between the CO₂ capture rate and the COE. This is explained by the reduced electricity output due to the energy demand for solvent regeneration and CO₂ compression, and the increased capital costs for the capture equipment. For an increase of the CO₂ capture rate, the specific CO₂ emissions decrease and reach a minimum at around 85% of CO₂ capture. This translates to an optimum in the CO₂ avoidance costs as already noted by sensitivity analysis. This can be explained by the fact that the FGR is a decision variable and that at high FGR more syngas has to be produced leading to higher emissions. In the optimisation high FGR are favoured. CO₂ capture in a process configuration with 50% FGR reduces the efficiency by around 8%-points and increases the electricity production costs up to 20% compared to a conventional NGCC plant. This leads to CO₂ avoidance costs in the range of 48\$/t_{CO₂,avoided} with a natural gas price of 9.7\$/GJ_{NG}.

A detailed analysis of the electricity production costs shows that nearly 80% of the costs are due to the purchase of natural gas. Consequently, the resource price evolution has a big influence on the process competitiveness. Sensitivity analysis on the natural gas price highlights the impact on the electricity production costs and on the CO₂ avoidance costs. To reach the target of 25\$/t_{CO₂,avoided} (20€/t_{CO₂,avoided}) set by the GTCO₂ project (Griffin and Mantzaras (2012)) without a decrease of the investment costs, a natural gas price as low as 2.7\$/GJ_{NG} would be theoretically required which would lead to a decrease of the production of 2/3. However, the lowest realistic natural gas price that can be assumed according to the ZEP study (ZEP (2011)) is around 5.5\$/GJ_{NG}. Assuming a natural gas price of 5.5\$/GJ_{NG}, the target could also be reached by a decrease of the capital investment around 40%, respectively a 20%

5.4. Performance evaluation of post-combustion CO₂ capture processes

investment decrease and gas price of 4\$/GJ_{NG}. The introduction of a carbon tax will also improve the competitiveness of post-combustion CO₂ capture processes. These economic aspects are discussed in detail in Chapter 8.

Figure 5.7: Pareto optimal frontiers for different NGCC configurations with post-combustion CO₂ capture.

5.4.4 Energy integration improvement: District heating

The detailed analysis of the composite curve of the NGCC plant with CO₂ capture in Figure 5.3 (right) reveals that part of the excess heat could not be valorised by the steam network. These heat losses at around 80°C, removed by cooling water, have the right temperature to feed a district heating network and could consequently be valorised. Considering a district heating (DH) network with a supply temperature of 80°C and a return temperature of 50°C, Figure 5.8 illustrates the potential reduction of the energy losses. For this case, 46MW could be recovered for district heating. This allows to substitute the equivalent amount of natural gas, when one considers that a conventional boiler produces the same amount of heat from natural gas with an efficiency of $\eta_{boiler} = 85\%$. Taking into account this in the overall efficiency definition, expressed by Eq. 5.3, the district heating contribution would lead to an efficiency increase of 6%-points as reported in Table 5.5.

$$\begin{aligned}
 \epsilon_{tot,DH} &= \frac{\Delta \dot{E}^-}{\Delta h_{NG,in}^0 \cdot \dot{m}_{NG,in} - \Delta h_{NG,subs}^0 \cdot \dot{m}_{NG,subs}} \\
 &= \frac{\Delta \dot{E}^-}{\Delta h_{feed,in}^0 \cdot \dot{m}_{feed,in} - \frac{1}{\eta_{boiler}} \cdot \dot{Q}_{DH}^-} \quad (5.3)
 \end{aligned}$$

Considering that this heat could be sold at 120\$/MWh, the electricity production costs could be reduced by around 23%. For a yearly operation of 5000h/y the COE is increased by 7%. Around 81Mt_{CO2}/y could be avoided through the substitution of the emissions from conventional district heating. For CO₂ capture options, there is consequently a potential to recover excess heat for district heating. This analysis shows how the energy integration analysis allows to identify potential process improvements and optimal integrated process designs.

Table 5.5: Performance of the NGCC plant with 90% CO₂ capture with MEA without and with district heating DH (natural gas price 9.7\$/GJ_{NG}, operation 7500h/y).

	no CC	90% capture no DH	90% capture DH

$\epsilon_{tot,DH}$ [%]	58.7	49.6	55.5
CO _{2,emitted} [kg/GJ _e]	105.1	14.9	14.9 (10.3kg _{CO2,substituted} /GJ _e)
COE [\$/GJ _e]	18.8	23.7	18.4

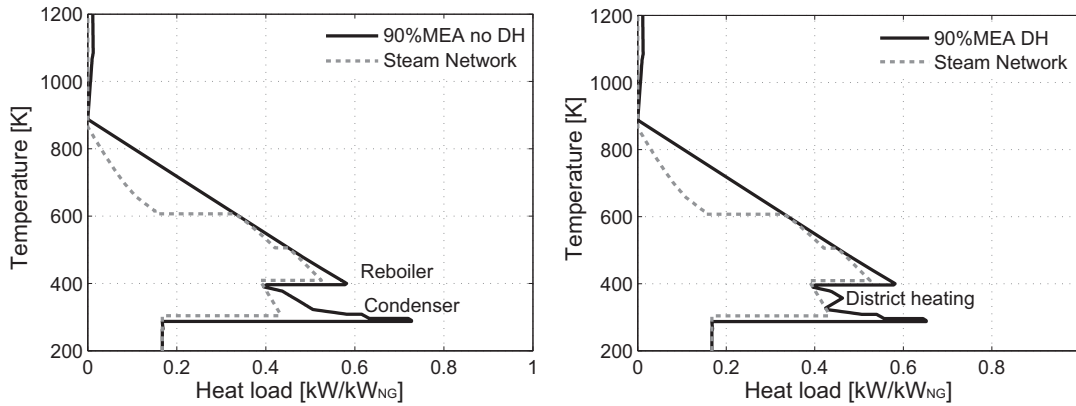

Figure 5.8: Integrated composite curves with steam network integration for the NGCC plant with 90% of post-combustion CO₂ capture without (left) and with district heating (right).

5.5 Conclusions

The systematic comparison and multi-objective optimisation of different NGCC process configurations with post-combustion CO₂ capture have shown that FGR does not impact considerably the process efficiency but improves the economics of CO₂ capture in gas turbine combined cycle power plants by increasing the CO₂ concentration in the flue gas and reducing the CO₂ capture cost and consequently the electricity production costs. Post-combustion CO₂ capture reduces the efficiency up to 9%-points and increases the production costs by around 25%. With 50% FGR, the CO₂ avoidance costs are decreased by more than 10% to around 47\$/t_{CO2,avoided} considering a natural gas price of 9.7\$/GJ_{NG}. The competitiveness of these processes reveals to depend on the resource price and on the introduction of a carbon tax, which is assessed in detail in Chapter 8.

6 Thermo-economic comparison of post-combustion CO₂ capture by amines and chilled ammonia

The large energy penalty of post-combustion CO₂ capture by chemical absorption with amines has been revealed in Chapter 5. As a promising alternative having a lower regeneration energy demand, the chilled ammonia process (CAP) developed by Alstom is studied here in more detail. In addition, it is highlighted how process improvements reducing the exergy losses can be identified by the detailed analysis of the composite curves.

6.1 Introduction

The chilled ammonia process is proclaimed to be a high-potential technology for CO₂ capture. The core process operations are the low temperature (0-10°C) absorption of CO₂ with an aqueous ammonia solution and the subsequent regeneration at higher temperature (Section 2.2.2). The main advantages are energy-efficient capture of CO₂, high purity CO₂, no degradation and low-cost globally available reagent (Alstom (2012)). Even if the chilled ammonia process benefits from a lower regeneration energy demand and from a higher pressure CO₂ product compared to amine processes, the process may become uncompetitive because of the large refrigeration loads required for the cooling down to the absorption temperature. According to Darde et al. (2010) a heat requirement lower than 2 GJ/t_{CO2} can be reached for the desorption at 90-110°C for specific rich-CO₂ loadings and ammonia concentrations. Jilvero et al. (2011) report a reboiler duty in the range of 2.2-2.8 GJ/t_{CO2}, which leads to an efficiency decrease in the power plant between 8-10%-points depending on the available cooling water temperature. They conclude that the chilled ammonia process is beneficial in processes where low grade heat is already available. Only a few studies evaluate the efficiency of the total power plant system, most focus on the chilled ammonia process itself. In these studies, conclusions are drawn principally based on thermodynamic analysis and no detailed energy integration and economic evaluations are performed. By applying the developed systematic methodology, the objective of this study is to compare the performance of the post-combustion CO₂ capture by chilled ammonia and amines, and to assess the trade-offs between CO₂ capture, energy

Chapter 6. Thermo-economic comparison of post-combustion CO₂ capture by amines and chilled ammonia

efficiency and economic penalty.

To compare the performance of the chemical absorption with MEA, studied in Section 5.4, with the chilled ammonia process for post-combustion CO₂ capture in an NGCC plant, the NGCC plant model previously described in Sections 5.3.1 (Figure 5.1) is combined with the chilled ammonia model that has been described in detail in Section 2.3. Typical operating conditions and design parameters of the chilled ammonia process illustrated in Appendix Figure B.2 are reported in Table 2.4. First a detailed comparison is made for a selected base case scenario with 50% FGR and 85% CO₂ capture and then a multi-objective optimisation is performed. The performance calculations are made for a plant capacity in the order of 580-590MW_{th,NG} of natural gas (i.e. fixed volumetric flowrate at the compressor inlet (Table B.2)) and for the economic assumptions given in Table 1.2. The results presented in Section 5.4 have been updated for a yearly operation of 7500h/y.

6.2 Post-combustion CO₂ capture process performance comparison: Amines versus chilled ammonia

The performance results of the different NGCC power plants configurations without and with post-combustion CO₂ capture by MEA or ammonia, capturing 85% of the emissions, are summarised in Table 6.1 and discussed in the following sections. The key process design parameters are based on literature data and are reported in Appendix Table D.5.

Table 6.1: Performance of NGCC power plants configurations without CO₂ capture and with 85% post-combustion CO₂ capture with MEA and chilled ammonia. The corresponding operating conditions are reported in Appendix Table D.5.

System	NGCC	Post-comb. MEA	Post-comb. CAP
Feed [MW _{th,NG}]	588.7	585.6	586.4
η_{CO_2} [%]	0	84.5	85.4
Power Balance			
Net power [MW _e]	328	294	293
$\dot{E}_{Consumption}^+$ [MJ _e /GJ _{e,net}]	-	97	124
$\dot{E}_{SteamNetwork}^-$ [MJ _e /GJ _{e,net}]	340	339	365
$\dot{E}_{GasTurbine}^-$ [MJ _e /GJ _{e,net}]	660	758	759
Performance (Assumptions Table 1.2)			
ϵ_{tot} [%]	58.7	50.2	50.02
CO ₂ emissions [kg _{CO2} /GJ _e]	105	15	14
Investment [\$/kW _e]	555	1028	1210
COE [\$/GJ _e]	18.3	23.8	24.6
Avoidance costs [\$/t _{CO2,avoided}]	-	61	69

6.2. Post-combustion CO₂ capture process performance comparison: Amines versus chilled ammonia

6.2.1 Energy integration

The difference in the energy demand of both processes can be clearly seen by the energy integration, illustrated by the composite curves in Figure 6.1. The shift in the reboiler duty and hence in the steam consumption from the steam network is depicted by the length of the plateau around 400 K. For the chilled ammonia process, the integration of the refrigeration cycle, cooling the the solvent down to the absorber temperature of 5°C, is detailed in Figure 6.2.

Figure 6.1: Composite curves with steam network integration for the NGCC plant with 85% of post-combustion CO₂ capture with MEA and CAP.

Figure 6.2: Integrated composite curve of the refrigeration unit in the NGCC configuration with post-combustion CO₂ capture by CAP.

The difference in the mechanical energy demands is reflected by the power balance reported in Figure 6.3. In the chilled ammonia process the steam network generates about $26\text{MJ}_e/\text{GJ}_{e,net}$

Chapter 6. Thermo-economic comparison of post-combustion CO₂ capture by amines and chilled ammonia

of electricity more, due to the lower steam consumption in the reboiler for the solvent regeneration. For the CO₂ compression to 110 bar, the power consumption is about 70% lower for the CAP process, since the reboiler operates already at 25 bar. However, the power consumption for the CO₂ capture is over 50% higher for the CAP process due to the electricity consumption in the refrigeration cycle, which translates into a 26MJ_e/GJ_{e,net} higher overall electricity consumption. To assess the trade-off between the reboiler duty and the refrigeration duty, the energy demands are expressed in terms of exergy in Table 6.2 considering an ambient temperature of 20°C.

Table 6.2: Specific exergy demands, expressed in GJ/t_{CO2}, of the CO₂ capture with MEA and chilled ammonia for the configurations reported in Table 6.1.

System	Post-comb. MEA	Post-comb. CAP
Reboiler duty [GJ/t _{CO2}]	0.823	0.579
Refrigeration duty [GJ/t _{CO2}]	0	0.408
CO ₂ compression [GJ/t _{CO2}]	0.345	0.085

The net electricity generation and the efficiency are comparable for both processes, since the benefits from the reboiler duty and the CO₂ compression are balanced by the refrigeration penalty of the CAP process. There is hence a trade-off between the steam consumption for the solvent regeneration and the electricity consumption for the refrigeration to 5°C in the present scenario. It is considered that cooling water is available at 20°C. When the plant is operated in an Northern country, cooling water at 5°C could be available (Jilvero et al. (2011)) and consequently the refrigeration penalty would be less important and the process competitiveness would be increased.

Figure 6.3: Comparison of the power balance for the NGCC plant with 85% post-combustion CO₂ capture by MEA and CAP (Table 6.1) (left). Zoom on the power consumption (right).

6.2.2 Economic performance

The economic performance of both processes is compared in Figure 6.4. The capital investment for the CAP process is about 18% higher due to the investment for the refrigeration unit (Figures 6.4 (left)). This translates into an electricity production costs increase of only 3%, since the resource purchase contributes to over 80% to the COE and the specific annual investment less than 10%, as detailed in Figure 6.4 (right). Consequently, these two post-combustion CO₂ capture process options yield similar performances and both technologies are competitive.

Figure 6.4: Comparison of the investment buildup (left) and of production cost buildup (right) for the NGCC plant with 85% post-combustion CO₂ capture by MEA and CAP (Table 6.1).

6.3 Multi-objective optimisation: Amines versus chilled ammonia

A multi-objective optimisation is performed to assess the performance and competition between post-combustion CO₂ capture with MEA and CAP in an NGCC plant. The CO₂ capture rate is maximised and the COE minimised with regard to the decision variables given in Tables 5.1 & 2.2 & 2.4. The results in Figure 6.5 reveal the trade-off between the CO₂ capture rate, the costs and the efficiency for the post-combustion with MEA and CAP.

For a CO₂ capture rate of 85%, both processes yield the same performance as discussed in the previous Section 6.2. At higher capture rates, post-combustion with MEA is more competitive than post-combustion with CAP. The MEA process yields higher efficiencies and lower costs than the CAP process, due to the trade-off between reboiler duty, refrigeration and CO₂ compression in the CAP process described in Figure 6.6. The reboiler duty of the CAP process increases with the CO₂ capture rate, which leads to a decrease of the electricity generation in the steam network. In addition, the benefit from the CO₂ compression is not sufficient to outweigh the increase of the refrigeration duty. Whereas for capture rates below 85%, the advantage from the CO₂ compression and the reboiler duty makes the CAP process more competitive than the MEA process for CO₂ capture in natural gas fed power plants. Consequently, the process competitiveness depends on the CO₂ capture rate and hence on the introduction of a carbon tax as discussed in Chapter 8.

Chapter 6. Thermo-economic comparison of post-combustion CO₂ capture by amines and chilled ammonia

Figure 6.5: Pareto optimal frontiers (left) and CO₂ capture - efficiency trade-off (right) for post-combustion CO₂ capture with MEA and CAP in an NGCC plant.

Figure 6.6: Trade-off along the Pareto optimal frontiers between the power consumption and the power generation by the steam network for the post-combustion CO₂ capture with MEA and CAP in an NGCC plant.

6.4 Chilled ammonia process improvement

The competitiveness of the CAP process reveals to depend on the refrigeration duty and consequently on the cooling utility for the absorption. The absorber and refrigeration unit integration and design are investigated here more in detail in order to assess the influence on the process performance and identify possible process improvements.

6.4.1 Energy integration improvement: Absorber design

In the previous studies, the absorber has been modelled as a single stage flash unit. The cooling down to the absorption temperature and the condensation heat load have been satisfied by a refrigeration cycle (compression heat pump) using ammonia as a refrigerant. Instead of removing all the heat at the lowest temperature (i.e. at the absorption temperature), it would be preferable from the energy integration point of view to cool down continuously and remove the condensation heat at different temperature levels, in such a way to reduce the exergy

losses and increase the process performance. The detailed analysis of the energy integration and the absorber design, reveal that this could be achieved by considering an absorption column with several stages operating at different temperatures, instead of one single flash separation unit. The absorption reaction being exothermic, the temperature increases and consequently the column has to be cooled down in order to improve the absorption rate. To take advantage of the temperature profile in the column with regard to the refrigeration, side cooling at each stage has to be introduced. The absorption column is modelled as a series of four flash units with recycling and heat exchange at each separator. This model is preferred to the detailed column simulation by a RADFRAC column because of convergence matters. In fact, the initialisation of the stage cooling in a RADFRAC column is quite difficult, especially if the aim is to optimise the heat removal at each stage. Whereas in the series of flash units model, the tearings of the cyclic streams converge better, even when changing the temperature levels. In order to model the column accurately by the series of flash separators, the gas and lean solvent are cooled down to the absorption temperature ($0-10^{\circ}C$). The temperature of the top stage flash unit and the temperature increase of the subsequent flash separators are decision variables, which are optimised in the multi-objective optimisation of the global system. The objectives are the minimisation of the COE and the maximisation of the CO_2 capture rate. The Pareto results are illustrated in Figure 6.7 and compared to the one reported in Figure 6.5 (single flash stage model). It can be seen that by improving the quality of the process integration, post-combustion CO_2 capture with chilled ammonia becomes more competitive at high capture rates. This highlights the importance of the quality of the process integration and its influence on the process competitiveness and the decision-making.

Figure 6.7: Pareto optimal frontiers (left) and power consumption (right) for the NGCC plant with post-combustion CO_2 capture by MEA and CAP modelled by a series of flash separators and a single stage flash.

Compared to the single flash modelling, the important difference is that the condenser duty has to be removed at higher temperature and could be satisfied completely or partially by conventional cooling water. Consequently, less cold utility has to be delivered by the refrigeration cycle and the electrical power demand is reduced and hence the efficiency increased and the COE reduced, as detailed in Figure 6.7. Since the flash units are optimised for each capture rate, the refrigeration power consumption is minimised for every point of the Pareto curve.

Chapter 6. Thermo-economic comparison of post-combustion CO₂ capture by amines and chilled ammonia

Compared to the single stage flash unit absorption model, the power consumption is reduced and does not increase considerably with the capture rate as shown in Figure 6.7 (right). For a capture rate of 90%, the improvement of the CAP process performance through process integration is reported in Table 6.3 and detailed by the composite curves in Figures 6.9-6.11.

Table 6.3: Performance comparison for NGCC power plants with 90% post-combustion CO₂ capture with MEA and chilled ammonia modelled by a single flash and a series of flash units. The corresponding operating conditions are reported in Appendix Table D.6.

System	Post-comb. MEA	Post-comb. CAP 1 Flash unit	Post-comb. CAP Flash series
Feed [MW _{th,NG}]	588.4	586.6	588.6
η_{CO_2} [%]	89.5	90.1	89.7
Power Balance			
Net power [MW _e]	291.8	274.2	299.9
$\dot{E}_{CO_2,capture}^+$ [MJ _e /GJ _{e,net}]	47.6	3.1	4
$\dot{E}_{Refrigeration}^+$ [MJ _e /GJ _{e,net}]	0	116.87	19.8
$\dot{E}_{CO_2,compression}^+$ [MJ _e /GJ _{e,net}]	38.1	10.8	5.8
\dot{E}_{POX}^+ [MJ _e /GJ _{e,net}]	22.5	18.5	15.1
$\dot{E}_{SteamNetwork}^-$ [MJ _e /GJ _{e,net}]	341.3	335.2	301.7
$\dot{E}_{GasTurbine}^-$ [MJ _e /GJ _{e,net}]	766.9	814	743
Performance (Assumptions Table 1.2)			
ϵ_{tot} [%]	49.6	46.7	50.9
CO ₂ emissions [kg _{CO2} /GJ _e]	14.9	8.7	8.5
Investment [\$/kW _e]	909	1259	785
COE [\$/GJ _e]	23.7	26.2	22.5
Avoidance costs [\$/t _{CO2,avoided}]	60	82	44

The change of the CO₂ capture unit integration in the NGCC plant is highlighted in Figure 6.8. The advantage of satisfying the condenser duty with cooling water is revealed by the lower energy requirement below the ambient temperature. The integrated composite curve of the refrigeration cycle highlights this difference as well in Figure 6.9. The cogeneration potential is represented by the steam network integration in Figure 6.10. The decrease of the electricity consumption for the refrigeration by 97MJ_e/GJ_{e,net} leads to an overall energy efficiency increase from 46.8 to 50.9% for a plant with 90% of post-combustion CO₂ capture.

6.4. Chilled ammonia process improvement

Figure 6.8: Comparison of the CO₂ capture unit integration for the NGCC plant with 90% of post-combustion CO₂ capture by CAP based on a single stage flash model (left) and on a series of flash units (right) (Table 6.3).

Figure 6.9: Comparison of the refrigeration integration for the NGCC plant with 90% of post-combustion CO₂ capture by CAP based on a single stage flash model (left) and on a series of flash units (right) (Table 6.3).

The detailed analysis of the power balance in Figure 6.11 highlights the decrease of the power consumption for the refrigeration, yielding a higher net electricity output and consequently a higher efficiency. Due to the decrease of the compression power, the capital investment and the electricity production costs are decreased from 26.2 to 22.5\$/GJ_e, as illustrated in Figure 6.12. Under these conditions the CAP process performs better in terms of energy efficiency and costs than the MEA process. For an NGCC plant with a capture rate of 90% the energy efficiency is increased by 1.3%-points for the CAP process compared to the MEA process and the COE is reduced by 1.2\$/GJ_e. This shows that the competitiveness of this process configuration highly depends on the process integration quality and on the available cooling utility for the chilled ammonia process. A sensitivity analysis on the cooling water temperature, reveals that the availability of low grade heat highly influences the performance of this CO₂

Chapter 6. Thermo-economic comparison of post-combustion CO₂ capture by amines and chilled ammonia

capture option. A decrease of 5°C of the available cold utility, would reduce the refrigeration power consumption by 22%. Consequently, this option is especially competitive in Northern countries.

6.4.2 Energy integration improvement: Refrigeration unit design

The preceding results have revealed that the refrigeration unit integration is a key element for the performance of the post-combustion CO₂ capture with chilled ammonia in an NGCC plant. Through a detailed analysis of the refrigeration unit integration, some additional improvements leading to a decrease of the exergy losses and an increase of the process performance, are identified. The analysis of the grand composite curve plotted in Carnot factor axis in Figure 6.13 (left) allows to identify the exergy losses by the area between the curve and the vertical axis. There are mainly three zones which can be depicted: at the level of the exhaust gas cooling at high temperature, of the CO₂ capture and of the refrigeration unit. At first the refrigeration unit integration is analysed in detail with the aim of identifying improvements that allow to reduce the exergy losses. The integrated composite curve of the refrigeration unit in Figure 6.13 (right), shows that these losses are due to the fact that the cooling utility is delivered by evaporation at constant temperature, while the streams have to be cooled down continuously from the ambient temperature to the absorption temperature.

In order to overcome this, it is proposed to insert a cooling cycle based on an ammonia-water mixture, illustrated in Figure 6.14. The major advantage of this cycle consists in the possibility of partially evaporating ammonia, due to the large boiling point difference between both compounds of the mixture. This leads in the H-T diagram to a slope for the evaporation, and not to a horizontal plateau at constant temperature as for the single compound evaporation. The main steps of this cycle are: expansion of the gas mixture, partial evaporation of ammonia, liquid-vapour separation, gas phase compression and liquid phase pumping, and mixing and condensation. The key decision variables are the ammonia concentration in the aqueous solution, the evaporation temperature and the cycle pressure.

Chapter 6. Thermo-economic comparison of post-combustion CO₂ capture by amines and chilled ammonia

Figure 6.13: Energy integration results for the NGCC plant with 90% post-combustion CO₂ capture with CAP modelled by a series of flash unit and including a refrigeration cycle with ammonia: Grand composite curve in Carnot factor axis (left). Integrated composite curve of refrigeration unit (right).

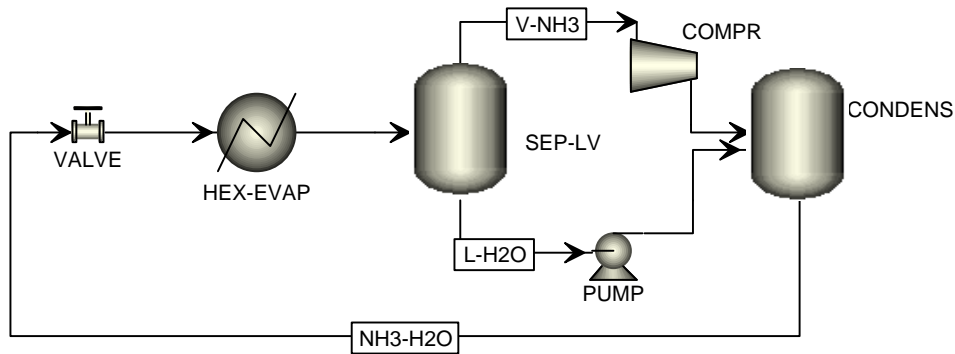

Figure 6.14: Refrigeration cycle using an ammonia-water mixture as refrigerant.

For the base case cycle, an aqueous solution with an NH₃ concentration of 62%mol, an evaporation temperature of 263.8 K and a condensation pressure of 7.8 bar have been considered. The performance results are summarised and compared in Table 6.4. The cycle performance is expressed by the coefficient of performance (COP) defined by the ratio of the cooling provided over the electrical energy consumption. As a comparison, the theoretical maximum thermal efficiency of a Carnot cycle operating between $T_H=268$ K and $T_C=293$ K is 8.5. In Figure 6.15 it is shown how this base case refrigeration cycle configuration affects the energy integration.

6.4. Chilled ammonia process improvement

Investment [\$/kW _e]	785	771	744
COE [\$/GJ _e]	22.5	22.3	21.85
Avoidance costs [\$/t _{CO2,avoided}]	44	41	36

Figure 6.15: Integrated composite curve of the ammonia-water refrigeration cycle for the NGCC plant with 90% post-combustion CO₂ capture with chilled ammonia (left) (Table 6.4: Refrig. NH₃-H₂O). Zoom below ambient temperature (right).

Looking in detail at the refrigeration integration in Figure 6.15 (right), it is noticed that the performance could still be increased by reducing the exergy losses. In fact, the optimal process design depends on the NH₃/H₂O ratio of the refrigerant and on the ΔT_{min} in the heat exchangers. The sensitivity analysis results in Figure 6.16, show how the NH₃ concentration influences the thermodynamic and economic performance. When reducing, the NH₃ concentration, the slope representing the evaporation in the H-T diagram changes and consequently the exergy losses can be reduced.

Chapter 6. Thermo-economic comparison of post-combustion CO₂ capture by amines and chilled ammonia

Figure 6.16: Influence of the ammonia concentration of the refrigerant on the performance of the NGCC plant with 90% post-combustion CO₂ capture with chilled ammonia including an ammonia-water refrigeration cycle.

The lowest exergy losses and consequently the highest thermodynamic efficiency can be reached with a low ΔT_{min} in the heat exchanger. The influence of the ΔT_{min} on the performance is illustrated in Figure 6.17. A low ΔT_{min} will lead to a large heat exchange area and consequently to high investment costs. There is a trade-off between the energy efficiency and the costs. With regard to the investment, the lowest cost is achieved for a $\Delta T_{min}/2$ of 2 yielding a good compromise between the heat exchanger and the compressor costs.

Figure 6.17: Influence of the ΔT_{min} in the refrigeration cycle heat exchangers on the performance of the NGCC plant with 90% post-combustion CO₂ capture with chilled ammonia including an ammonia-water refrigeration cycle.

6.4. Chilled ammonia process improvement

Based on these results, the optimal process design for the refrigeration unit is identified. This design is characterised by a $DT_{min}/2$ of 2, a NH_3 concentration of 42.3%mol in the refrigerant, an evaporation temperature of 291 K and a condensation pressure of 5.1 bar. Compared to the configuration with the ammonia refrigeration, this option leads to an efficiency increase from 50.9 to 52.3% and to a cost decrease of 0.65\$/GJ_e, as reported in Table 6.4 (Refrig. NH_3 vs Refriger. Opt. $\text{NH}_3\text{-H}_2\text{O}$). This performance increase is mainly related to the increase of the heat pumping coefficient of performance from 5.7 to 7.2. Figures 6.18 & 6.19 reveal the improvement in terms of energy integration and exergy losses reduction compared to the ammonia refrigeration cycle. Both refrigeration cycles have the advantage of using compounds that are used in the chilled ammonia process and so available in the plant.

Figure 6.18: Comparison of the grand composite curve in Carnot factor axis of the NGCC plant with 90% post-combustion CO_2 capture with chilled ammonia including an ammonia or ammonia-water refrigeration cycle (Table 6.4: Refriger. NH_3 and Refriger. Opt. $\text{NH}_3\text{-H}_2\text{O}$).

Figure 6.19: Comparison of the integrated composite curve of the ammonia and ammonia-water refrigeration cycle in the NGCC plant with 90% post-combustion CO_2 capture with chilled ammonia (left) (Table 6.4: Refriger. NH_3 and Refriger. Opt. $\text{NH}_3\text{-H}_2\text{O}$). Zoom below ambient temperature (right).

Chapter 6. Thermo-economic comparison of post-combustion CO₂ capture by amines and chilled ammonia

Pursuing the same strategy, additional improvements can be identified by the analysing Figure 6.18. The remaining exergy losses have already been depicted in Figure 6.13. In addition to these, the steam network integration can be improved by adjusting the steam condensation level to the cooling water temperature. This allows to slightly increase the electricity generation by the steam expansion and consequently the efficiency. By applying the same heat pumping principle, as for the refrigeration unit, the integration of the CO₂ capture unit can be improved by transferring heat from the lean solvent and the CO₂ cooling to the stripper to satisfy the reboiler duty. When introducing a compression heat pump using a NH₃/H₂O solution with an optimised NH₃ concentration of 87%mol and improving the steam network integration, the energy efficiency is increased by 0.38%-points to 52.64% and the COE is increased by 0.4\$/GJ_e as reported in Table 6.5 (EI Opt. NH₃/H₂O). The electricity generation by the steam network is increased by about 31.6MJ_e/GJ_{e,net} through the heat pumping consuming about 26MJ_e/GJ_{e,net}. The additional investment of the heat pumping is around 126\$/kW_e. The improvement of the energy integration is highlighted in Figure 6.20 by the reduction of the exergy losses.

Figure 6.20: Comparison of the grand composite curve in Carnot factor axis of the NGCC plant with 90% post-combustion CO₂ capture with chilled ammonia including an ammonia-water refrigeration cycle and heat pumping (left). $\dot{E}_{SteamNetwork}^-$ [MJ _e /GJ _{e,net}]	313.97	345.60	376.77
$\dot{E}_{GasTurbine}^-$ [MJ _e /GJ _{e,net}]	727.98	722.73	716.96
Performance (Assumptions Table 1.2)			
ϵ_{tot} [%]	52.26	52.64	53.06
Investment [\$/kW _e]	744	870	968
COE [\$/GJ _e]	21.85	22.26	22.53
Avoidance costs [\$/t _{CO₂,avoided}]	36	40	43

The alternative is to do a mechanical vapor recompression of sub-atmospheric pressure steam that is evaporated to recover the low temperature heat available, similar to the CO₂ capture integration improvement discussed in Section 3.4.2 for H₂ production plants. The heat pumping improves the overall energy efficiency to 53.1% and increases the COE by 2.3% compared to the configuration without heat pumping (Table 6.5:Refrig. NH₃/H₂O and EI Opt. MVR). The electricity generation by the steam network is increased by about 62.8MJ_e/GJ_{e,net} through the heat pumping consuming about 52MJ_e/GJ_{e,net}. The additional investment of the heat pumping is around 224\$/kW_e. Figure 6.21 shows the improvement of the energy integration. The exergy losses decrease is highlighted by the grand composite curve plotted in Carnot factor axis in Figure 6.21 (left). This alternative performs better since more heat can be transferred, which increases the electricity cogeneration by the steam network. For the heat pumping with NH₃/H₂O the lower temperature is limited by the process design and operating conditions. To improve the integration further one option which could be studied is a multiple stage heat pump system.

This step by step approach based on the results analysis shows how process improvements can be identified and optimal process configurations designed based on the optimisation results. This detailed analysis points out that the competitiveness of the chilled ammonia process highly depends on the quality of the process integration, especially of the absorber and the refrigeration utility. Compared to the chemical absorption with amines, this option reveals to be promising for post-combustion CO₂ capture concepts.

Chapter 6. Thermo-economic comparison of post-combustion CO₂ capture by amines and chilled ammonia

Figure 6.21: Comparison of the grand composite curve in Carnot factor axis of the NGCC plant with 90% post-combustion CO₂ capture with chilled ammonia including an ammonia-water refrigeration cycle and MVR (left). Integrated composite curve of the MVR in the NGCC plant with 90% post-combustion CO₂ capture with chilled ammonia (right).

6.5 Conclusions

The chilled ammonia process is proclaimed to be a promising alternative to post-combustion CO₂ capture with chemical absorption with amines in NGCC plants. The main advantage is the lower energy requirement for solvent regeneration in the CAP process. However, there is a trade-off between the energy benefit from the reboiler duty and the CO₂ compression, and the energy consumption for refrigeration to the absorption temperature (0-10°C). The consistent comparison and multi-objective optimisation of both options with regard to the energy and cost penalty of post-combustion CO₂ capture reveals that the process integration quality and the ambient temperature and availability of low grade heat are major concerns for the competitiveness of the chilled ammonia process. When the refrigeration integration is not optimised, the MEA process performs better at capture rates above 85%, since the refrigeration penalty outweighs the benefits from the CAP process. However, when the integration of the absorption column and the refrigeration are improved the CAP process becomes more competitive than the MEA process for each capture rate because of the lower reboiler duty and the lower CO₂ compression work. The energy efficiency of 49.6% for an NGCC plant with 90% post-combustion CO₂ capture with MEA can be increased to around 52.3% with the chilled ammonia process and the COE decreased from 23.7 to 21.8\$/GJ_e. This increase of the efficiency results from the 29MJ_e/GJ_{e,net} lower CO₂ compression power and the lower energy demand for the CO₂ capture outbalancing the electricity consumption for the refrigeration being in the order of 13.8MJ_e/GJ_{e,net}. By applying a systematic approach, it is shown how potential process improvements can be identified from the optimisation results by analysing in detail the energy integration results. For natural gas fired power plants applications, the competitiveness of these two technologies is consequently primarily defined by the technology availability and the economic scenario discussed in Chapter 8.

7 Process design optimisation strategy to develop energy and cost correlations of CO₂ capture processes

In the previous chapters the integration of CO₂ capture in power plants is studied and optimised. The optimisation of such complex integrated energy systems is quite time consuming, therefore the goal is here to develop a methodology to set-up simpler parameterised models of the CO₂ capture process. This approach presented in Tock and Maréchal (2012d) has been applied to study post-combustion CO₂ capture by chemical absorption with amines.

7.1 Introduction

To evaluate the impact of CO₂ capture on the power plant performance, thermodynamic, economic and environmental aspects have to be considered. When these analyses are performed by applying computer-aided tools as presented in the previous chapters, some challenges arise especially with regard to the computation time. Changing the design conditions of the ab- and desorption columns together with the flow of amines reveals to be sensitive to convergence and heavy in computation time, especially when the optimisation is to be done together with the variation of the CO₂ concentration and with the purpose of finding the best economical design from the CO₂ capture point of view. Recent studies have investigated the potential of replacing complex unit models of highly non-linear processes by compact yet accurate surrogate models reproducing the results of the rigorous model in a fraction of the simulation time without losing accuracy (Sipocz et al. (2011), Henaou and Maravelias (2010, 2011), Biegler and Lang (2012)). In Biegler and Lang (2012) it is shown how reduced order models based on flowsheet optimisation can increase the efficiency of energy processes.

The idea is to develop an approach for setting-up a blackbox model of the CO₂ capture unit predicting the investment, as well as the heat demands and their temperature levels required for the combined heat and power integration model, by using correlations and neural networks that are set up from the optimisation results of the complex first-principle CO₂ capture unit model described in Section 2.3.1. The advantage of this approach with regard

Chapter 7. Process design optimisation strategy to develop energy and cost correlations of CO₂ capture processes

to the optimisation problem formulation is that the optimised CO₂ capture subproblem can be introduced in a larger process to perform optimisations of the global problem, and with regard to energy integration, that information about the heat demand and the temperature levels are conserved. This approach is applied to study flue gas recirculation (FGR) and CO₂ capture (CC) in NGCC power plants described and discussed in detail in Chapter 5.

7.2 Process design optimisation strategy

The approach to develop a simpler parameterised model of the CO₂ capture unit (i.e. subproblem) to be used in the overall process design optimisation (i.e. global problem) is implemented using process design techniques combining process modelling with established flowsheeting tools, and process integration in a multi-objective optimisation framework as illustrated in Figure 7.1. The thermo-economic modelling methodology follows the principles explained in Chapter 1.

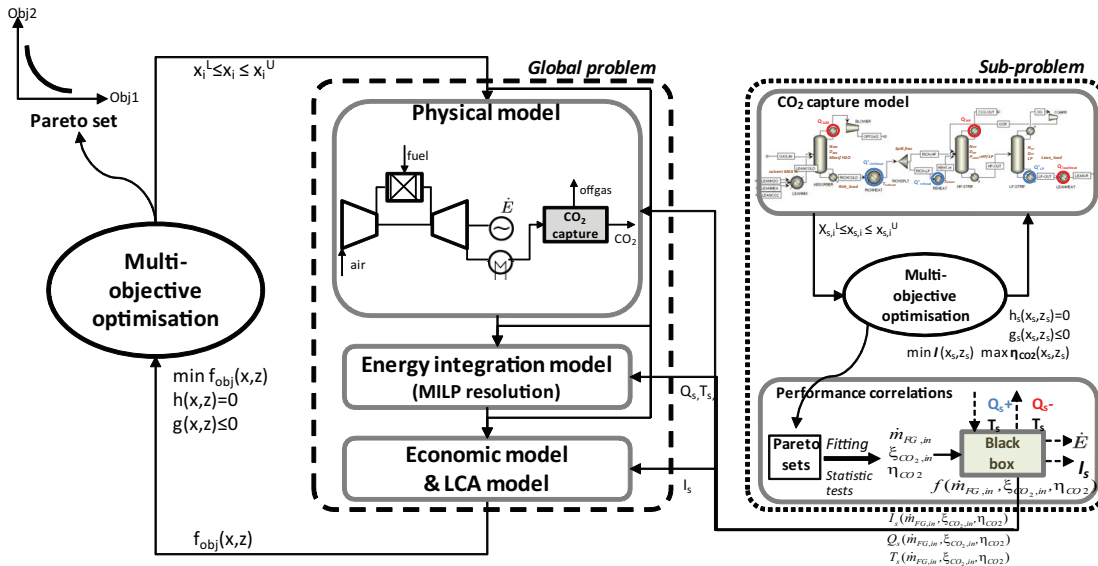

Figure 7.1: Illustration of the process optimisation strategy to develop simpler parameterised CO₂ capture models.

The strategy is illustrated by the development of a simplified model for CO₂ capture by chemical absorption with amines. The developed first-principle CO₂ capture model corresponds to the one described in Section 2.3.1 (Figure 2.3). CO₂ compression to 110 bar is not included in the capture unit itself, but accounted in a separate model. A CO₂ purity of over 98%wt is targeted from a typical post-combustion flue gas consisting mainly of N₂, CO₂, excess O₂ and water. The CO₂ capture unit performance is expressed by the investment cost I , the CO₂ capture rate ($\eta_{CO_2} = \frac{\dot{n}_{CO_2, captured}}{\dot{n}_{CO_2, inFG}}$) and the energy demand (i.e. reboiler duty \dot{Q}_{LP} , electricity \dot{W}) and is mainly influenced by the design decision variables given in Table 2.2.

The selected input variables for the simpler parameterised blackbox model reflecting the process behaviour are the flue gas mass flow (\dot{m}_{FG}) and the CO₂ concentration in the flue gas (ξ_{CO_2}) as illustrated in Figure 7.2. The absorber inlet temperature and pressure are kept constant by a blower and heat exchanger. The only decision variable is hence the CO₂ capture rate (η_{CO_2}). Consequently, the number of decision variables of the overall process is smaller than the one for the subproblem since some parameters are internal to the blackbox system. The output parameters of the blackbox model are the investment, mechanical and thermal energy demand and the associated temperature levels.

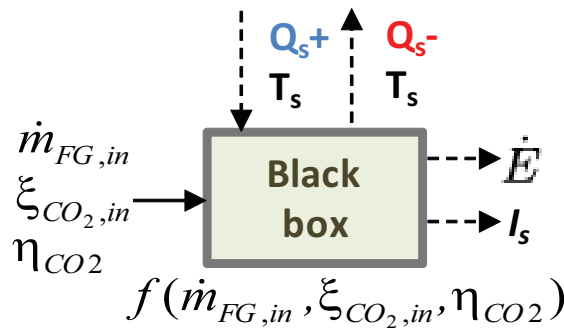

Figure 7.2: Blackbox model of the CO₂ capture process.

7.2.1 Subproblem optimisation

For different flue gas compositions (ξ_{CO_2} : 0.065, 0.074, 0.081 and 0.09wt-) and flows (\dot{m}_{FG} : 655, 955, 1455, 1955, 2455 and 2955 t/h) an optimisation of the CO₂ capture subproblem is first performed. The multi-objective optimisation problem is solved by applying an evolutionary algorithm computing a set of optimal solutions in the form of a Pareto front. The objectives are to maximise the CO₂ capture rate η_{CO_2} and to minimise the capital investment I with regard to the decision variables in Table 2.2. It is assumed that the objectives are not influenced by the pressure drop and the heat load. It has been demonstrated by sensitivity analyses that minimum pressure drops and heat loads are correlated with the maximum CO₂ capture rate. Consequently, the assumption is valid and the optimum of the subproblem is contained in the optimum of the global problem. The Pareto optimal frontiers computed for the different process configurations are illustrated in Figure 7.3. The influence of the flowrate on the equipment size and consequently on the investment is strongly reflected. Moreover, the investment is slightly affected by the CO₂ capture rate. Based on these optimisation results of the first-principle MEA unit model, the goal is to develop a simplified parameterised blackbox model described in Figure 7.2.

Figure 7.3: Pareto optimal frontiers showing the trade-off between investment and CO₂ capture rate for different \dot{m}_{FG} and ξ_{CO_2} in chemical absorption with MEA.

7.2.2 Surrogate model development

By fitting the generated Pareto fronts reported in Figure 7.3, regression correlations and neural networks are defined to predict the thermo-economic performance of the CO₂ capture unit with regard to the input variables η_{CO_2} (x_1), \dot{m}_{FG} (x_2) and ξ_{CO_2} (x_3). Statistical tests are carried out to validate the proposed correlations. The F statistic is applied to test the model validity against the assumption that at least one coefficient of the correlation is significant. In addition, the validity of each coefficient is verified by the t -test following a Student's t distribution, if the null hypothesis is supported. The approach is illustrated here explicitly for setting up the investment cost correlations. The development of the correlations for the mechanical power, the heat load and the temperature levels follows the same approach (Appendix F).

CO₂ capture investment cost correlation

The goal is to develop a correlation of the investment I with regard to the input variables: $I=f(\eta_{CO_2}, \dot{m}_{FG}, \xi_{CO_2})=f(x_1, x_2, x_3)$. It is to note that the developed correlations for the investment cost do not follow the conventional cost estimation approach since they deal with the optimised investment computed from simulation with regard to certain decision variables. Three different approaches for fitting are discussed here and the detailed models are reported in Appendix F.

Polynomial fit. In a first attempt, multi-dimensional polynomial correlations are set up. Therefore, correlations are drawn for each data series with fixed ξ_{CO_2} ($I=f_{\xi_{CO_2}}(\eta_{CO_2}, \dot{m}_{FG})$) based on Eq.7.1 yielding for each one coefficient of determination values (R^2) around 0.98. According to the statistical tests, additional terms do not improve the goodness of fit. To include the variation with regard to ξ_{CO_2} , a linear variation of the coefficients p_i in Eq.7.1 ($p_i = \kappa_{i,1} + \kappa_{i,2}\xi_{CO_2}$) is first assumed. The statistical tests results reported in Table 7.1 show that some terms are not significant which leads to the final expression given by Eq.7.2.

$$f_{x3}(x_1, x_2) = p_{00} + p_{10}x_1 + p_{01}x_2 + p_{20}x_1^2 + p_{11}x_1x_2 \quad (7.1)$$

$$f(x_1, x_2, x_3) = k_0 + k_1x_1 + k_2x_2 + k_3x_1x_2 + k_4x_1x_3 + k_5x_2x_3 + k_6x_1x_2x_3 + k_7x_1^2x_3 \quad (7.2)$$

Table 7.1: Regression results for the investment cost correlation leading to Eq.7.2. ($t_{0.95}[1538]=1.96$, $F_{0.95}[7;1538]=3.23$)

	cst	x_1	x_2	x_3	x_1x_2	x_1x_3	x_2x_3	$x_1x_2x_3$	x_1^2	$x_1^2x_3$	R^2	F-value
Coefficient	33.663	-117.33	-1.93E-5	0	1.2E-4	-366.04	4.7E-4	-4.5E-4	0	796.38	0.977	9565
t-value	-	-12.18	-3.38	1.64	14.4	-2.87	7.53	-4.7	0.45	6.2		
pvalue	-	1.16E-32	7.4E-4	0.099	3.2E-44	0.004	8.3E-14	2.8E-6	0.65	6.6E-10		

Shortcut fit. In a second attempt, a correlation based on a shortcut model including the known physical relations in the absorption and desorption columns is set up. The number of stages is related to the absorbed fraction through the Kremser equation (Eq.7.3) assuming stage equilibrium instead of rate-based model, which allows together with the flue gas mass flowrate (\dot{m}_{FG}) to estimate the diameter (d) and height (h) through column design heuristics and consequently the investment costs I according to Eqs. 7.4-7.6. The constant parameters in these functions are defined by solving a minimisation problem in the least-square sense. A hybrid method combining mathematical programming and evolutionary algorithm for finding a good initial point has been used for this purpose.

$$N = a_1 \cdot \log\left(\frac{a_2}{1 - \eta_{CO_2}} + a_3\right) + a_4 \quad (7.3)$$

$$d = f(\dot{m}_{FG}, \xi_{CO_2}) \quad (7.4)$$

$$h = f(N, d) \quad (7.5)$$

$$I = f(h, d) \quad (7.6)$$

Neural network. As a last approach, the neural network (NN) fitting tool from MATLAB (MathWorks Inc.) using the Levenberg-Marquardt backpropagation algorithm for network training is applied on the optimisation results dataset (i.e. training 55% of data, validation 25%, testing 20%). The two-layer feed-forward network with sigmoid hidden neurons and linear output neurons, illustrated in Figure 7.4, is well suited to fit such multi-dimensional

mapping problems.

Figure 7.4: Scheme of the neural network.

Fitting results The goodness of fit of these approaches is compared in Figure 7.5 for the capital investment. The different fits give a good estimation of the capital investment costs.

Figure 7.5: Fitted investment (Polynomial fit - polyfit Eq.7.2, fit based on shortcut model - shortcut fit, neural network - NN) versus calibration optimisation results.

Heat load and power consumption correlation

Following the same approach as for the investment cost estimation, correlations are developed for each heat load and for the overall energy consumption. For the polynomial fits the validity of each term is verified by statistic tests and for the neural networks the MATLAB (MathWorks Inc.) fitting tool is used. The details of these correlations are reported in Appendix F.

7.3 Application: NGCC with post-combustion CO₂ capture

To illustrate the approach, the integration of post-combustion CO₂ capture in power plants is studied. Therefore, the developed parameterised CO₂ capture blackbox models are integrated with a natural gas fired power plant model to optimise the process design with CO₂ capture as illustrated in Figure 7.1. The investigated process consists of a natural gas reheat gas turbine combined cycle with flue gas recirculation (FGR) and CO₂ capture studied in Chapter 5. The performance of the overall process comprising the integration of the parameterised CO₂ capture models is compared based on thermo-economic considerations assessing also the energy and economic costs of capturing CO₂ and the impact of CO₂ recirculation. For the economic performance evaluation the assumptions given in Table 1.2 are considered.

7.3.1 Base case comparison

The performance of the post-combustion CO₂ capture in the NGCC power plant is first assessed with the first-principle MEA model and then compared with the results obtained with the different blackbox models. For these base case configurations around 50% of FGR and 85% CO₂ capture are considered. The performance results are summarised in Table 7.2 and compared to a conventional NGCC plant without CO₂ capture. CO₂ capture decreases the efficiency by over 8%-points and increases the production costs by up to one third. These results are in the same range as the one given in Finkenrath (2011) reporting for a conventional NGCC an efficiency of 56.6%, CO₂ emissions of 102.8kg_{CO2}/GJ_e and COE of 21.3\$/GJ_e and for a NGCC with post-combustion CO₂ capture an efficiency of 48.4%, CO₂ emissions of 15.3kg_{CO2}/GJ_e and COE of 28.3\$/GJ_e.

Table 7.2: Performance results of the base case NGCC plant configurations with 85% post-combustion CO₂ capture based on the first-principle MEA model and on different blackbox models.

Scenario	η_{CO_2} [%]	ϵ_{tot} [%]	CO ₂ emitted [kg/GJ _e]	COE [\$/GJ _e]	Avoidance costs [\$/t _{CO₂,avoided}]
NGCC	0	58.75	105.08	18.32	-
MEA model	85.11	50.3	12.92	22.92	49.89
Polyfit	86.9	47.78	13.85	24.44	67.05
Shortcut fit	86.9	47.78	13.85	24.35	66.05
NN	86.9	46.70	14.17	24.97	73.11

The comparison of the results obtained with the first principle model with the one obtained with the blackbox model yields a difference in the production costs around 6% and in the efficiency of around 5%. This difference is essentially due to the overestimation of the reboiler duty in the blackbox models, as it can be seen on the composite curves in Figure 7.6.

The blackbox models overestimate the penalty of CO₂ capture on the power plant performance slightly. However, these simplified parameterised models reproduce the major trends and allow to reduce the computation time significantly as shown in Table 7.3. The shortcut fit

Chapter 7. Process design optimisation strategy to develop energy and cost correlations of CO₂ capture processes

including known physical relations performs slightly better than the other ones. Consequently, these simplified models allow to make a preliminary analysis of CO₂ capture process options.

Figure 7.6: Comparison of the composite curves with steam network integration for the base case scenarios reported in Table 7.2.

Table 7.3: Computation time comparison for multi-objective optimisation of post-combustion CO₂ capture in the NGCC plant based on the first-principle MEA model and on different blackbox models (400 evaluations and initial population of 30).

Scenario	time 1 run [h:mm:ss]	time moo [h:mm:ss]
MEA model	0:01:57	10:08:33
BB Polyfit	0:01:05	4:54:32
BB Shortcut fit	0:01:03	4:56:17
BB NN	0:01:04	4:59:11

7.3.2 Global problem optimisation

To study the influence of CO₂ capture and flue gas recirculation on the power plant performance in more detail, a multi-objective optimisation of the global problem is performed. The objectives are the minimisation of the electricity production costs (COE) and the maximisation of the overall CO₂ capture rate (η_{CO_2}). The decision variables for the power plant are the flue gas recirculation and in the case where syngas has to be injected the hydrogen production temperature and the steam to carbon ratio. Since the flue gas flowrate and the CO₂ concentration are defined by the power plant model, the number of decision variables for the parameterised CO₂ capture model is reduced to one, the CO₂ capture rate, compared to 15

7.3. Application: NGCC with post-combustion CO₂ capture

for the first principle MEA model (Table 2.2). By using the blackbox models calibrated on the subproblem optimisation results for the optimisation of the global system, the hypothesis is made that for a given CO₂ capture rate the optimal solution corresponds to the minimal investment. The generated Pareto fronts in Figure 7.7 reveal the trade-off between the CO₂ capture rate and the electricity production costs. This trade-off is explained by the reduced electricity output due to the energy demand for solvent regeneration and CO₂ compression yielding a lower efficiency, and the increased capital investment costs for the capture equipment.

Figure 7.7: Pareto optimal frontiers of the global problem optimisation based on the first-principle MEA model and on different blackbox models.

Compared to the optimisation problem results including the first-principle MEA unit model (MEA model), the accuracy is nearly maintained for the problems including the different blackbox models up to 87% of CO₂ capture as illustrated by Figure 7.7. The comparison of the results in Table 7.4 for compromise Pareto solutions yielding a CO₂ capture rate of 87%, shows that the generated process configurations are similar. In fact, the optimised values of the FGR differ by less than 2%. For a chosen process configuration, the detailed CO₂ capture unit design can be recomputed subsequently based on the first principle CO₂ capture model. The values of the required input parameters defined in Table 2.2 can be approximated by interpolation from the data series used for the blackbox models calibration (Section 7.2.1) based on a griddata approach. The overall performance, design and operating conditions assessed in this way for the compromise configurations obtained through optimisation of the power plant with the parameterised CO₂ capture models are very close to the one resulting from the optimisation with the first principle CO₂ capture model. This high concordance is shown by the composite curves in Figure 7.8. This reveals that the subproblem optimum is included in the global problem optimum for solutions having a CO₂ capture rate below 87%.

Chapter 7. Process design optimisation strategy to develop energy and cost correlations of CO₂ capture processes

Table 7.4: Performance of the compromise NGCC plant configurations with 87% post-combustion CO₂ capture based on the first-principle MEA model and on different blackbox models.

Scenario	η_{CO_2} [%]	ϵ_{tot} [%]	CO ₂ emit [kg/GJ _e]	COE [\$/GJ _e]	Avoidance costs [\$/t _{CO₂,avoided}]	FGR [-]
NGCC	0	58.75	105.08	18.32	-	0
MEA model	86.94	50.28	16.16	22.80	50.35	0.539
Polyfit	87.02	50.29	12.93	23.20	52.93	0.528
Shortcut fit	87.16	50.6	13.23	22.90	49.90	0.543
NN	87.45	49.90	13.44	23.30	54.40	0.522

Figure 7.8: Composite curves for the compromise scenario generated by the first principle MEA model through optimisation and through recomputation of the parameterised polynomial model with the detailed MEA model.

At high CO₂ capture rates, there is however a divergence in the solutions. The optimisation of the power plant performance with the parameterised CO₂ capture models leads to process designs with low FGR (<12%), while the optimisation with the first-principle CO₂ capture model favours FGR above 50% at high CO₂ capture rates. This difference in the design of the power plant leads to a different design of the CO₂ capture unit due to the changes in the CO₂ concentration and the flue gas flow rate. Consequently, the assessed efficiencies and costs diverge. When recomputing the solution generated by the parameterised blackbox model with the first principle MEA model, a process design with a lower CO₂ capture rate (83% instead of 90%), higher efficiency and lower production costs is obtained. This indicates that the hypothesis that the subproblem optimum is included in the global problem optimum is not valid for high CO₂ capture rates. In fact, there is a compromise between the investment and the energy demands, which both affect the production costs. Consequently, it is possible to find for a given CO₂ capture rate a solution with a higher capital investment yielding a higher efficiency and lower COE. By recalculating the optimal solution found with the first-principle model with

the parameterised model, the solution yields higher specific production costs per ton of CO₂ captured than the optimal solution found with the parameterised model. This explains why this solution has not been retained during the optimisation with the parameterised model. In fact the parameterised model cannot find this solution. In order to reflect this behaviour in the parameterised blackbox models, a solution would be to calibrate these models on the minimisation of the production costs accounting the heat demand at its exergy value, or on the minimisation of the exergy losses instead of the investment. Once the Pareto sets are generated with the modified objective function, the blackbox models of the CO₂ capture unit can be set up following the approach described here. The hypothesis of the optimality of the subproblem in the global problem has hence to be valid in order to take advantage from the reduction of the number of decision variables of the parameterised model in the global problem optimisation.

Using the simple blackbox models in the global problem optimisation, has the advantage of reducing the computation time considerably once the simplified model is set up. If the same number of evaluations is considered for each optimisation problem the computation time is reduced over 45%, as reported in Table 7.3. However, because of the changes in the number of decision variables, the number of evaluations for reaching a same level of convergence is different. It is noted that for the optimisation of the power plant with the first principle MEA model the convergence of the Pareto front is not considerably improved between 400 and 2000 evaluations. While for the optimisation of the power plant with the parameterised CO₂ capture model convergence is nearly reached around 180 evaluations for a same initial population. By taking into account the reduction of the number of evaluations in the optimisation, the use of the parameterised model leads to an additional computation time decrease which favours the use of this kind of simplified models in optimisation problems formulations. Consequently, such a quick first optimisation is appropriate for the preliminary design and evaluation of process options with CO₂ capture.

7.4 Conclusions

A strategy applying multi-objective optimisation for developing energy and cost correlations of CO₂ capture process units is presented. The advantage of this approach is that the simple parameterised models are developed based on optimisation results by applying polynomial fitting and neural networks. Consequently, the number of decision variables of the global problem is reduced compared to the subproblem optimisation. Using the parameterised blackbox models of the chemical absorption unit in the global optimisation of a power plant with CO₂ capture reduces the complexity and computation time without losing much accuracy for capture rates up to 87%. The inclusion of predictions of each heat load and the corresponding temperature level is advantageous with regard to the overall process integration. It is shown that the accuracy of the parameterised models highly depends on the model calibration. In fact, the hypothesis that the optimal solution of the global problem corresponds to the minimum investment for a given CO₂ capture rate reveals to be not valid at high capture

Chapter 7. Process design optimisation strategy to develop energy and cost correlations of CO₂ capture processes

rates because there is a compromise between capital investment and energy efficiency. A solution would be to calibrate the parameterised CO₂ capture models on the minimisation of the production costs accounting the heat demand at its exergy value instead of on the investment. The proposed approach to develop simplified models based on optimisation results is promising for the preliminary design and evaluation of process options with CO₂ capture, especially with regard to the computation time reduction and the reduction of the number of decision variables. However, in order to predict the process behaviour accurately in the whole space of the decision variables, the calibration data set has to be chosen in such a way that the hypothesis of the subproblem optimality is satisfied.

8 Systematic comparison of CO₂ capture options

In the previous chapters different pre- and post-combustion CO₂ capture process options have been described and optimised. It was highlighted that the competitiveness of CO₂ capture in electricity generating processes is highly influenced by the resource price and the introduction of a carbon tax. In this chapter it will be studied how the economic scenario affects the optimal process design and influences decision-making. In addition, the environmental benefit of capturing CO₂ will be investigated in detail by performing a LCA analysis for the different optimal process configurations that have been identified. Part of these results are summarised in Tock and Maréchal (2012f).

8.1 Introduction

The introduction of CO₂ capture in power plants, results in a performance penalty in terms of energy and cost, while it leads to an advantage with regard to the environmental impact. The process competitiveness on the energy market depends therefore on energetic, economic and environmental considerations simultaneously. As shown in the previous Chapters 3-6, different technologies and resources are in competition. A detailed comparison between the different process options, that are summarised in Figure 8.1, is made here in order to assess the impact of the CO₂ capture concept and technology, and of the resource type. To make a consistent comparison of the environmental impacts of fossil and renewable resources fed processes, the impacts of the whole life cycle from the resource extraction to the final product have to be taken into consideration. Therefore, life cycle impact assessment (LCIA) is performed here following the approach described in Gerber et al. (2011) and Gerber (2012).

The previous studies have shown that the prize competitiveness of CO₂ capture highly depends on the economic scenario, primarily on the resource purchase. The introduction of a carbon tax will favour CO₂ capture solutions in fossil resources fuelled power plants in the medium-term, before a switch to renewable resources in the long-term. In this chapter, these trade-offs are studied in detail and it is shown how the economic scenario influences the decision-making.

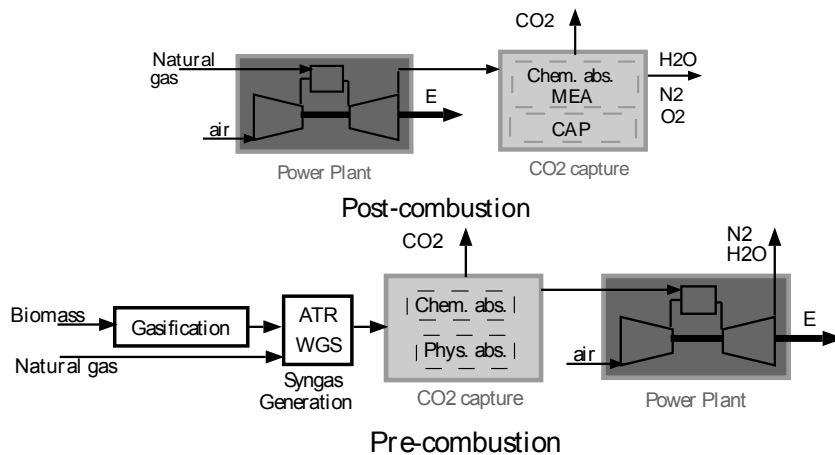

Figure 8.1: Investigated CO₂ capture options.

8.2 Performance comparison of CO₂ capture in power plants

The process performance of the compromise solutions identified from the optimisation results in the previous Chapters 3-6 is compared in detail in the following paragraphs.

8.2.1 Thermo-economic performance

The thermo-economic performance of the different compromise solutions capturing 90% of the CO₂ emissions for the natural gas based electricity generating processes and 60% for the biomass configurations is summarised in Figure 8.2 and Table 8.1. The details of the process design parameters are reported in Appendix Tables D.4 & D.7. Pre-combustion CO₂ capture processes reveals to perform slightly better in terms of energy efficiency than post-combustion CO₂ capture processes. In fact, in pre-combustion CO₂ capture processes the energy demand for CO₂ capture is lower, however the capital investment is larger because of the more complex installation. The electricity production costs are hence comparable for both concepts, since the higher productivity compensates the additional investment almost for the pre-combustion CO₂ capture processes. CO₂ capture in biomass fed processes leads to a lower electrical production efficiency and to higher costs due to the limited biomass conversion efficiency and to the high investment costs for the gasification process. However, these renewable processes have the advantage of capturing biogenic CO₂ and will thus become interesting if a carbon tax is introduced as shown in Section 8.3. It has to be noted that the considered biomass plant's capacity of $380\text{MW}_{th,BM}$ is much lower than the one of the natural gas plants (580 and $725\text{MW}_{th,NG}$). The biomass plant's scale is limited by the biomass availability and the logistics of wood transport, as explained in Gerber et al. (2011). The influence of the plant's capacity could be evaluated in a future economies of scale analysis based on the developed thermo-environmental models.

8.2. Performance comparison of CO₂ capture in power plants

Figure 8.2: Performance results of the different power plant options with CO₂ capture reported in Table 8.1. For natural gas fed processes a capture rate of 90% is considered and 60% for biomass fed processes.

Table 8.1: Performance of the different power plant options with CO₂ capture. For natural gas fed processes a capture rate of 90% is considered and 60% for biomass fed processes. The corresponding operating conditions are reported in in Appendix Tables D.4 & D.7.

8.2.2 Environmental performance

In order to evaluate the environmental impacts of the whole process chain, life cycle assessment is performed. The major principles of LCA have been summarised in Section 1.3.4 and Gerber et al. (2011). The scope of this study being to evaluate power plants with CO₂ capture, 1 GJ_e of net electricity produced is chosen as a functional unit (FU=1GJ_e). In the life cycle inventory phase every flow, crossing the system boundaries as an extraction or an emission, which is necessary to one of the unit processes, is identified and quantified based on the process layouts described in Figures 3.2, 3.3 and 5.1. The major process steps are resource extraction, syngas production, gas treatment and CO₂ removal, and heat and power generation.

The data available from the Ecoinvent database (Ecoinvent) are used to compute the different contributions of the unit processes. For the life cycle impact assessment, different impact methods are considered: IPCC 07, Impact 2002+ (endpoint categories), Ecoindicator 99 (hierarchical perspective) and CML 2001. The IPCC 07 method calculates the global warming potential by using the characterisation factors of different gaseous emissions published by the International Panel on Climate Change in 2007 (IPCC). The global warming potential over 100 years is computed in terms of CO₂ equivalent emissions. In addition to the climate change impact, the impacts on the resources, the human health and the ecosystem quality are evaluated based on the damage-oriented Ecoindicator 99 method and the Impact 2002+ method. The CML method uses in opposition a problem-oriented approach. The considered impacts categories include the most currently used ones: acidification potential (European), climate change (GWP 100 years), eutrophication potential (generic) and stratospheric ozone depletion (ODP steady state). The results obtained with these impact methods are summarised in Table 8.1 for the different process options and discussed in detail hereafter.

With regard to the assessment of the global warming potential expressed in terms of CO₂ equivalent emissions, it has to be noted that fossil, biogenic and sequestered CO₂ emissions from power plants are handled in a different manner. The GWP of fossil CO₂ emissions is standardised to 1, while for biogenic CO₂ emissions the GWP is considered as 0. When CO₂ is sequestered, there is consequently a different effect on the GWP depending on the CO₂ origin. Storage of fossil CO₂ accounts as zero to GWP, while storage of biogenic CO₂ leads to a GWP of -1. The negative balance is due to the fact that the released CO₂ was previously fixed in the plant as hydrocarbon by photosynthesis.

The climate change impact of the different process options is detailed in Figure 8.3 for the IPCC 2007 method. Compared to a conventional NGCC plant without CO₂ capture, the benefit of capturing CO₂ can clearly be seen. For the natural gas fed processes, the major contributions to the greenhouse gas emissions are coming from the natural gas and from the uncaptured CO₂. With CO₂ capture, the contribution from the natural gas is slightly larger because of the lower power plant efficiency. For biomass fed processes, the advantage of capturing biogenic CO₂ is revealed by the negative overall CO₂ balance.

8.2. Performance comparison of CO₂ capture in power plants

Figure 8.3: Comparison of the climate change impact of power plants without and with CO₂ capture based on the impact method IPCC 07 for 1GJ_e. Contributions that are harmful are labelled with a *p* and beneficial ones with an *n*.

The damages on the other impact categories assessed with the Impact 2002+ and Ecoindicator 99 method are reported in Figure 8.4.

Figure 8.4: Comparison of the life cycle impacts of power plants without and with CO₂ capture based on the impact methods Impact 2002+ (left) and Ecoindicator 99-(h.a) (right) for 1GJ_e. Contributions that are harmful are positive and beneficial ones negative.

It is to note that for the Impact 2002+ method the climate change impact is considered separately from the human health impact taking into account human toxicity, respiratory effects, ionising radiation, ozone layer depletion and photochemical oxidation. While for the Ecoindicator 99 method, climate change impacts are aggregated with carcinogenic, ionising

Chapter 8. Systematic comparison of CO₂ capture options

radiation, ozone layer depletion and respiratory effects in the human health impact category. For natural gas fed processes, the largest impact is coming from the resources followed by the climate change, the human health and the ecosystem. While for biomass based processes, the impact on the ecosystem is much more important. The detailed contributions to these impact categories are presented for the Ecoindicator 99 method in Figures 8.5-8.7 and discussed hereafter.

For natural gas based processes with CO₂ capture, the impact on the resources reported in Figure 8.5 is large since fossil resources are depleted. Due to the energy demand for CO₂ capture and compression, the natural gas consumption is increased to produce 1 GJ of electricity compared to a conventional plant without CO₂ capture having a higher productivity. For processes using biomass, which is a renewable resource, the impact on the resources is not significant, however the impact on the ecosystem is important as shown in Figure 8.6. The usage of renewable resources, such as wood, influences of course the ecosystem. The largest contribution is however attributed to rape methyl ester (RME) consumed in the cold gas cleaning step. RME is produced from colza which is cultivated with insecticides. These insecticides have a large impact on the ecosystem. To reduce this impact alternative colza cultivation methods, the usage of other types of oils, and the development of alternative cleaning methods have to be investigated. When using palm biodiesel instead of RME, the ecosystem impact could be reduced by 35%. Based on the results from Section 3.4, analysing the production of H₂ production from biomass, one possible option would be to use this H₂ to produce ammonia for the fertiliser industry. Using renewable resources to produce ammonia will considerably reduce the environmental impact as reported in Tock et al. (2012g) and Perrenoud (2012), and consequently also the fertiliser impact.

Figure 8.5: Contributions to the resources impact based on the impact method Ecoindicator 99- (h.a) for 1GJ_e of electricity produced by power plants without and with CO₂ capture.

8.2. Performance comparison of CO₂ capture in power plants

Figure 8.6: Contributions to the ecosystem impact based on the impact method Ecoindicator 99-(h.a) for 1GJ_e of electricity produced by power plants without and with CO₂ capture.

Regarding the impact on the human health illustrated in Figure 8.7, CO₂ capture in power plants is advantageous.

Figure 8.7: Contributions to the human health impact based on the impact method Ecoindicator 99-(h.a) for 1GJ_e of electricity produced by power plants without and with CO₂ capture. Contributions that are harmful are labelled with a *p* and beneficial ones with an *n*.

The reduction of the CO₂ emissions by CO₂ storage reduces the impact on the human health through the reduction of the climate change impact, accounted with the Ecoindicator 99 method in the human health impact. Pre-combustion CO₂ capture processes have a larger impact on the human health compared to post-combustion CO₂ capture processes due to the

Chapter 8. Systematic comparison of CO₂ capture options

larger NO_x emissions. For biomass based processes the olivine consumed in the gasification constitutes a large contribution. However, the negative impact from the capture of biogenic CO₂ leads to a low overall impact on the human health.

With regard to the acidification potential assessed with the CML method, the major contributions are the resources, the NO_x emissions and for biomass fed processes the RME, as reported in Figure 8.8. The comparison of the CO₂ capture options with the conventional NGCC plant shows that the impact is comparable. Only post-combustion CO₂ capture processes yielding slightly lower NO_x emissions have a lower impact. For the NO_x emissions estimation, power industry standards limiting the NO_x emissions to 25-45ppm have been considered. It has been assumed that the NO_x emissions do not exceed 30ppm. Consequently, technologies have to be available and implemented to abate the emissions to this level. This assumption explains the acidification potential trends. Similarly the eutrophication potential, mainly defined by the feedstock and the NO_x emissions, is comparable for pre-combustion CO₂ capture processes and slightly lower for post-combustion CO₂ capture processes as reported in Figure 8.9. Biomass based processes favoured with regard to the climate change impact, have a twice as high eutrophication impact. This is mainly due to the large contribution of the RME. As previously discussed this impact could be decreased by using alternative cultivation methods or gas cleaning technologies. The impact to the stratospheric ozone depletion is negligible for each CO₂ capture option.

Figure 8.8: Contributions to the acidification potential based on the impact method CML01 for 1GJ_e of electricity produced by power plants without and with CO₂ capture.

8.2. Performance comparison of CO₂ capture in power plants

Figure 8.9: Contributions to the eutrophication potential based on the impact method CML01 for 1GJ_e of electricity produced by power plants without and with CO₂ capture.

The comparison of the environmental impacts of CO₂ capture in power plants clearly reveals the benefit of reducing greenhouse gas emissions on the climate change. Taking into account also other environmental impacts, no clear decision in favour of one specific capture concept can be made. With regard to the resources depletion and the climate change, the most promising solution is obviously CO₂ capture in power plants using renewable resources which leads to a negative CO₂ balance. Similar conclusions can also be drawn for CO₂ capture in H₂ plants as reported in Appendix E.

In order to evaluate the environmental competitiveness of these power plants options with CO₂ capture, a comparison with other power plants options using fossil or renewable resources, like coal fired power plants, hydro power, nuclear or solar is made. The environmental impacts of these processes are taken from Ecoinvent (Ecoinvent) for the IPCC 2007 and the Ecoindicator 99 method. The results reported in Figures 8.10&8.11 show that compared to conventional fossil power plants, CO₂ capture is advantageous especially in terms of the climate change impact. Renewable alternatives, such as hydroelectricity and photovoltaic (PV) being in competition with the biomass based processes, are promising solutions for the future because of the low environmental impacts. Compared to these processes, the renewable biomass fed processes have the advantage of capturing biogenic CO₂ and yielding a negative CO₂ balance. However, the impacts of gas cleaning and treatment have to be improved by future developments, as discussed previously, to improve the overall environmental performance. Nuclear power plants remain to be heavily discussed due to the risks and impacts of the radioactive waste and are at the time being abandoned by many European politicians.

Chapter 8. Systematic comparison of CO₂ capture options

8.3 Influence of the economic scenarios on the competitiveness of the configurations

The analysis of the economic performance in Chapters 3-6 has revealed that the resource price highly influences the electricity production costs. In order to evaluate the competitiveness of the different CO₂ capture options in power plants applications, sensitivity analysis is first performed on the resource price and the influence of the introduction of a carbon tax is investigated. Then the influence of the economic scenario on the optimal process design and the decision-making is studied.

The analysis of the fossil fuel market over the last years, reveals diverse patterns over time and with regard to the geographic location (i.e. Europe, the United States and Japan) (IEA (2012, 2011b), European Commission (2011, 2010) and Eurostat), as reported in Appendix G. The large fluctuations result from multiple factors affecting the trading. The natural gas price evolution goes in pair with the oil price, while the coal price does not follow the oil price and is predicted to stabilise around 5\$/GJ_{coal} in 2030 (European Commission (2011)). Consequently, the gas to coal price ratio is projected to increase steadily and will together with the carbon price influence investment decisions in the power sector. European gas prices are about twice as high as US gas prices and are projected to be 10\$/GJ_{NG} in 2020, 12\$/GJ_{NG} in 2030 and 16\$/GJ_{NG} in 2050 for the *EU 'Reference'* energy scenario (European Commission (2011)). Future natural gas prices highly depend on the future impact of shale gas which is controversy. Consequently, it is very difficult to project future gas prices.

In a similar way, the carbon tax price is influenced by multiple factors. The emission trading system (ETS) directive has been established in the European Union to promote greenhouse gas emissions reductions in a cost effective and economically efficient manner (European Commission (2012)). The carbon price drop from around 25€/t_{CO2} in 2008 to below 10€/t_{CO2} in the second half of 2011. This evolution coincides with the buildup in surplus of allowances and international credits, and with the financial crisis. According to the predictions from the Energy Roadmap 2050 (European Commission (2011)), carbon tax prices will rise moderately until 2030 and significantly in the last two decades providing support to low carbon technologies and energy efficiency. For the current policy initiatives (CPI) scenario, taking into account the latest policies on energy efficiency, taxation and infrastructure, the carbon tax is predicted to increase to 15€/t_{CO2} in 2020, to 32€/t_{CO2} in 2030 and to 51€/t_{CO2} in 2050. In Switzerland, the situation is different since the carbon tax price is not affected continuously by trading. A tax of 12CHF/t_{CO2} was introduced in 2008 and increased to 36 CHF/t_{CO2} in 2010 in order to reach the target of 33% of emissions reductions in 2020 compared to 1990 (BAFU 2012). With the actual evolution this target might still not be reached, therefore an increase to 60CHF/t_{CO2} could be foreseen for 2014 and to 72CHF/t_{CO2} (or 84CHF/t_{CO2}) in 2016 and 96CHF/t_{CO2} (or 120CHF/t_{CO2}) in 2020 (Schweizerische Bundesrat (2012)). The maximal tax is however limited to 120CHF/t_{CO2}.

Due to this large uncertainty in costs projections, several scenarios are investigated here in

order to assess the influence on the competitiveness of the different CO₂ capture options in power plants applications. More details about the price fluctuations and predictions, and the distribution functions of the economic assumptions are reported in Appendix G.

8.3.1 Sensitivity analysis

For some compromise electricity generating process solutions with CO₂ capture, reported in Table 8.1, a sensitivity analysis is performed on the resource purchase price to see the impact on the electricity production costs. The results in Figure 8.12 clearly reveal a linear dependence between the COE and the gas price. Since the specific annual investment is comparable for these process configurations, the process competitiveness is determined primarily by the resource purchase. Without the introduction of a carbon tax, the conventional NGCC plant without CO₂ capture is the most competitive option. However, when a carbon tax of 35\$/t_{CO2} is introduced, its benefit is reduced and the scenarios with 90% of CO₂ capture become competitive. The break even natural gas price for which the post-combustion CO₂ capture process becomes competitive is around 6\$/GJ_{NG} for a carbon tax of 35\$/t_{CO2}. Consequently, there is a trade-off between the natural gas price and the carbon tax.

Figure 8.12: Influence of the natural gas purchase price on the electricity production costs without (- -) and with (-) the inclusion of a carbon tax of 35\$/t_{CO2} for the process configurations reported in Table 8.1.

The influence of the carbon tax on the electricity production costs considering a natural gas price of 9.7\$/GJ_{NG} and a biomass price of 5\$/GJ_{BM} respectively is illustrated in Figure 8.13. Under these conditions, the break even carbon tax is around 50\$/t_{CO2} for post-combustion CO₂ capture with MEA and around 62\$/t_{CO2} for pre-combustion CO₂ capture with Selexol. Due to the benefit of capturing biogenic CO₂, CO₂ capture in biomass fed power plants becomes competitive with natural gas fed processes for a carbon tax of 62\$/t_{CO2}. The inclusion

8.3. Influence of the economic scenarios on the competitiveness of the configurations

of a carbon tax will hence promote biomass based processes. In these analyses, the CO₂ capture rate and thus the process design are fixed. However, it is evident that there is a trade-off between the economic performance and assumptions, and the process design, in particular the CO₂ capture rate. This issue is addressed in detail in the following Section 8.3.2.

Figure 8.13: Influence of the carbon tax on the electricity production costs without and with CO₂ capture for a natural gas price of 9.7\$/GJ_{NG} and a biomass price of 5\$/GJ_{BM} for the process configurations reported in Table 8.1.

8.3.2 Economic scenarios influence

In order to study the influence of the economic scenario on the process design, it is focused on three different capture options, namely post-combustion CO₂ capture with MEA applied to the NGCC plant and pre-combustion CO₂ capture with Selexol in natural gas fuelled power plants (i.e. ATR) and in biomass based power plants. The analyses are based on the Pareto optimal frontiers that are resulting from the multi-objective optimisations made in Sections 4.4 & 6.3 (Figures 4.5 & 6.5). These optimisations maximising the energy efficiency and/or the CO₂ capture rate and/or minimising the production costs have revealed the trade-off between energy efficiency, costs and CO₂ capture. For each scenario the process configurations yielding the lowest COE are identified on the following graphs by a red circle.

The influence of the inclusion of a carbon tax on the economic performance is illustrated in Figure 8.14. It can be seen that with a low carbon tax (20\$/t_{CO2}), the CO₂ capture rate does not significantly impact the electricity production costs. While, the inclusion of a high carbon tax (65\$/t_{CO2}) favours process configurations with a high CO₂ capture rate leading to lower electricity production costs. In addition, the renewable biomass fed process becomes competitive under these conditions. With a carbon tax of 20\$/t_{CO2}, the COE of the reference

Chapter 8. Systematic comparison of CO₂ capture options

plant without CO₂ capture becomes 20.4\$/GJ_e, respectively 25.2\$/GJ_e with a tax of 65\$/tCO₂. With high CO₂ taxes, pre- and post-combustion CO₂ capture is advantageous with regard to an NGCC plant without CO₂ capture.

Figure 8.14: Influence of the carbon tax on the electricity production costs for different CO₂ capture process options.

The optimal CO₂ capture rate is consequently defined by the economic considerations. The trade-off between the resource price and the carbon tax is illustrated in Figure 8.15. It can be seen that a low resource price (5.5\$/GJ_{NG}) and a high carbon tax (65\$/tCO₂) favour process configurations with a high CO₂ capture rate. While process configurations with lower capture rates are more competitive for the other economic conditions.

In order to study the influence of the economic scenario on the competitiveness of the process configurations more in detail two different economic scenarios are compared with the base case assumptions reported in Table 1.2. For each economic scenario the major assumptions are summarised in Table 8.2.

Table 8.2: Definition of the economic scenarios.

Scenario	Base	Low	High
Resource price [\$/GJ _{res}]	9.7	14.2	5.5
Carbon tax [\$/tCO ₂]	35	20	55
Yearly operation [h/y]	7500	4500	8200
Expected lifetime [y]	25	15	30
Interest rate [%]	6	4	8

8.3. Influence of the economic scenarios on the competitiveness of the configurations

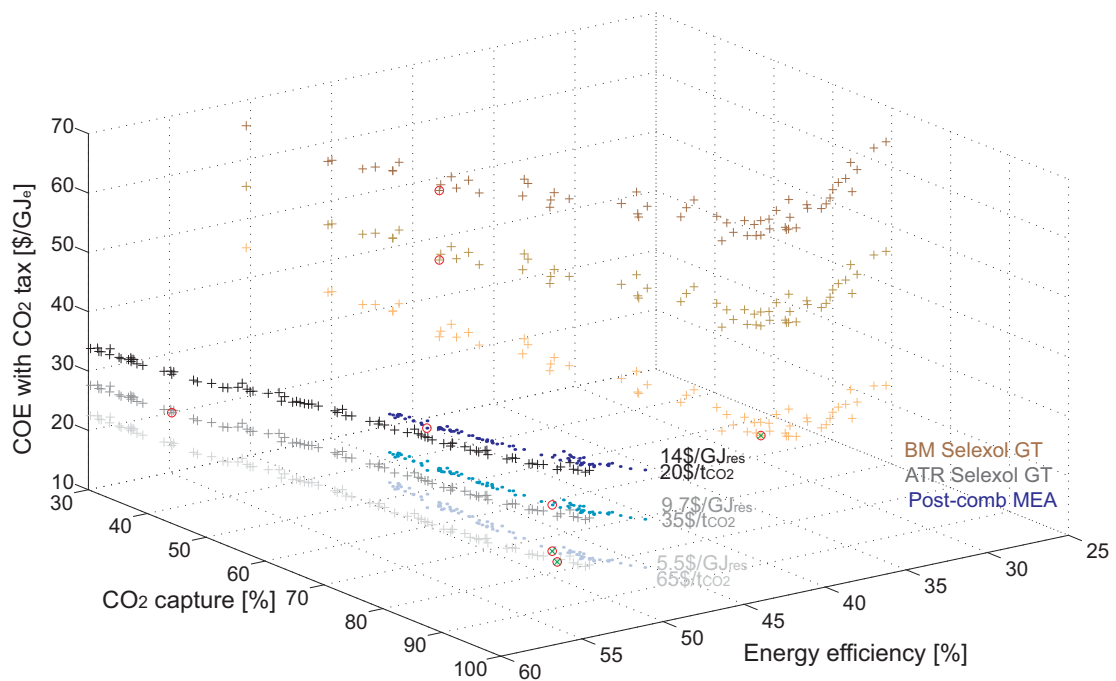

Figure 8.15: Influence of the carbon tax and of the resource price on the electricity production costs for different CO₂ capture process options.

For power plants with pre-combustion CO₂ capture with Selexol, it is highlighted in Figure 8.16 how the optimal process design is influenced by the economic scenario. For part load operation, high resource prices and a low carbon tax (*low*), CO₂ capture is not beneficial. While for medium load operation, low resource price and high carbon tax (*high*), process configurations with high CO₂ capture rates are favoured. For the economic scenario *high*, the electricity production costs (incl. CO₂ tax) decrease with increasing CO₂ capture rates (Figure 8.16 (left)) can be explained by the profit from the carbon tax. Compared to a conventional NGCC plant without CO₂ capture, the process competitiveness can be expressed by the CO₂ avoidance costs calculated based on the COE including the carbon tax. It is considered that the reference plant is also submitted to the different economic scenarios. When including the carbon tax, the COE of the NGCC plant becomes 27.5\$/GJ_e for the *low*, 21.99\$/GJ_e for the *base* and 17\$/GJ_e for the *high* economic scenario, respectively. Figure 8.16 (right) reveals that with the base case assumptions CO₂ avoidance costs below 50\$/t_{CO₂,avoided} can be reached for capture rates above 40%, while for the economic scenario *low*, negative CO₂ avoidance costs can be reached for capture rates above only 30%. Above 40% CO₂ capture, the decrease of the CO₂ avoidance costs with the CO₂ capture rate increase is less distinct. For power plants with post-combustion CO₂ capture similar trends are revealed in Figure 8.17.

Chapter 8. Systematic comparison of CO₂ capture options

Figure 8.16: Influence of the economic scenarios defined in Table 8.2 on the performance of pre-combustion CO₂ capture with Selexol in a natural gas fired power plant using ATR.

Figure 8.17: Influence of the economic scenarios defined in Table 8.2 on the performance of post-combustion CO₂ capture with MEA in a natural gas fired power plant.

For biomass based power plants an optimum with regard to the CO₂ capture rate can clearly be identified in Figure 8.18. At capture rates above 70%, the production costs increase due to the increase in capital costs and the decrease in efficiency, which are not compensated by the benefit of the carbon tax (Figure 8.18 (left)). Below 70% of CO₂ capture, the capture of an additional unit of CO₂ does not impact significantly the COE. The CO₂ avoidance costs variation in Figure 8.18 (right) translates these trends and shows the advantage of capturing biogenic CO₂. Even if, the biomass conversion is lower and the capital investment larger than for natural gas based processes, biomass conversion processes become hence competitive under specific economic conditions due to the benefit from the carbon tax.

8.3. Influence of the economic scenarios on the competitiveness of the configurations

Figure 8.18: Influence of the economic scenarios defined in Table 8.2 on the performance of pre-combustion CO₂ capture with Selexol in a biomass fed power plant.

These results clearly reveal the dependence of the CO₂ capture competitiveness on the economic scenario and consequently on the decision-making with regard to the CO₂ capture rate and the process configuration.

The comparison in Figure 8.19 of the results for these three electricity generating processes with CO₂ capture shows again how the choice of the optimal process configuration is affected by the economic scenario. The 2D representation in Figure 8.20, highlights the competition between different configurations. For the economic scenario *low*, post-combustion CO₂ capture processes perform best in terms of the electricity production costs for each capture rate. For the base case assumptions, pre- and post-combustion CO₂ capture in natural gas fuelled power plants perform equally in terms of COE for capture rates between 60 and 75%, whereas biomass based processes are more expensive. While for the economic scenario *high*, CO₂ capture in biomass fed processes generating green electricity becomes much more competitive. For natural gas fed power plants, pre-combustion CO₂ capture is advantageous with regard to the COE for capture rates below 75% and post-combustion CO₂ capture for higher capture rates. For high capture rates post-combustion CO₂ capture in NGCC plants seems to perform best with regard to the electricity production costs, while pre-combustion CO₂ in natural gas fed power plants is advantageous in terms of energy efficiency and CO₂ capture in biomass based power plants is beneficial with regard to the environmental performance. Consequently, there is a competition between the different processes. The production priority and scope define the decision that has to be taken. In Section 8.3.2, an approach to support decision-making from these Pareto results under different economic scenarios will be presented.

Chapter 8. Systematic comparison of CO₂ capture options

Figure 8.19: Influence of the economic scenarios defined in Table 8.2 on the performance of electricity generating processes with CO₂ capture.

Figure 8.20: Influence of the economic scenarios defined in Table 8.2 on the performance of electricity generating processes with CO₂ capture - 2D representation.

8.3. Influence of the economic scenarios on the competitiveness of the configurations

Monte Carlo simulation

Considering the uncertainty of the economic assumptions, a Monte Carlo simulation can be performed in order to evaluate the impact on the economic performance. For this purpose, the input economic parameters presented in Table 8.2 are described by distribution functions presented in detail in Appendix G.2. In addition, an uncertainty of $\pm 30\%$ (Turton (2009)) is included for the capital investment estimation. The characteristics of the distribution functions (i.e. uniform, normal or beta distribution) describing the different variables are defined in Table 8.3.

Table 8.3: Parameters of the distribution functions for the economic assumptions (illustrated in Appendix Figures G.4 & G.5).

	Distribution	Parameter A	Parameter B	Parameter C
Resource price [$\$/G_{Res}$]	Normal	$\mu=9.7$	$\sigma=2.5$	-
Carbon tax [$\$/t_{CO_2}$]	Beta	a=2	b=1.5	cst=100
Yearly operation [h/y]	Beta	a=3.9	b=1.2	cst=8600
Interest rate [-]	Normal	$\mu=0.06$	$\sigma=0.01$	-
Economic lifetime [y]	Beta	a=5.8	b=4	cst=40
Investment [-]	Uniform	a=-0.3	b=0.3	-

The objective functions for the Monte Carlo simulation are the minimisation of the electricity production costs including the carbon tax and the minimisation of the CO₂ avoidance costs. In the CO₂ avoidance costs calculation, it is assumed that the COE includes the carbon tax and that the reference NGCC plant's COE is also subject to the economic scenario variation. A Monte Carlo simulation is performed to evaluate the competitiveness of the different compromise process configurations reported in Table 8.1. Figure 8.21 summarises the results for the conventional NGCC plant without CO₂ capture and for the different electricity generating process configurations with CO₂ capture (i.e. 90% of CO₂ capture for natural gas fed processes and 60% for biomass ones). For each scenario, the performance reported in Table 8.1 for the base case economic assumptions (Table 1.2) is highlighted by a characteristic marker. The performance variation with the economic scenario is illustrated by the area with the corresponding colour. The area represents the boundary of the objective functions variation, when changing the economic assumptions according to the distribution functions. For the NGCC reference plant, the COE variation is pointed out for two extreme economic scenarios. These results reveal that by taking into account the uncertainty of the economic assumptions, the different CO₂ capture processes compete with conventional NGCC plants if a carbon tax is introduced. For certain economic scenarios, negative CO₂ avoidance costs are achieved, which underline that CCS can become a competitive alternative compared to NGCC plants without CO₂ capture.

Here the Monte Carlo approach has been applied to the results in order to study the influence of the economic assumptions. Following the stochastic methodology presented in Dubuis (2012), uncertainty could in addition be included in the design and multi-objective optimisation of the energy systems.

Figure 8.21: Assessment of the influence of the economic assumptions uncertainty on the COE and CO₂ avoidance costs accounting for a CO₂ tax, for the configurations presented in Table 8.1. The markers represent the performance for the base case economic scenario, and the corresponding coloured area the variation of the COE with the economic conditions.

Decision-making

The previous results have shown that the various process options are in competition and that the competitiveness of the process configurations highly depends on the economic scenario. In order to support decision-making based on the Pareto results obtained for different economic scenarios, a selection approach is proposed here. To illustrate this approach, it is focused again on the three representative capture options, namely post-combustion CO₂ capture with MEA applied to the NGCC plants and pre-combustion CO₂ capture with Selexol in natural gas fuelled power plants based on ATR and in biomass fired power plants. The analyses are based on the optimisation results, revealing the trade-off between energy efficiency and CO₂ capture (Sections 4.4 & 6.3, Figures 4.5 & 6.5). The economic scenarios are defined by the distribution functions given in Table 8.3.

Looking at results such as in Figure 8.19, it is not obvious which configuration has to be chosen from the Pareto results. The aim is here to propose an approach which allows to identify the optimal process design from the Pareto-optimal solutions taking into account the economic conditions sensitivity. First a series of 1000 economic scenarios is randomly generated by applying the distribution functions given in Table 8.3. For every single economic scenario the economic performance (i.e. COE including carbon tax) of the Pareto-optimal solutions is then recomputed. From the Pareto-optimal solutions the five best configurations that yield the lowest COE (including CO₂ tax) are then identified. After having identified the five most economically competitive configurations for all the economic scenarios, it is possible to see if some configurations are dominating or if some are never part of the five best performing ones. In order to evaluate this quantitatively, the probability to be part of the five best performing configurations is then assessed for each point of the Pareto front. This allows finally to identify

8.3. Influence of the economic scenarios on the competitiveness of the configurations

the most economically competitive process configurations in the wide range of economic scenarios.

For the NGCC plant with post-combustion CO₂ capture, Figures 8.22&8.23 reveal how the choice of the optimal process configurations is influenced by the economic scenario. Process configurations with CO₂ capture rates between 80 and 85% appear to be the best choice for a large range of economic scenarios. Configurations with lower capture rates are mainly selected for economic scenarios with a carbon tax below 35\$/t_{CO2}, as previously discussed.

Figure 8.22: Natural gas fired power plant performance with post-combustion CO₂ capture with MEA: Probability of each point to be part of the top 5 configurations yielding the best economic performance under different economic scenarios.

Figure 8.23: Natural gas fired power plant performance with post-combustion CO₂ capture with MEA: Influence of the economic scenario on the electricity production costs (incl. a carbon tax) of the best 5 economic performance configurations.

Chapter 8. Systematic comparison of CO₂ capture options

The results for natural gas or biomass fired power plants with pre-combustion CO₂ capture with Selexol represented in Figures 8.24 & 8.25 respectively, reveal that process configurations with intermediate CO₂ capture rates are the best choice for a large range of economic conditions. For natural gas fuelled power plants, over 80% of pre-combustion CO₂ capture becomes competitive with high carbon taxes (>45\$/t_{CO2}) and low resource prices.

Figure 8.24: Natural gas fired power plant performance with pre-combustion CO₂ capture with Selexol: Probability of each point to be part of the top 5 configurations yielding the best economic performance under different economic scenarios (left) and respective influence on the electricity production costs including a carbon tax (right).

Figure 8.25: Biomass fired power plant performance with pre-combustion CO₂ capture with Selexol: Probability of each point to be part of the top 5 configurations yielding the best economic performance under different economic scenarios (left) and respective influence on the electricity production costs including a carbon tax (right).

Instead of choosing the best configuration for a given power plant and CO₂ capture scenario, the same approach could be used to identify the best configuration with regard to the different process options. When considering the three investigated CO₂ capture options together for the decision-making, the configurations yielding the best economic performance for different economic conditions are identified in Figure 8.26. These results reveal that post-combustion CO₂ capture is the best economic choice for capture rates between 70 and 85%. Pre-combustion CO₂ capture configurations, being slightly more expensive for similar capture rates, yield however slightly better efficiencies. Depending on the production scope, this could affect decision-making for the more expensive solution. For some marginal economic scenarios (i.e.

8.3. Influence of the economic scenarios on the competitiveness of the configurations

high CO₂ tax, low biomass purchase price, low gasifier investment), CO₂ capture in biomass fed power plants becomes a competitive alternative. This is also illustrated in Figure 8.27 showing the variation of the COE of the most economically competitive configurations and the upper and lower borderline performance of all the Pareto-optimal solutions. The economic conditions corresponding to the lower and upper boundary are respectively: 5042//7260h/y, 7.29//62.3\$/GJ_{res}, 89//55.8\$/tCO₂, 6.3//4.1% interest, 25.5//20y lifetime and -23//+25% investment costs estimation.

Figure 8.26: Power plants performance with CO₂ capture: Influence of the economic scenario on the top 5 configurations yielding the best economic performance. Decision-making based on the Pareto front (black points) (left) and corresponding probability of each point to be part of the top 5 configurations yielding the best economic performance under different economic scenarios (right).

Figure 8.27: Power plants performance with CO₂ capture: Influence of the economic scenario on the decision-making based on the top 5 configurations yielding the best economic performance (left) 2D representation showing the trade-off between COE and energy efficiency (right).

As shown in Figure 8.27 and already discussed previously, biomass fed processes are not competitive for the base case economic scenario and post-combustion CO₂ capture performs best for capture rates around 70-85%. However, when gas prices increase (i.e. moving toward upper boundary) the natural gas based processes become uncompetitive compared

Chapter 8. Systematic comparison of CO₂ capture options

to base case biomass configurations. These results point out the competition between the different processes and the influence of the economic scenario on the decision-making. This competition is also highlighted in Figure 8.28 evaluating the overall competitiveness of each Pareto-optimal solution compared to the most-economically competitive solution for the considered economic scenarios. These results clearly show the close competition between post- and pre-combustion CO₂ capture and reveal again the influence of the CO₂ capture rate.

Figure 8.28: Relative competitiveness of each Pareto optimal solution with regard to the most economically competitive solution for the considered economic scenarios (right). Zoom on the relative competitiveness of CO₂ capture in natural gas fired power plants (left).

The performance results of the most economically competitive process designs for each CO₂ capture scenario are summarised in Table 8.4 and the process design parameters are reported in Appendix Tables D.8 & D.9.

From these results, it can be concluded that CO₂ capture becomes economically competitive for captures rates between 70 and 85% when a carbon tax is applied. The various natural gas fed power plants designs with CO₂ capture lead to an average efficiency decrease of 8% (2.3-13.7%). The energy integration of the natural gas fuelled power plant configurations with post-combustion with MEA and pre-combustion with Selexol is compared by the composite curves in Figure 8.29. For the other configurations the process design and energy integration is reported in Appendix D (Figures D.1-D.3). Taking into account the uncertainty of the economic projections the variation in the electricity production costs including a CO₂ tax are illustrated in Figure 8.30 and compared with a conventional NGCC plant without CO₂ capture. These results show that CCS can become an energy, cost and environmental-efficient alternative on the future energy market.

8.3. Influence of the economic scenarios on the competitiveness of the configurations

Figure 8.29: Integrated composite curves of the most economically competitive natural gas fired power plant options with post-combustion CO₂ capture with MEA (left) and with pre-combustion CO₂ capture with Selexol (right) reported in Table 8.4.

Figure 8.30: Comparison of the most economically competitive power plant options with CO₂ capture based on the economic performance variation, with regard to the different economic scenarios, expressed by the COE including CO₂ tax (Table 8.4).

After this comparative study applying first a systematic methodology for generating process configurations by multi-objective and then a selection tool for supporting decision-making based on the Pareto-optimal solution, one could ask about how the objective function choice influences the optimal process design. From the discussion in Appendix C, it turns out that ideally three objectives, including a thermodynamic, economic and environmental dimension, have to be considered, respectively two objectives whereof one combines two of these dimensions. By changing the objective function different optimal process configurations could emerge, because of the close competition between the different process options. In order to reveal the optimal process design with regard to different objectives the same analysis could be repeated for several objective functions in a future study.

8.4 Market competition of CO₂ capture in power plants

When evaluating the market competition of CO₂ capture in power plants applications, it is inevitable to compare the thermo-environmental performance with the other competitors on the electricity market. In this study, it was focused on pre- and post-combustion CO₂ capture in natural gas or biomass fuelled power plants. Beside other alternative renewable solutions, one major competitor using a fossil resource has not been addressed here, namely coal fired power plants. By applying the same concepts and technologies, CO₂ could be captured in coal fired power plants to reduce the global CO₂ emissions. In addition, the oxy-fuel and chemical looping combustion options for CO₂ capture have not been evaluated. As mentioned in the introductory chapter several research studies have investigated CO₂ capture in coal fired power plants and oxy-fuel combustion options over the last years. However, no holistic approach including simultaneously energetic, economic and environmental considerations has been applied. By applying the systematic thermo-environmental modelling and optimi-

8.4. Market competition of CO₂ capture in power plants

sation approach developed in this thesis, coal fired power plants capturing CO₂ by post-, pre- or oxy-fuel combustion could be included in the superstructure and compared with the other options in a future study. Following this approach, the energy integration of several pre-combustion CO₂ capture options in coal fired power plants has already been optimised in Urech et al. (2012). However, no economic and LCA aspects have been included yet.

In order to assess the competitiveness of the different processes, the performance results of this study are compared with literature data for CO₂ capture in power plants, including pre-, post- and oxy-fuel combustion concepts. The results published by IEA (Finkenrath (2011)) for electricity generation in OECD countries and by ZEP (ZEP (2011)) for European countries are considered. Tables 8.5 & 8.6 summarise the results for different power plant systems with and without CO₂ capture.

Table 8.5: Performance results reported by IEA (Finkenrath (2011)) for OECD countries. The costs range takes into account the variation of the resource price with regard to the countries. For the efficiency the OECD average value is given.

The results reported in this study for the optimal configurations with 90% of CO₂ capture (Table 8.1) and for the configurations yielding the best economic performance under various economic scenarios (Table 8.4) are in agreement with these literature data for CO₂ capture in NGCC power plants. This confirms that the applied systematic methodology computes reliable results. The energy efficiency results of this study are slightly better than reported ones, because of the performance improvement by optimal process integration. This is also

highlighted in Urech et al. (2012) for CO₂ capture in coal fired power plants. Compared to natural gas fuelled power plants, CO₂ capture in coal fired power plants results in slightly lower cost penalty due to the larger CO₂ concentration in the flue gas. However, the energy penalty for CO₂ capture and compression leads to an energy efficiency drop to 30% for the electricity generation.

Looking at the thermodynamic performance, CO₂ capture in biomass based plants can consequently compete with coal fired power plants. But coal fired power plants keep a big advantage with regard to the economic performance due to the low coal price. The specific CO₂ emissions of coal fired power plants being more than twice as high as for natural power plants, 227kg_{CO₂}/GJ_e compared to 103kg_{CO₂}/GJ_e, the introduction of a carbon tax will greatly penalise conventional coal fired power plants without CO₂ capture. Consequently, the introduction of a carbon tax will favour CCS and renewable biomass based processes. The environmental benefit of CO₂ capture has already been revealed in Figure 8.11. These results show that CO₂ capture has to be regarded as a competitive option for future sustainable energy systems.

8.5 Conclusions

The study of the process performance under different economic scenarios has revealed the influence on the competitiveness of the process configurations. The choice of the optimal process design is highly influenced by the resource price and the introduction of a carbon tax. When a high carbon tax is introduced, high CO₂ capture rates become attractive and negative CO₂ avoidance costs can be reached. Due to the advantage of capturing biogenic CO₂, biomass fed power plants become also competitive. With regard the economic performance post-combustion CO₂ capture in NGCC plants seems to perform best at capture rates around 70-85%, while pre-combustion CO₂ in natural gas fired power plants is advantageous in terms of energy efficiency and CO₂ capture in biomass based power plants is beneficial from an environmental point of view. Consequently, there is a competition between the different processes and the different objectives. The choice of the optimal process configuration is hence defined by the production scope and the priorities given to the different thermo-economic criteria.

Conclusions

To meet the targets of sustainable development and greenhouse gas emissions reduction, the deployment of cost-competitive innovative low-carbon energy conversion systems is decisive. The design of such complex integrated energy conversion systems represents an important challenge for the engineers and requires the development of process design tools taking into account energetic, economic and environmental aspects simultaneously. In this thesis, a systematic framework for studying, designing and optimising complex integrated energy systems is developed. The proposed thermo-environmental optimisation strategy is applied for the comprehensive and consistent analysis, comparison and optimisation of fuel decarbonisation process options. The environmental benefit, and the energy and cost penalty of CO₂ capture in H₂ and power generation plants, fuelled with either fossil or renewable resources, is assessed in a uniform manner for different carbon capture technologies. The process competitiveness is systematically evaluated by taking into account several aspects, such as the process configuration and design, the energy price fluctuation and the introduction of a carbon tax. Based on the optimisation results, trade-offs are assessed to support decision-making and identify optimal process configurations with regard to the polygeneration of H₂, electricity, heat and captured CO₂. The approach turns out to be well suited to target the best possible performance and eliminate solutions that are not worth to be investigated further. This developed tool can consequently support decision-making and serve process engineers in the research and development of optimal plant designs taking into account economic, energetic and environmental considerations simultaneously.

The proposed methodology combines flowsheeting models, energy integration techniques, economic evaluation and life cycle assessment in a multi-objective optimisation platform. Such an integrated, holistic approach is rarely applied in conventional studies. The dissociation of the system models from the system design methods turns out to be valuable for assembling process unit models developed with different software. Candidate process technologies for fuel decarbonisation processes producing H₂ and/or electricity are identified and assessed in a superstructure, and thermo-environmental models are developed. Due to the uniform structure of the models, the superstructure can be easily extended and updated with additional options in the future. These models, taking into account different resources and technology options, are flexible and robust to reflect accurately the influence of the operating conditions on the chemical conversion and on the energy demand. There is consequently a

Conclusions

trade-off between the level of detail of the models and their robustness. When experimental data are available, a systematic parameter validation of the developed models can be performed, which could then be applied for the design of experiments.

The analyses of the fuel decarbonisation processes have pointed out that process integration is a major concern. The competitiveness of the different process configurations is highly influenced by the rational energy recovery through cogeneration valorising the heat losses by electricity generation. When capturing CO₂ by chemical absorption with amines, the introduction of mechanical vapour recompression turns out to improve the quality of the process integration by making more heat available for cogeneration and consequently reducing the overall energy efficiency penalty between 5 and 20% depending on the process configuration. Moreover it appears that, by improving the quality of the refrigeration integration, the chilled ammonia process outperforms the chemical absorption with MEA for post-combustion CO₂ capture in NGCC plants. The energy efficiency of the chilled ammonia process capturing 90% of the emissions of an NGCC plant can be increased from 46.7% to about 53% by improving the quality of the process integration. This emphasises the need for a detailed analysis of the process integration results before the final process design and decision-making. The inclusion of the process integration in the design process has the advantage of reflecting the influence of the design and operation on the thermo-environmental performance of an energy balanced system.

The economic performance evaluation has highlighted that the energy price sensitivity and the environmental policy highly influence the market competitiveness of the process configurations. The resource purchase contributes to more than two thirds of the electricity production costs, while the annualised capital investment only amounts for around 10% and the maintenance for the remaining part. In this study, the investment costs are estimated based on equipment sizing and costing heuristics, which allows to easily re-evaluate the performance for different plant sizes. This consistent, uniform approach, estimating the costs with an error of $\pm 30\%$, allows to compare process options and to rank systems. However, for making investment decisions the availability of reliable commercial cost data is crucial. When real market data are available, the cost estimations used in this thesis can be validated and the results from the comparative study verified and updated.

The comparison of the whole life cycle environmental impacts of H₂ and power generation plants has revealed the benefit of CO₂ capture with regard to the global warming impact. The capture of biogenic CO₂ emissions from biomass fired power plants leads to a negative CO₂ balance and is consequently promising. However, to improve the overall environmental impact the harmful contributions from gas cleaning and treatment have to be decreased.

A multi-objective optimisation of the thermo-environmental performance was performed in order to assess the trade-offs with respect to the process configuration and operating conditions, and to support decision-making. The energy and cost penalty of different CO₂ capture concepts and technologies, applied in H₂ and power generation plants, was consistently

evaluated and compared based on the optimisation results. Within the goal of assessing the impact of CO₂ capture, the chosen objectives were to maximise the CO₂ capture rate and the energy efficiency. The generated Pareto optimal frontiers provide knowledge about promising configurations and offer the choice among several alternatives. By introducing the fluctuation of the resource purchase price, the carbon tax and the economic assumptions, the costs are evaluated for different economic scenarios. An approach for supporting decision-making based on the Pareto-optimal solutions is proposed.

CO₂ capture decreases the electrical generation efficiency by 9%-points and increases the production costs by around 25%. This penalty is related on the one hand to the capture cost and on the other hand to the compression cost. The compression penalty corresponds to about 2%-points of the efficiency decrease and is hardly avoidable when one wants to transport and store the CO₂. The CO₂ compression cost could be partly avoided when the CO₂ is reused for other purposes. The comparison between pre-combustion and post-combustion CO₂ capture in natural gas fed power plants reveals that pre-combustion CO₂ capture by physical absorption with Selexol capturing 90% of the emissions yields a 3%-points higher efficiency (52.6%) than post-combustion CO₂ capture by chemical absorption with MEA yielding an efficiency of 49.6%. This can be explained by the lower energy consumption for solvent regeneration in physical absorption processes. However, the economic performance is comparable with 24.5 and 23.7\$/GJ_e respectively for a natural gas price of 9.7\$/GJ_{NG}. With regard to a conventional NGCC plant, having an efficiency of 58.7% and yielding electricity production costs of 18.3\$/GJ_e, the economic competitiveness of these options highly depends on the introduction of a carbon tax and on the natural gas price. Without a carbon tax, the CO₂ avoidance costs are 60\$/t_{CO₂,avoided} and 66\$/t_{CO₂,avoided} for post-combustion and pre-combustion CO₂ capture in natural gas fuelled power plants, respectively. When a carbon tax is introduced, CO₂ capture processes become economically attractive. For a natural gas price of 9.7\$/GJ_{NG}, the break even carbon tax is around 50\$/t_{CO₂} for post-combustion with MEA and around 62\$/t_{CO₂} for pre-combustion CO₂ capture with Selexol. Due to the advantage of capturing biogenic CO₂, biomass fed power plants yielding an efficiency of around 35% become also competitive from an environmental and economic point of view. Compared to CO₂ capture in coal fired power plants, yielding an efficiency around 33%, biomass based processes are competitive from a thermodynamic point of view. The economic performance turns out to be highly dependent on the resource price and on the imposed carbon tax. Post-combustion CO₂ capture in NGCC plants seems to perform best with regard to the economic performance, while pre-combustion CO₂ capture in natural gas fired power plants appears to be the most attractive from the energy efficiency point of view. The gain in efficiency is however not compensated by the increase of the investment. It could be mentioned here that the fuel options have not been evaluated here. These could make the pre-combustion more advantageous by increasing the efficiency of the hydrogen conversion. CO₂ capture in biomass based power plants is beneficial from an environmental point of view, but these plants require more investment and are highly penalised by the efficiency of the biomass conversion. Biomass conversion processes become however competitive when CO₂

Conclusions

taxes are high ($>65\$/t_{CO_2}$) and when cheap biomass is available, for example waste biomass. Consequently, there is a competition between the various process options and the different objectives. The choice of the optimal process configuration is hence defined by the production scope, the priorities given to the different criteria and the market conditions. To support decision-making an approach is proposed to identify the most economically competitive configuration for a wide range of economic scenarios.

When including the fluctuation of the resource price, the carbon tax and the other economic assumptions, through distribution functions, it is pointed out that CO_2 capture becomes economically competitive for capture rates between 70 and 85% and not for rates up to 95% as commonly supposed. Taking into account the different economic scenarios, the electricity production costs and CO_2 avoidance costs are in the range of $9-41\$/GJ_e$ and $-62-135\$/t_{CO_2,avoided}$, respectively. Negative avoidance cost meaning that the CO_2 capture becomes more economical than the conventional process for the given economic conditions. An NGCC plant configuration with post-combustion CO_2 capture capturing 83% of the emissions turns out to be the best compromise solution. However, pre-combustion CO_2 capture processes are in close competition. From an environmental point of view, CO_2 capture in biomass fuelled power plants is also a promising alternative which might become economically viable; if technology development and deployment proceeds and/or if high CO_2 taxes are imposed.

It can be concluded that CO_2 capture in power plants fuelled with fossil or renewable resources, is a promising solution which can become competitive in a medium term on the energy market. To reliably establish the technology on a large scale, R&D efforts should continue to address the technology availability issues and focus on the reduction of the energy and cost penalty of CCS.

Perspectives

The proposed process engineering method turns out to be a powerful tool to compare systematically different process options, assess trade-offs and support decision-making under different economic scenarios. The framework has the potential to be applied for studying all kinds of energy conversion systems. By expanding the superstructure with additional options, the energy market competitiveness can be accurately simulated with the aim of supporting decision-making. The constant upgrade, expansion and validation of the thermo-environmental models is one of the major future tasks. For making investment decisions, the availability of market equipment cost data would be an asset. Further optimisations based on three objectives (i.e. energetic, economic and environmental) could be performed in order to assess the trade-offs with regard to multiple objectives. However, increasing the number of objectives induces a larger computation time and difficulties for results visualisation and interpretation. Regarding the prospects of CO_2 capture options, several additional issues concerning power plants and H_2 applications have to be considered, as discussed here below.

CO₂ capture in coal fired power plants

With respect to CO₂ emissions mitigation in the electricity production, CO₂ capture in coal fired power plants, inducing most of the emissions, has to be investigated in addition to the natural gas and biomass options studied here. Compared to NGCC plants, coal fired power plants, yielding a 25% lower efficiency and around 50% higher CO₂ emissions, are actually competitive due to the low coal price. The introduction of a carbon tax and CO₂ capture would consequently penalise the performance of these plants. In Urech et al. (2012), a detailed energy integration analysis and optimisation of three different pre-combustion CO₂ options in an IGCC plant is performed using the methodology presented here. Compared to the conventional IGCC plant, CO₂ capture introduces an energy penalty of 7.6-8.6%-points for the different systems. For a consistent competitiveness evaluation, this study has to be completed with an economic and environmental evaluation by applying the proposed systematic thermo-environmental optimisation methodology. The developed superstructure of fuel decarbonisation options has hence to be extended by including the coal fired power plants options and oxy-fuel combustion processes in order to assess the potential of CO₂ capture in the different power plant systems.

H₂ as an energy vector

In the pre-combustion CO₂ capture processes, the H₂ intermediate generated from fossil or renewable resources could, instead of being burnt in gas turbine to generate electricity, be used as a fuel in fuel cell systems or as a product for many other applications, such as ammonia production for example.

Fuel cell applications. Fuel cell applications are regarded as promising alternatives on the future energy market. In Maréchal et al. (2005) and Autissier et al. (2007), a thermo-economic optimisation of two different types of fuel cells systems; PEMFC (Proton Exchange Membrane Fuel Cell) and SOFC (Solid Oxide Fuel Cell), using natural gas as a resource, was performed and revealed the potential of this technology. With such systems an efficiency around 50-60% could be reached, however to be competitive the equipment cost has to be reduced through technology developments increasing the reliability. An innovative hybrid SOFC-gas turbine system has been presented in Facchinetti et al. (2011). This system can reach an energy efficiency up to 80% with CO₂ separation through oxy-fuel combustion. Instead of using natural gas as a resource, renewable resources could also be used in fuel cell applications. The systematic process integration and optimisation of a SOFC-gas turbine hybrid cycle fuelled with hydrothermally gasified waste biomass made in Facchinetti et al. (2012) demonstrates the considerable potential of the system that allows for converting wet waste biomass into electricity at an energy efficiency of up to 63%, while simultaneously enabling the separation of biogenic carbon dioxide for further use or sequestration. Through optimal process integration the first law efficiency is improved by around 4% with respect to a non-integrated system. These studies emphasise that fuel cell applications have to be considered as promising options

Conclusions

on the future energy market, even when including CO₂ capture.

Ammonia production from biomass. Alternatively, the H₂-rich fuel generated from biomass gasification could be used to produce ammonia instead of generating electricity. This process studied in detail in Tock et al. (2012g) and Perrenoud (2012), reveals again the importance of process integration and highlights the benefit with regard to the environmental impact. When using a renewable resource, such as wood, and capturing the CO₂ emissions, the environmental impact of the fertiliser industry, which is mainly based on ammonia, could be reduced considerably. Consequently, the H₂ production from renewable resources has to be investigated not only for applications in the power sector but also as chemical.

The comparison of some performance results in Table 8.7, reveals the interest of studying in detail the different applications of H₂-rich fuel produced from fossil and renewable resources with regard to the future energy market. A consistent thermo-environmental comparison and optimisation of the different options could be made in a future study by following the systematic approach presented in this thesis.

In the perspective of a sustainable energy future driven by greenhouse gas constraints, CO₂ emissions have to be decreased, energy conversion efficiency has to be increased and fossil resources have to be progressively replaced by renewable resources. For the purpose of designing such complex integrated energy conversion systems and guiding decision-making and development, the systematic framework developed in this thesis proves to be beneficial. It turns out that process integration is a key point on which future developments have to focus. In the way towards a renewable future, CO₂ capture and storage applied to H₂ and power generation plants fuelled with fossil resources appears to be a competitive transitional solution for mitigating climate change. CO₂ capture in thermo-chemical conversion biomass based processes reveals also to be a promising alternative for the polygeneration of H₂ heat, electricity and captured CO₂ on the future energy market.

A Cost correlations comparison

This appendix reveals the difficulty of estimating accurately the equipment costs when taking into account the influence of the plant size and of the operating conditions. Several design heuristics for process sizing and cost correlations are compared by evaluating the costs of CO₂ capture by chemical absorption.

To estimate the investment costs for chemical absorption, different approaches are found in literature in addition to the one from Turton (2009) and Ulrich and Vasudevan (2003) described in Section 1.3.4. After a brief description of the various approaches, the results of these estimations are compared here.

In Klemeš et al. (2007) a techno-economic model is established to evaluate the capital cost and the on-going costs associated with each component and with the net CO₂ release with regard to the design parameters (i.e. plant size, flue gas characteristics, capture technology, efficiency,...). The facilities that are accounted for are: the flue gas blower, absorber, regenerator, solvent processing area, MEA reclaimer, steam extractor, heat exchanger, pumps and CO₂ compressor. Parametric cost estimation relationships are defined for different CO₂ capture rates (90%, 85% and 80%) for plant sizes in the range of 300-2000MW_e. The cost estimations are defined as a function of the plant size [MW_e] or as a function of the amount of CO₂ avoided [Mt_{CO2}] according to relations Eq.A.1 and Eq.A.2 respectively. The parameters of these cost functions are defined for: the process facilities cost PFC [M\$], total capital requirement TCR [M\$], annual TCR [M\$/y], operating and maintenance cost O&M (variable, fixed, total) [M\$/y], sorbent [M\$/y], steam [M\$/y], electricity [M\$/y], waste disposal [M\$/y] and the total annual cost [M\$/y].

$$Cost = A + B * (plant\ size\ [MW]) \quad (A.1)$$

$$Cost = A' + B' * (amount\ CO_2\ avoided\ [MtCO_2]) \quad (A.2)$$

Appendix A. Cost correlations comparison

In Chauvel et al. (2001) the equation Eq.A.3 is reported to estimate the base cost (P_B) in french francs ($1FF_{1998} = 0.17\$_{1998}$) of a distillation unit and material and installation factors are given to calculate the capital cost.

$$P_B[FF_{1985}] = e^{(4.3588+0.5848\ln(\dot{m}_{dist})-0.7540\ln(\ln(vr))-0.3477\ln(x_l)-0.1138\ln(P))} \quad (A.3)$$

with \dot{m}_{dist} the molar flow of the distillate [kmol/h], vr the relative volatility, x_l the molar fraction [%] of light component in the feed and P the pressure at the top of the column.

A detailed method for columns sizing and cost estimation based on the diameter, number of stages and pressure is also outlined in Chauvel et al. (2001). Based on the size, the weight of the material is defined and the costs are estimated for the different components of the column.

Another procedure for estimating the capital costs for vertical packed bed gas absorbers using counter-current flow to remove gaseous pollutants is described in Mussatti (2002). Cost estimates from gas absorber vendors for a range of tower dimensions (height, diameter) are used to fit a linear relation between the total tower cost (TTC [$\$_{1991}$]) and the absorber surface area S [$f t^2$] expressed by Eq.A.4. To take into account the construction material a material factor is introduced. The total installation costs including tower cost, packings, auxiliaries, instrumentation and installation are also defined.

$$TTC[\$_{1991}] = 115 * S[f t^2] \quad (A.4)$$

The results of the described cost correlations are compared for one base case scenario with the flue gas characteristics given in Table A.1 and the base case chemical absorption process parameters given in Table 2.2. The number of stages and the column diameter are fixed, while the HETP is calculated by $HETP=(diameter)^{0.3}$. For the columns a maximal diameter of 5m is considered. If the diameter value calculated by Eq.1.11 is higher, several units operating in parallel are considered.

Table A.1: Flue gas characteristics for the comparison of the investment cost estimates of a chemical absorption installation.

Flue Gas	Mass flow [t/h]	CO ₂ [%wt]	H ₂ O [%wt]	O ₂ [%wt]	N ₂ [%wt]
FG ₁	600	6	5	3	86
FG ₂	900	5	15	0	80
FG ₃	1700	14.5	2	5	78.5

The results in Table A.2 clearly reveal a large range of variation in the estimations. In addition, the correlations behave differently with regard to the changing composition and the size increase. This reveals the difficulty of estimating accurately the equipment costs when taking into account the influence of the plant size and of the operating conditions.

Table A.2: Influence of the cost correlations on the capital investment estimation [M\$] of a chemical absorption unit for CO₂ capture from the flue gas (Table A.1).

B Process units flowsheets

This appendix reports the conceptual flowsheets of different process units involved in the studied fuel decarbonisation processes.

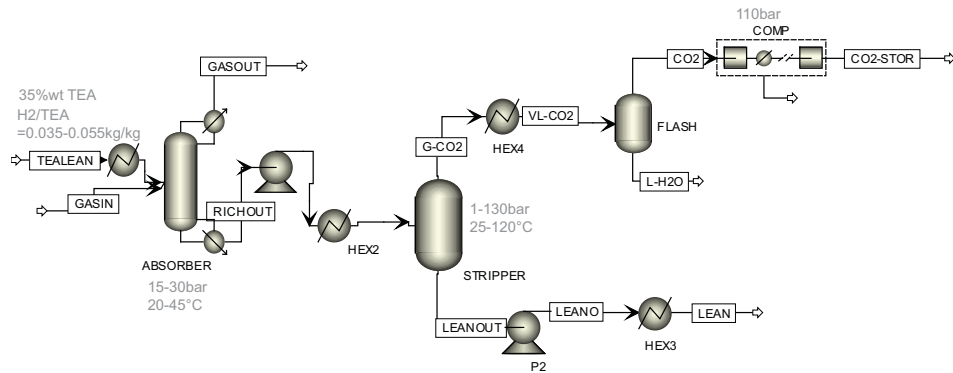

Figure B.1: Flowsheet of the chemical absorption process using an aqueous TEA solution.

Figure B.2: Flowsheet of the chilled ammonia process.

Appendix B. Process units flowsheets

Figure B.3: Flowsheet of the physical absorption process using the Selexol solvent.

Figure B.4: Flowsheet of the physical absorption process using the Rectisol solvent.

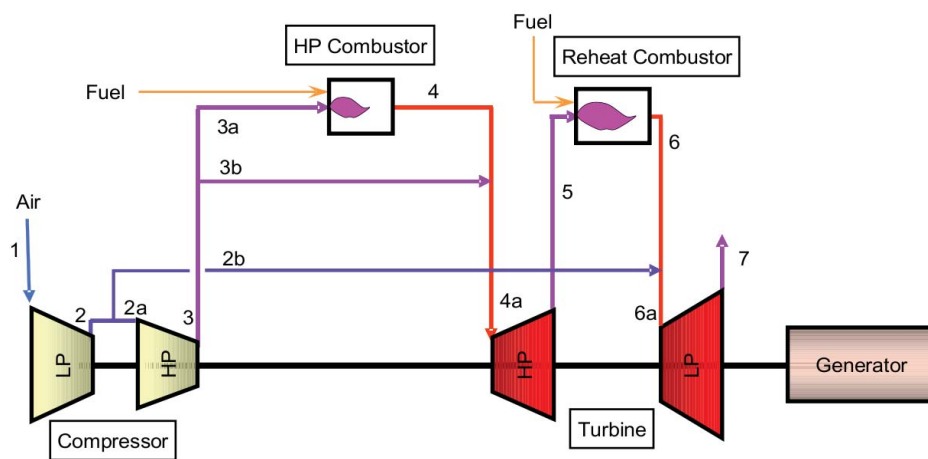

Figure B.5: Generic gas turbine model with reheat combustion.

In collaboration with the FHNW the generic gas turbine model with reheat combustion (without FGR) illustrated in Figure B.5 has been developed based on the characteristics given

in Table B.1. In order to model the recirculation the assumptions reported in Table B.2 are made. The air composition (%mol) is 77 N₂, 20.74 O₂, 1.009 H₂O, 0.9271 Ar and 0.0316 CO₂.

Table B.1: Characteristics of the generic gas turbine model with reheat combustion illustrated in Figure B.5.

Stream	Mass Flow [kg/s]	Temperature [°C]	Remarks
11	500.0	15.0	Standard, wet Air p=1atm
2	500.0	466.6	p2/p1=20, $\epsilon_{isentropic}=83\%$
2a	390.0	466.6	x.2a=78 %vol
2b	110.0	466.6	
3	390.0	560.6	p3/p2=1.5; $\epsilon_{isentropic}=88\%$
3a	226.2	560.6	x.3a=58 %vol
3b	163.8	560.6	
4	231.9	1447.1	$\epsilon_{combustion}=100\%$
4a	395.7	1106	
5	395.7	942.0	p4/p5=1.875, $\epsilon_{isentropic}=87\%$
6	402.2	1477.0	$\epsilon_{combustion}=100\%$
6a	512.2	1283.6	
7	512.2	631.7	p6/p7=16, $\epsilon_{isentropic}=88\%$

Table B.2: Modelling assumptions of the generic gas turbine model with reheat combustion and FGR illustrated in Figure B.5.

Constants	Remarks
$V_1=400\text{m}^3/\text{s}$	Constant volumetric flow rate to maintain velocity triangle in compressor
$X_{2a}=77\%$	With FGR, the split fractions of these flows are given by the geometry and the type of fluid. It is assumed that they are constant.
$X_{3a}=61\%$	
$T_{4a}=1100^\circ\text{C}$	The inlet flow temperature of the turbines is limited by the capacity of the blade cooling system and is controlled by the air excess in the combustor.
$T_{6a}=1300^\circ\text{C}$	

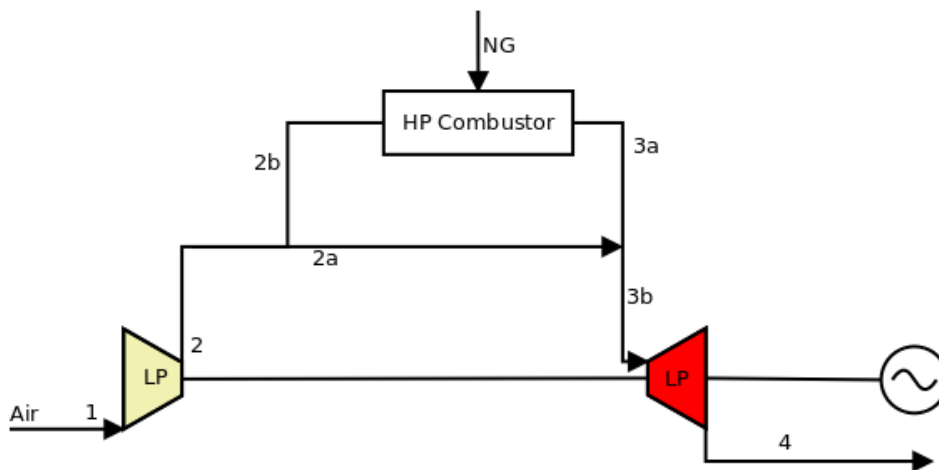

Figure B.6: Generic gas turbine model with a single combustion stage.

C Objective function choice

In this appendix the influence of the objective function choice on the Pareto-optimal solutions is discussed. For studying CO₂ capture options in power plants, energetic, economic and environmental aspects are of concern. Consequently, appropriate performance indicators that can be considered as objective function for the optimisation are the energy efficiency, the CO₂ capture rate, the specific CO₂ emissions per GJ of electricity produced, the capital investment costs and the production costs.

The influence of the objective function choice on the generated Pareto-optimal solutions is discussed here for the multi-objective optimisation of the pre-combustion CO₂ capture with Selexol and the post-combustion CO₂ capture with MEA in a natural gas fired power plant.

The following objective function choices are first analysed for the electricity production process from natural gas with pre-combustion CO₂ capture with Selexol:

- maximising the efficiency ϵ_{tot} and maximising the CO₂ capture rate (CC) η_{CO_2}
- minimising the specific CO₂ emissions $\text{kg}_{CO_2}/\text{GJ}_e$ and minimising the investment
- minimising the specific CO₂ emissions $\text{kg}_{CO_2}/\text{GJ}_e$ and minimising the production costs COE
- maximising ϵ_{tot} , maximising η_{CO_2} and minimising COE

The variation in terms of thermodynamic, environmental and economic performance of the Pareto-optimal solutions obtained with the various objective functions is reported in Figures C.1&C.2. These results show that:

- The optimisation of the CO₂ capture rate and of the efficiency leads to the optimisation of the CO₂ capture integration. The solutions that emerge have a higher efficiency and lower environmental impact but are more expensive than the solutions from the optimisation including an economic objective.

- When the COE is considered as objective, slightly lower production costs can be reached compared to the optimisation with regard to the efficiency and the CO₂ capture rate. This decrease of the COE results from lower capital investment costs and not from a higher efficiency. In fact, for a given efficiency the decrease of the production costs is linked to the lower CO₂

Appendix C. Objective function choice

capture rate (i.e. higher environmental impact). An increase of the CO₂ capture level would go in pair with an additional investment and lead to suboptimal solutions with regard to the COE. In the same way, the efficiency is decreased for a given CO₂ capture level. This illustrates the trade-off between CO₂ capture, cost and efficiency.

- When the investment and the specific emissions are optimised, solutions with a low capture rate and a high efficiency emerge, since the CO₂ capture is penalised by the costs.

Figure C.1: Trade-off between thermodynamic and environmental performance of the pre-combustion CO₂ capture in a natural gas fired power plant assessed for different objective functions choices.

Figure C.2: Trade-off between thermodynamic and economic performance of the pre-combustion CO₂ capture in a natural gas fired power plant assessed for different objective functions choices.

The comparison between the solutions generated by the COE and the investment optimisation points out the low contribution of the investment to the COE which is mainly defined by the resource price and consequently correlated to the efficiency. For the post-combustion CO₂ capture in an NGCC plant this trend is highlighted by studying the optimisation results of:

- maximising the efficiency ϵ_{tot} and maximising the CO₂ capture rate (CC) η_{CO_2}
- minimising the specific CO₂ emissions kg_{CO_2}/GJ_e and minimising the COE (including a carbon tax)
- maximising η_{CO_2} and minimising COE

The results reported in Figure C.3 reveal that the Pareto-optimal solutions are almost not influenced by the choice of the objective function. This characteristic underlines the strong correlation between the efficiency and the COE and supports the choice of the two objective functions; energy efficiency and CO₂ capture rate.

Figure C.3: Trade-off between thermodynamic, environmental and economic performance of post-combustion CO₂ capture in a natural gas fired power plant assessed for different objective functions choices.

A multi-objective optimisation with regard to three objectives (i.e. thermodynamic, economic and environmental) would probably be the best choice, but much more time consuming. In this study, the energy efficiency and the CO₂ capture rate were chosen as objective function for the pre-combustion processes. The economic dimension was included to support decision-making, by studying the influence of the economic scenario on the economic competitiveness of the Pareto-optimal solutions reflecting the trade-off between the energy penalty and the CO₂ capture (Chapter 8). This choice was made with the aim of optimising the CO₂ capture unit integration. As the electricity production costs are mainly defined by the resource price, the COE and the efficiency are highly correlated and the multi-objective optimisations with regard to two objectives, including no economic dimension were considered to be appropriate. In addition, it was assumed that minimising the CO₂ capture rate goes in pair with the investment minimisation. However, this a posteriori analysis shows that for the pre-combustion scenario there is a bias in the results, whereas for post-combustion scenarios the assumptions are confirmed.

As shown in Figures C.1&C.2, the Pareto solutions for the pre-combustion CO₂ capture by Selexol in a natural gas fuelled power plant are influenced in a greater extent by the choice of the objective function. This could be explained by the higher capital investment costs induced by the complex installation, including a reforming and shift reactor. The different compromise configurations that are identified from these results for a given energy efficiency are compared in Table C.1.

When no economic indicator is included in the objective function, the optimal solution yielding an efficiency around 52% captures between 10 and 15% more CO₂, but leads to around 2% higher production costs. The detailed analysis of the process designs reveals that

Appendix C. Objective function choice

in this solution the reforming is operated at a higher temperature and that the S/C ratio is lower.

Table C.1: Performance comparison of compromise solutions, assessed from different multi-objective optimisations of pre-combustion CO₂ capture in a natural gas fuelled power plants.

Objectives	max ϵ_{tot} max η_{CO_2}	min $\text{kg}_{CO_2,emitted}/\text{GJ}_e$ min Invest.	min $\text{kg}_{CO_2,emitted}/\text{GJ}_e$ max COE	max ϵ_{tot} max η_{CO_2} max COE
Process Performance				
ϵ_{tot} [%]	52.58	52.73	52.53	52.50
η_{CO_2} [%]	89.14	74.90	79.64	80.71
$\text{kg}_{CO_2,emitted}/\text{GJ}_e$	14.99	26.55	21.62	20.49

Appendix E. H₂ processes: Environmental impacts

Figure E.1: Comparison of the climate change impact of H₂ processes without and with CO₂ capture (Table E.1) based on the impact method IPCC07 for 1GJ_{H2}. Contributions that are harmful are labelled with a p and beneficial ones with an n.

Figure E.2: Comparison of the life cycle impacts of H₂ processes without and with CO₂ capture (Table E.1) based on the impact method Impact 2002 (left) and Ecoindicator99-(h.a) (right) for 1GJ_{H2}. Contributions that are harmful are positive and beneficial ones negative.

Figure E.3: Influence of the economic scenarios defined in Table 8.2 on the performance of H₂ processes with CO₂ capture.

F Parameterised CO₂ capture models

The details of the parameterised CO₂ capture models presented in Chapter 7 are given here. By applying different approaches, correlations have been developed based on the flowsheet illustrated in Figure 2.3 for estimating the investment costs, the power consumption, the heat loads and the corresponding temperature levels.

F.1 Polynomial fit

Table F.1: Parameterised CO₂ capture model: Polynomial fit.

Term	cst	η_{CO_2}	\dot{m}_{FG}	$\eta_{CO_2}\dot{m}_{FG}$	$\eta_{CO_2}\xi_{CO_2}$	$\dot{m}_{FG}\xi_{CO_2}$	$\eta_{CO_2}\dot{m}_{FG}\xi_{CO_2}$	$\eta_{CO_2}^2$	$\eta_{CO_2}^2\xi_{CO_2}$
$\dot{Q}_{leanheat}$ [W]	$6.251 \cdot 10^7$	$-1.097 \cdot 10^8$	0	-23.99	0	$-1.314 \cdot 10^3$	-540.4	$5.9 \cdot 10^7$	0
$\dot{Q}_{richheat}$ [W]	$-8.954 \cdot 10^6$	0	-39.17	89.102	0	$1.615 \cdot 10^3$	-709.93	0	0
$\dot{Q}_{Absorber}$ [W]	$6.412 \cdot 10^7$	$-1.836 \cdot 10^8$	-23.7435	-33.839	0	0	-47.279	$1.229 \cdot 10^8$	0
\dot{Q}_{HP} [W]	$1.353 \cdot 10^7$	0	0	-24.499	0	0	-295.44	0	0
Pre_Richheat T [$^{\circ}C$]	26.759	2.8955	$1.563 \cdot 10^{-6}$	$-1.092 \cdot 10^{-6}$	120.825	0	0	0	28.918
\dot{E} [kW _e]	$7.568 \cdot 10^7$	$-3.779 \cdot 10^4$	$-6.2 \cdot 10^{-3}$	0.0416	$-9.441 \cdot 10^4$	0.148	-0.148	0	$2.382 \cdot 10^5$
I [M\$]	33.7	-117.41	$-1.933 \cdot 10^{-5}$	$1.26 \cdot 10^{-4}$	-366.8	$4.8 \cdot 10^{-4}$	$-4.577 \cdot 10^{-4}$	0	797.6

Table F.2: Parameterised CO₂ capture model: Polynomial fit \dot{Q}_{reheat} .

Term	cst	\dot{m}_{FG}	$\dot{m}_{FG}\xi_{CO_2}$	$\eta_{CO_2}\dot{m}_{FG}\xi_{CO_2}$	$\eta_{CO_2}^2\dot{m}_{FG}\xi_{CO_2}$	$\eta_{CO_2}\dot{m}_{FG}^2\xi_{CO_2}$	$\eta_{CO_2}\dot{m}_{FG}\xi_{CO_2}^2$	$\eta_{CO_2}\dot{m}_{FG}^2\xi_{CO_2}^2$	$\dot{m}_{FG}^2\xi_{CO_2}^2$
$\dot{Q}_{Reheat,specific}$ [W/ $^{\circ}C$]	$4.029 \cdot 10^4$	-0.3035	19.848	9.120	0.7325	$2.848 \cdot 10^{-6}$	-25.018	$-2.56 \cdot 10^{-5}$	$1.602 \cdot 10^{-6}$

With the aim of performing energy integration, the heat loads and the corresponding temperature levels have to be estimated for the parameterised CO₂ capture model. Several temperature levels that are not varying considerably with the input variables are considered as constant. The absorber offgas temperature (GAS_OUT) is fixed to 39.65 $^{\circ}C$, the preheating of the lean solvent (preleanheat T) to 120 $^{\circ}C$, the richheat temperature to 105 $^{\circ}C$ and the reheat temperature to 125 $^{\circ}C$. The heat load of the *reheat* heat exchanger is highly influenced by the split fraction and the temperatures which are decision variables in the first principle model. Consequently, the heat load is predicted based on the specific heat load normalised by the factor $(1-split) \cdot \Delta T$. This factor is approximated with regard to the input variables (η_{CO_2} , \dot{m}_{FG} ,

Appendix F. Parameterised CO₂ capture models

ξ_{CO_2}) by interpolation from the dataset that is used to set up the blackbox model. The same approach is applied to estimate the heat load of the low pressure desorber \dot{Q}_{LP} .

The goodness of fit is illustrated in Figure E1 for the total power consumption.

Figure E1: Fitted total power consumption (Polynomial fit - polyfit, neural network - NN) versus calibration optimisation results.

F.2 Shortcut fit

By applying the shortcut fit approach, the investment costs I are estimated based on the columns height and diameter according to equations Eqs.F.2 -F.6.

$$d = 0.0284 \cdot \dot{m}_{FG}^{0.5} \cdot \xi_{CO_2}^{0.1254} \quad (E1)$$

$$N = 4 + 15 \cdot \ln(1/(1 - \eta_{CO_2})) \quad (E2)$$

$$HETP = 3.258 \cdot d^{7.5568} \quad (E3)$$

$$h = N \cdot HETP \quad (E4)$$

$$F = 10^{3.0532 + 0.3273 \cdot \log(h) + 0.0305 \cdot \log(h^2)} / 10^6 \quad (E5)$$

$$I = -2.7409 + 1.0208 \cdot F \quad (E6)$$

G Economic Scenarios

This appendix summarises data for the projections of the gas and carbon tax evolution in the European Union and in Switzerland. Based on this information different economic scenarios are set up to assess the competitiveness of the process configurations. The distribution functions for the different economic assumptions are described and illustrated.

G.1 Market price evolution

The natural gas price fluctuation and projection for different time horizons and geographical locations are reported in Figures G.1-G.3.

Figure G.1: Fluctuation of the natural gas price (industrial consumers) from 2001 to 2012 for some European Union states (Eurostat).

Appendix G. Economic Scenarios

Figure G.2: Fluctuation of the natural gas import price [\$/MBtu] from 1984 to 2011 in different countries (IEA (2012)).

Figure G.3: Fossil fuel price fluctuation and projection to 2050 for the EU 'Reference' energy scenario (European Commission (2011)).

With regard to the future carbon tax, the European Commission has published different predictions based on various energy scenarios represented in Table G.1.

Table G.1: ETS prices in $\text{€}_{08}/t_{CO2}$ (European Commission (2011)).

Scenario	2020	2030	2040	2050
Reference	18	40	52	50
CPI	15	32	49	51
High Energy Efficiency	15	25	87	234
Diversified supply technologies	25	52	95	265
High RES	25	35	92	285
Delayed CCS	25	55	190	270
Low nuclear	20	63	100	310

G.2 Distribution functions

The price variation presented in Section G.1 is described by a probability distribution function. Based on the available data, the appropriate distribution is selected and the parameters are identified. For the different economic assumptions the parameters of the probability density functions are reported in Table 8.3 and the distributions are represented in Figures G.4&G.5.

The normal or Gaussian distribution is a continuous probability distribution that has a bell-shape probability density function (Eq.G.1). The parameter μ is the mean and σ^2 is the variance and σ the standard deviation.

The continuous uniform distribution is characterised by the lower a and upper b endpoint defining the distribution support. Each point in this interval is equally probable. The probability density function for $x \in [a, b]$ is given by Eq.G.2.

The beta distribution is a continuous probability distribution that is defined in the interval $[0,1]$ and is parameterised by two positive shape parameters a and b . This distribution characterised by the probability density function Eq.G.3 is frequently applied to model the behaviour of random variables limited to a finite interval.

$$f(x; \mu, \sigma^2) = \frac{1}{\sigma\sqrt{2\Pi}} e^{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2} \tag{G.1}$$

$$f(x) = \frac{1}{a-b} \tag{G.2}$$

$$f(x; a, b) = cst \cdot x^{a-1} \cdot (1-x)^{b-1} \tag{G.3}$$

Appendix G. Economic Scenarios

Figure G.4: Distribution functions of the resource price, the carbon tax and the yearly operation.

Figure G.5: Distribution functions of the interest rate, the lifetime and the investment cost estimation error.

Nomenclature

Abbreviations

ATR	Autothermal Reforming
AZEP	Advanced Zero Emissions Power Plant
BBA	Chemical absorption blackbox model
BM	Biomass
BtL	Biomass to Liquid
CAP	Chilled Ammonia Process
CC	Carbon Capture
CCS	Carbon Capture and Storage
CGC	Cold Gas Cleaning
CLC	Chemical Looping Combustion
COE	Cost Of Electricity
COM	Operation and Maintenance Cost
COP	Coefficient Of Performance
CPI	Current Policy Initiatives Scenario
CPO	Catalytic Partial Oxidation
DEA	Diethanolamine
DH	District Heating
E_{imp}	Electricity Import
EI 99	Ecoindicator 99
EOR	Enhanced Oil Recovery
ETS	Emission Trading System
FG	Flue Gas
FGR	Flue Gas Recirculation
FHNW	Fachhochschule Nordwestschweiz
FICFB	Fast Internally Circulating Fluidised Bed
FU	Functional Unit
GT	Gas Turbine
GWP	Global Warming Potential
HETP	Height Equivalent to a Theoretical Plate
HEX	Heat Exchanger
HHV	Higher Heating Value

6.10 Comparison of the steam network integration for the NGCC plant with 90% of post-combustion CO ₂ capture by CAP based on a single stage flash model (left) and on a series of flash units (right) (Table 6.3).	100
6.11 Comparison of the power balance for the NGCC plant with 90% of post-combustion CO ₂ capture by CAP modelled by a single stage flash or a series of flash units (left). Zoom on the power consumption buildup (right) (Table 6.3).	100
6.12 Comparison of the investment buildup (left) and production cost buildup (right) for the NGCC plant with 90% of post-combustion CO ₂ capture by CAP modelled by a single stage flash or a series of flash units (Table 6.3).	101
6.13 Energy integration results for the NGCC plant with 90% post-combustion CO ₂ capture with CAP modelled by a series of flash unit and including a refrigeration cycle with ammonia: Grand composite curve in Carnot factor axis (left). Integrated composite curve of refrigeration unit (right).	102
6.14 Refrigeration cycle using an ammonia-water mixture as refrigerant.	102
6.15 Integrated composite curve of the ammonia-water refrigeration cycle for the NGCC plant with 90% post-combustion CO ₂ capture with chilled ammonia (left) (Table 6.4: Refrig. NH ₃ -H ₂ O). Zoom below ambient temperature (right).	103
6.16 Influence of the ammonia concentration of the refrigerant on the performance of the NGCC plant with 90% post-combustion CO ₂ capture with chilled ammonia including an ammonia-water refrigeration cycle.	104
6.17 Influence of the ΔT_{min} in the refrigeration cycle heat exchangers on the performance of the NGCC plant with 90% post-combustion CO ₂ capture with chilled ammonia including an ammonia-water refrigeration cycle.	104
6.18 Comparison of the grand composite curve in Carnot factor axis of the NGCC plant with 90% post-combustion CO ₂ capture with chilled ammonia including an ammonia or ammonia-water refrigeration cycle (Table 6.4: Refrig. NH ₃ and Refrig. Opt. NH ₃ -H ₂ O).	105
6.19 Comparison of the integrated composite curve of the ammonia and ammonia-water refrigeration cycle in the NGCC plant with 90% post-combustion CO ₂ capture with chilled ammonia (left) (Table 6.4: Refrig. NH ₃ and Refrig. Opt. NH ₃ -H ₂ O). Zoom below ambient temperature (right).	105

List of Figures

6.20	Comparison of the grand composite curve in Carnot factor axis of the NGCC plant with 90% post-combustion CO ₂ capture with chilled ammonia including an ammonia-water refrigeration cycle and heat pumping (left). Integrated composite curve of the heat pumping using a ammonia-water mixture in the NGCC plant with 90% post-combustion CO ₂ capture with chilled ammonia (right).	106
6.21	Comparison of the grand composite curve in Carnot factor axis of the NGCC plant with 90% post-combustion CO ₂ capture with chilled ammonia including an ammonia-water refrigeration cycle and MVR (left). Integrated composite curve of the MVR in the NGCC plant with 90% post-combustion CO ₂ capture with chilled ammonia (right).	108
7.1	Illustration of the process optimisation strategy to develop simpler parameterised CO ₂ capture models.	110
7.2	Blackbox model of the CO ₂ capture process.	111
7.3	Pareto optimal frontiers showing the trade-off between investment and CO ₂ capture rate for different \dot{m}_{FG} and ξ_{CO_2} in chemical absorption with MEA.	112
7.4	Scheme of the neural network.	114
7.5	Fitted investment (Polynomial fit - polyfit Eq.7.2, fit based on shortcut model - shortcut fit, neural network - NN) versus calibration optimisation results.	114
7.6	Comparison of the composite curves with steam network integration for the base case scenarios reported in Table 7.2.	116
7.7	Pareto optimal frontiers of the global problem optimisation based on the first-principle MEA model and on different blackbox models.	117
7.8	Composite curves for the compromise scenario generated by the first principle MEA model through optimisation and through recomputation of the parameterised polynomial model with the detailed MEA model.	118
8.1	Investigated CO ₂ capture options.	122
8.2	Performance results of the different power plant options with CO ₂ capture reported in Table 8.1. For natural gas fed processes a capture rate of 90% is considered and 60% for biomass fed processes.	123
8.3	Comparison of the climate change impact of power plants without and with CO ₂ capture based on the impact method IPCC 07 for 1GJ _e . Contributions that are harmful are labelled with a <i>p</i> and beneficial ones with an <i>n</i> .	125

8.4 Comparison of the life cycle impacts of power plants without and with CO ₂ capture based on the impact methods Impact 2002+ (left) and Ecoindicator 99-(h.a) (right) for 1GJ _e . Contributions that are harmful are positive and beneficial ones negative.	125
8.5 Contributions to the resources impact based on the impact method Ecoindicator 99-(h.a) for 1GJ _e of electricity produced by power plants without and with CO ₂ capture.	126
8.6 Contributions to the ecosystem impact based on the impact method Ecoindicator 99-(h.a) for 1GJ _e of electricity produced by power plants without and with CO ₂ capture.	127
8.7 Contributions to the human health impact based on the impact method Ecoindicator 99-(h.a) for 1GJ _e of electricity produced by power plants without and with CO ₂ capture. Contributions that are harmful are labelled with a <i>p</i> and beneficial ones with an <i>n</i>	127
8.8 Contributions to the acidification potential based on the impact method CML01 for 1GJ _e of electricity produced by power plants without and with CO ₂ capture.	128
8.9 Contributions to the eutrophication potential based on the impact method CML01 for 1GJ _e of electricity produced by power plants without and with CO ₂ capture.	129
8.10 Comparison of the environmental performance of electricity generating processes from Ecoinvent (Ecoinvent) and this study (Table 8.1) based on the IPCC impact method.	130
8.11 Comparison of the environmental performance of electricity generating processes from Ecoinvent (Ecoinvent) and this study (Table 8.1) based on the Ecoindicator impact method.	130
8.12 Influence of the natural gas purchase price on the electricity production costs without (- -) and with (-) the inclusion of a carbon tax of 35\$/t _{CO2} for the process configurations reported in Table 8.1.	132
8.13 Influence of the carbon tax on the electricity production costs without and with CO ₂ capture for a natural gas price of 9.7\$/GJ _{NG} and a biomass price of 5\$/GJ _{BM} for the process configurations reported in Table 8.1.	133
8.14 Influence of the carbon tax on the electricity production costs for different CO ₂ capture process options.	134
8.15 Influence of the carbon tax and of the resource price on the electricity production costs for different CO ₂ capture process options.	135

List of Figures

8.16 Influence of the economic scenarios defined in Table 8.2 on the performance of pre-combustion CO ₂ capture with Selexol in a natural gas fired power plant using ATR.	136
8.17 Influence of the economic scenarios defined in Table 8.2 on the performance of post-combustion CO ₂ capture with MEA in a natural gas fired power plant. . .	136
8.18 Influence of the economic scenarios defined in Table 8.2 on the performance of pre-combustion CO ₂ capture with Selexol in a biomass fed power plant.	137
8.19 Influence of the economic scenarios defined in Table 8.2 on the performance of electricity generating processes with CO ₂ capture.	138
8.20 Influence of the economic scenarios defined in Table 8.2 on the performance of electricity generating processes with CO ₂ capture - 2D representation.	138
8.21 Assessment of the influence of the economic assumptions uncertainty on the COE and CO ₂ avoidance costs accounting for a CO ₂ tax, for the configurations presented in Table 8.1. The markers represent the performance for the base case economic scenario, and the corresponding coloured area the variation of the COE with the economic conditions.	140
8.22 Natural gas fired power plant performance with post-combustion CO ₂ capture with MEA: Probability of each point to be part of the top 5 configurations yielding the best economic performance under different economic scenarios.	141
8.23 Natural gas fired power plant performance with post-combustion CO ₂ capture with MEA: Influence of the economic scenario on the electricity production costs (incl. a carbon tax) of the best 5 economic performance configurations.	141
8.24 Natural gas fired power plant performance with pre-combustion CO ₂ capture with Selexol: Probability of each point to be part of the top 5 configurations yielding the best economic performance under different economic scenarios (left) and respective influence on the electricity production costs including a carbon tax (right).	142
8.25 Biomass fired power plant performance with pre-combustion CO ₂ capture with Selexol: Probability of each point to be part of the top 5 configurations yielding the best economic performance under different economic scenarios (left) and respective influence on the electricity production costs including a carbon tax (right).	142

8.26	Power plants performance with CO ₂ capture: Influence of the economic scenario on the top 5 configurations yielding the best economic performance. Decision-making based on the Pareto front (black points) (left) and corresponding probability of each point to be part of the top 5 configurations yielding the best economic performance under different economic scenarios (right).	143
8.27	Power plants performance with CO ₂ capture: Influence of the economic scenario on the decision-making based on the top 5 configurations yielding the best economic performance (left) 2D representation showing the trade-off between COE and energy efficiency (right).	143
8.28	Relative competitiveness of each Pareto optimal solution with regard to the most economically competitive solution for the considered economic scenarios (right). Zoom on the relative competitiveness of CO ₂ capture in natural gas fired power plants (left).	144
8.29	Integrated composite curves of the most economically competitive natural gas fired power plant options with post-combustion CO ₂ capture with MEA (left) and with pre-combustion CO ₂ capture with Selexol (right) reported in Table 8.4.	145
8.30	Comparison of the most economically competitive power plant options with CO ₂ capture based on the economic performance variation, with regard to the different economic scenarios, expressed by the COE including CO ₂ tax (Table 8.4).	146
B.1	Flowsheet of the chemical absorption process using an aqueous TEA solution.	173
B.2	Flowsheet of the chilled ammonia process.	173
B.3	Flowsheet of the physical absorption process using the Selexol solvent.	174
B.4	Flowsheet of the physical absorption process using the Rectisol solvent.	174
B.5	Generic gas turbine model with reheat combustion.	174
B.6	Generic gas turbine model with a single combustion stage.	175
B.7	Syngas production by the ATR membrane reactor for injection in the combustion chamber of the NGCC plant with FGR.	176
C.1	Trade-off between thermodynamic and environmental performance of the pre-combustion CO ₂ capture in a natural gas fired power plant assessed for different objective functions choices.	178

List of Figures

C.2	Trade-off between thermodynamic and economic performance of the pre-combustion CO ₂ capture in a natural gas fired power plant assessed for different objective functions choices.	178
C.3	Trade-off between thermodynamic, environmental and economic performance of post-combustion CO ₂ capture in a natural gas fired power plant assessed for different objective functions choices.	179
D.1	Integrated composite curves of the most economically competitive natural gas fuelled power plant configuration with post-combustion CO ₂ capture with MEA (left) and chilled ammonia (right) reported in Table 8.4.	186
D.2	Integrated composite curves of the most economically competitive natural gas fuelled power plant configuration with pre-combustion CO ₂ capture by chemical absorption with TEA; ATR (left) and SMR (right) reported in Table 8.4.	186
D.3	Integrated composite curves of the most economically competitive biomass based power plant configuration with pre-combustion CO ₂ capture by Selexol (left) and TEA (right) reported in Table 8.4.	186
E.1	Comparison of the climate change impact of H ₂ processes without and with CO ₂ capture (Table E.1) based on the impact method IPCC07 for 1GJ _{H2} . Contributions that are harmful are labelled with a p and beneficial ones with an n.	188
E.2	Comparison of the life cycle impacts of H ₂ processes without and with CO ₂ capture (Table E.1) based on the impact method Impact 2002 (left) and Ecoindicator99-(h.a) (right) for 1GJ _{H2} . Contributions that are harmful are positive and beneficial ones negative.	188
E.3	Influence of the economic scenarios defined in Table 8.2 on the performance of H ₂ processes with CO ₂ capture.	189
F.1	Fitted total power consumption (Polynomial fit - polyfit, neural network - NN) versus calibration optimisation results.	192
G.1	Fluctuation of the natural gas price (industrial consumers) from 2001 to 2012 for some European Union states (Eurostat).	193
G.2	Fluctuation of the natural gas import price [\$/MBtu] from 1984 to 2011 in different countries (IEA (2012)).	194

G.3 Fossil fuel price fluctuation and projection to 2050 for the EU '*Reference*' energy scenario (European Commission (2011)). 194

G.4 Distribution functions of the resource price, the carbon tax and the yearly operation. 196

G.5 Distribution functions of the interest rate, the lifetime and the investment cost estimation error. 197

List of Tables

1	Comparison of CO ₂ capture processes (Figuroa et al. (2008), Kanniche et al. (2010), Radgen et al. (2005), Olajire (2010)).	6
2	Performance of state-of-the-art power plants configurations with and without CO ₂ capture based on references: Kanniche et al. (2010), Parsons et al. (2002), Rubin et al. (2007), Damen et al. (2006), Kvamsdal et al. (2007), Bolland and Undrum (2003), Chiesa and Consonni (2000), Zhang and Lior (2008), Lozza and Chiesa (2002b,a), Mann and Spath (1997), Carpentieri et al. (2005).	10
3	Performance of state-of-the-art H ₂ plants configurations with and without CO ₂ capture based on references: Longanbach et al. (2002), Bartels et al. (2010), Toonssen et al. (2008) and Hamelinck and Faaij (2002).	10
1.1	Assumptions for the sizing of the SMR and WGS reactors (Maréchal et al. (2005)).	22
1.2	Assumptions for the economic analysis.	24
1.3	Reference plants performance considered for the CO ₂ avoidance costs assessment.	27
2.1	Comparison of the physical and chemical ab- and adsorption processes for CO ₂ separation (Göttlicher (1999)).	37
2.2	Decision variables and feasible range for optimisation for the chemical absorption process using an aqueous MEA solution.	39
2.3	Decision variables and feasible range for optimisation for the chemical absorption process using an aqueous TEA solution.	39
2.4	Decision variables and feasible range for optimisation for the chilled ammonia process.	41
2.5	Decision variables and feasible range for optimisation for the physical absorption process using the Rectisol solvent.	41

List of Tables

2.6	Decision variables and feasible range for optimisation for the physical absorption process using the Selexol solvent.	42
3.1	Parameters for the energy-flow models of the pre-combustion CO ₂ capture processes using natural gas or biomass as a feedstock.	51
3.2	Operating conditions and feasible range for optimisation for the pre-combustion CO ₂ capture processes using natural gas or biomass as a feedstock.	52
3.3	Performance of H ₂ process configurations with pre-combustion CO ₂ capture. The net electricity output expressed in MJ of electricity per GJ of hydrogen is negative when the integrated process requires electricity importation and positive when it generates electricity. The corresponding operating conditions are reported in Appendix Table D.1.	58
3.4	Performance of the compromise power plants configurations with pre-combustion CO ₂ capture. The electricity balance is expressed in MJ of electricity per GJ of net electricity produced. The corresponding operating conditions are summarised in Appendix Table D.2.	65
4.1	Performance of the compromise H ₂ production process configurations with CO ₂ capture. The specific performances are expressed per GJ of H ₂ produced. The corresponding operating conditions are reported in Appendix Table D.3.	71
4.2	Performance of the compromise electricity generation configurations with pre-combustion CO ₂ capture. The specific performances are expressed per GJ of electricity produced. The corresponding operating conditions are reported in Appendix Table D.4.	75
5.1	Decision variables and feasible range for optimisation for the NGCC plant.	83
5.2	Steam network characteristics for the NGCC plant (Li (2006)).	84
5.3	Performance of the different natural gas combined cycle configurations without FGR and without CO ₂ capture (natural gas price 9.7\$/GJ _{NG} , operation 8000h/y)	85
5.4	Performance of the NGCC configurations without and with FGR and post-combustion CO ₂ capture (natural gas price 9.7\$/GJ _{NG} , operation 8000h/y).	86
5.5	Performance of the NGCC plant with 90% CO ₂ capture with MEA without and with district heating DH (natural gas price 9.7\$/GJ _{NG} , operation 7500h/y).	90

6.1	Performance of NGCC power plants configurations without CO ₂ capture and with 85% post-combustion CO ₂ capture with MEA and chilled ammonia. The corresponding operating conditions are reported in Appendix Table D.5.	92
6.2	Specific exergy demands, expressed in GJ/t _{CO2} , of the CO ₂ capture with MEA and chilled ammonia for the configurations reported in Table 6.1.	94
6.3	Performance comparison for NGCC power plants with 90% post-combustion CO ₂ capture with MEA and chilled ammonia modelled by a single flash and a serie of flash units. The corresponding operating conditions are reported in Appendix Table D.6.	98
6.4	Performance of the NGCC power plant with 90% post-combustion CO ₂ capture with chilled ammonia (series of flash units) including different refrigeration options.	103
6.5	Performance of NGCC power plants with 90% post-combustion CO ₂ capture with chilled ammonia (series of flash units) for different energy integration (EI) improvements.	107
7.1	Regression results for the investment cost correlation leading to Eq.7.2. ($t_{0,95}[1538]=1.96$, $F_{0,95}[7;1538]=3.23$)	113
7.2	Performance results of the base case NGCC plant configurations with 85% post-combustion CO ₂ capture based on the first-principle MEA model and on different blackbox models.	115
7.3	Computation time comparison for multi-objective optimisation of post-combustion CO ₂ capture in the NGCC plant based on the first-principle MEA model and on different blackbox models (400 evaluations and initial population of 30).	116
7.4	Performance of the compromise NGCC plant configurations with 87% post-combustion CO ₂ capture based on the first-principle MEA model and on different blackbox models.	118
8.1	Performance of the different power plant options with CO ₂ capture. For natural gas fed processes a capture rate of 90% is considered and 60% for biomass fed processes. The corresponding operating conditions are reported in in Appendix Tables D.4 & D.7.	123
8.2	Definition of the economic scenarios.	134
8.3	Parameters of the distribution functions for the economic assumptions (illustrated in Appendix Figures G.4 & G.5).	139

List of Tables

8.4	Performance of the most economically competitive power plant options with CO ₂ capture. The corresponding process design parameters are reported in Appendix Tables D.8 & D.9.	145
8.5	Performance results reported by IEA (Finkenrath (2011)) for OECD countries. The costs range takes into account the variation of the resource price with regard to the countries. For the efficiency the OECD average value is given.	147
8.6	Performance results reported by ZEP (ZEP (2011)) for European countries. The conservative, high-cost plant designs representing today's technology choices (Base) and the optimised cost estimations considering advanced future technology (Optim) are reported here. The costs ranges take into account the low and high resource price scenario. For the currency exchange 1.25\$/€ is used.	147
8.7	Performance comparison of H ₂ applications.	154
A.1	Flue gas characteristics for the comparison of the investment cost estimates of a chemical absorption installation.	170
A.2	Influence of the cost correlations on the capital investment estimation [M\$] of a chemical absorption unit for CO ₂ capture from the flue gas (Table A.1).	171
B.1	Characteristics of the generic gas turbine model with reheat combustion illustrated in Figure B.5.	175
B.2	Modelling assumptions of the generic gas turbine model with reheat combustion and FGR illustrated in Figure B.5.	175
B.3	Characteristics of the generic gas turbine model with a single combustion stage illustrated in Figure B.6.	176
B.4	Modelling assumptions of the generic gas turbine model with a single stage combustion and FGR illustrated in Figure B.6.	176
C.1	Performance comparison of compromise solutions, assessed from different multi-objective optimisations of pre-combustion CO ₂ capture in a natural gas fuelled power plants.	180
D.1	Operating conditions for the different compromise H ₂ process options with pre-combustion CO ₂ capture, whose performance results are reported in Table 3.3.	181

D.2	Operating conditions for the different compromise power plants options with pre-combustion CO ₂ capture, whose performance results are reported in Table 3.4.	182
D.3	Operating conditions for the different compromise H ₂ plant options with pre-combustion CO ₂ capture, whose performance results are reported in Table 4.1.	182
D.4	Operating conditions for the different compromise power plant options with pre-combustion CO ₂ capture, whose performance results are reported in Tables 4.2 & 8.1.	183
D.5	Operating conditions for the base case power plant options with post-combustion CO ₂ capture, whose performance results are reported in Table 6.1.	183
D.6	Operating conditions for the power plant options with 90% post-combustion CO ₂ capture, whose performance results are reported in Table 6.3.	184
D.7	Operating conditions for the different compromise power plant options with post-combustion CO ₂ capture, whose performance results are reported in Table 8.1.	184
D.8	Operating conditions for the most economically competitive power plant options with post-combustion CO ₂ capture, whose performance results are reported in Table 8.4.	185
D.9	Operating conditions for the most economically competitive power plant options with pre-combustion CO ₂ capture, whose performance results are reported in Table 8.4.	185
E.1	Performance of different H ₂ plant options with CO ₂ capture. For natural gas fed processes a capture rate of 90% is considered and 55% for biomass fed processes.	187
E1	Parameterised CO ₂ capture model: Polynomial fit.	191
E2	Parameterised CO ₂ capture model: Polynomial fit \dot{Q}_{reheat}	191
G.1	ETS prices in $\text{€}_{08}/t_{CO_2}$ (European Commission (2011)).	195

Curriculum Vitae

Personal details

Name	Laurence TOCK
Date of birth	25.04.1985
Nationality	Luxembourgish
Contact	laurence.tock@gmail.com

Education

- 2009 – 2013 École Polytechnique Fédérale de Lausanne, Switzerland
PhD thesis at the Industrial Energy Systems Laboratory
- 2004 – 2009 École Polytechnique Fédérale de Lausanne, Switzerland
MSc in Chemical engineering and biotechnology
- 1997 – 2004 Lycée Classique de Diekirch, Luxembourg
*Diplôme de fin d'études secondaires
orientation sciences et mathématiques*

Scientific experience and internships

- 2009 – 2013 Industrial energy systems laboratory, EPFL, Switzerland
*Teaching assistant and project supervision
Course: Modelling and optimisation of energy systems*
- 2007 Goodyear Innovation Centre Luxembourg, "Analytical Test Laboratory"
Internship 6 weeks
*Analysis and synthesis of new rubber mixtures
to develop a more robust and sustainable product*
- 2006 Goodyear Wire Plant Luxembourg, "QTECH Laboratory"
Internship 6 weeks
*Active participation in the chemical analysis and tests
allowing to control rigorously under time constraints the product quality*
